> *Wearing it as an outer layer is fine, I think it's quite comfortable. But if I were to wear it close to my skin, like a vest or a t-shirt, I definitely wouldn't want it to be polyester, because I find polyester too hot and sweaty when worn directly against the skin.*

During the co-design activities, participants were given fabric samples, including 100% cotton, cotton blends, wool blends, and polyester-spandex, and they were invited to annotate their preferences directly onto garment outline templates. Cotton and cotton-blend fabrics were the most frequently selected, accompanied by annotations such as "soft," "breathable," and "not itchy."

Comfort was also related to personal experiences and medical histories. For example, one participant noted that clothing design needs to consider changes in tactile sensitivity in the postoperative area:

> *I had a mastectomy. I don't have any breasts. I hate anything that scratches. It's just the normal is not normal anymore. You know what I mean?*

Compared to the sensing garments, the sensing furniture components such as the sensing pillow and cushion were generally perceived as more comfortable and less intrusive. This distinction was further supported by sensory ethnographic observations, which captured some participants' nuanced physical interactions with the garments. While wearing the smart clothing, some participants often made subtle adjustments to collars, pulled at sleeves, or ran their fingers along seam lines. Some participants hesitated before putting on the garment or asked whether the sensors would touch their skin directly. In contrast, interactions with the smart furniture were more relaxed. Most participants sat down without instruction, leaned back comfortably, and engaged in conversation while using the seat pad.

Contextual Integration and Lifestyle Compatibility

Participant feedback indicated that the acceptability of the system was closely related to its ability to seamlessly integrate into users' everyday lives, domestic environments, and personal routines. For example, smart furniture components were generally perceived as less intrusive and more acceptable for long-term and low-effort engagement:

> *People do tend to sit in the same seat every day, in the same place to watch TV. If someone was sitting there all day watching TV or doing something else, you'd find it very useful.*

In contrast, concerns were raised about the disruption that smart garments might cause to the unpredictability of daily routines. One participant described how the demand for continuous wear might not be compatible with their lifestyle:

> *I do so many things during the day. When I come back from the garden, I might have sweated or gotten dirty and need to change clothes and then, oops, I might forget to put on the smart garment again.*

This issue was further reflected in sensory ethnographic field notes, which captured several participants expressing uncertainty about whether they were "wearing it correctly" or whether the sensors would still function properly after shifting position.

During the co-design sessions, participants engaged with home layout templates, marking preferred sensor locations. They often placed sensors in areas associated with habitual furniture use, such as a reading chair, dining table, or frequently used seating areas. Some participants also proposed to integrate the system as part of standard domestic infrastructures in care homes: "You just install it when someone moves in for safety."

These insights suggest that smart loneliness monitoring systems should not only be conceived as stand-alone technologies, but rather as components within a broader ecosystem of smart living, with potential to be embedded into existing domestic practices and infrastructural frameworks.

Trust, Privacy, and Data Control

Conditional Trust and System Reliability

Participants across both workshops expressed a degree of trust in the smart loneliness monitoring system but consistently emphasized that trust in such technologies is not taken for granted. Several participants highlighted that trust would need to be earned over time, through demonstrable functionality and accuracy in real-life use:

> *I think I'd have to actually wear it and see it identify (my loneliness) without me saying anything. That would be the only way to really learn that it was working. What would happen at the end of the day? Would it give you a ping? Something to say "woo! Looks like you're lonely at the moment." And if I was in the middle of having a conversation with somebody and feeling perfectly fine, I know I would not trust it.*

Moreover, past experiences with commercial wearable monitoring devices appeared to shape users' current skepticism. One participant referenced their partner's experience:

> *My husband uses a Fitbit, but it clearly doesn't record his steps accurately. So I can't fully trust it.*

These encounters with inaccurate sensing may contribute to reserved user fatigue or doubts about the credibility of wearable sensors. These doubts also extended to smart monitoring systems, especially when applied to emotionally complex and subjective states like loneliness.

While most participants felt confident interpreting the outputs presented in the accompanying mobile app, they nonetheless highlighted a need for greater transparency and interpretability in system feedback. During the co-design sessions, participants proposed a range of suggestions to improve algorithmic explainability, including the addition of visual indicators such as:

> *Why is it saying I'm lonely?*
>
> *What data triggered this message?*

Another recommendation was the inclusion of a feedback confirmation mechanism, enabling users to validate the system feedback, thus contributing to a dynamic and trust-building model. One participant proposed a "check-in" feature, whereby if the system identified them as potentially lonely, they could choose to confirm or dismiss the notification. Over time, such feedback loops would allow the algorithm to learn from user responses, thereby refining its accuracy and building user confidence.

Customizable Data-Sharing Preferences

While participants acknowledged the potential value of sharing data with others particularly in the context of health or emotional support, several older adults highlighted the importance of retaining control over their data-sharing choices:

> *I feel that collecting this data all the time is quite intrusive. I might not want my daughter to know how I'm feeling at that moment, and I certainly don't want her using an app to monitor me. I want to stay in control of my emotions, and I feel this would take that control away.*

Conversely, another participant expressed openness to sibling-based support, provided that geographic distance warranted it. Interestingly, when asked, "You wouldn't want your daughter to see your data, would you want to see your mother's?" the participant hesitated. These responses highlight how data sharing preferences are relational and context-dependent and may vary depending on the role of the recipient as caregiver or care recipient.

Additionally, several participants expressed a preference for conditional sharing models, where data would only be shared under specific circumstances:

> *If I'm having a breakdown at home because I'm feeling lonely and haven't seen anyone for three weeks, then I do want them to know. But if I'm just feeling a bit off and can't be bothered to go to the coffee shop, I don't necessarily want to share that.*

During the co-design sessions, participants proposed improvements to the current permissions interface. Users expressed a desire to select which types of data such as

emotional states, activity levels, or physiological indicators would be visible to specific recipients, including family members, clinicians, or community caregivers. Some also suggested adding a dashboard that clearly shows "who can see what," along with visual indicators to support transparency and ease of management.

Ethical Concerns and Data Ownership

Across both workshops, while the majority of participants expressed openness toward the use of monitoring technologies, they also emphasized that trust in such systems depends not only on accuracy but also on transparency of purpose, data flow, and long-term governance.

A recurring concern was "Who owns the data?" and often followed by anxiety about potential commercial exploitation. As one participant asked: "What if the data gets sold? Who's to say it won't be sold?"

The prospect that personal health or emotional data might be commodified was troubling for many older adults, particularly given the lack of clear regulation surrounding data collected outside clinical systems.

Concerns also extended to the broader implications of artificial intelligence governance in connection with wearable monitoring systems: "I understand that these technologies are developed with good intentions, but I do worry that they could be repurposed for surveillance or behavioral manipulation."

During the co-design sessions, many older adults indicated that these ethical concerns did not necessarily result in rejection of the system. Rather, they expressed a desire for greater clarity regarding the system's governance model, data stewardship, and effective plans for future use. These findings suggest that ethical acceptability is not solely a matter of obtaining "informed consent" at the point of use but requires ongoing transparency and participatory data governance. Future iterations of the system should consider the development of interactive tools that clearly and accessibly communicate key information regarding data provenance ownership and rights.

Perceptions of Loneliness and the Limits of Detection

The Subjectivity of Loneliness

Some participants believed that loneliness is fundamentally a subjective and emotionally complex experience, one that cannot be directly inferred from behavioral or physiological signals alone. This perspective occurred in our earlier focus group discussions, where several participants questioned the assumption that sensor data could reliably infer emotional states: "What you feel inside can't be monitored by anyone, no sensor can pick that up."

Participants also noted that loneliness is highly individualized and not necessarily linked to physical solitude: "You can feel lonely in a crowded room but feel fine when you're alone."

This further raised questions among participants about whether the algorithm could accurately identify individualized feelings of loneliness. In response, the investigator (JR) clarified that while current algorithmic models may be developed from broad datasets, their core functionality is intended to adapt to individual patterns. The system is designed to learn over time with correct or incorrect feedback, establishing and refining a personalized emotional profile, thereby improving its accuracy.

Moreover, participants noted that loneliness is not exclusive to older adults but occurs across different ages and life stages, highlighting the need for the system to detect emotional nuance rather than demographic generalization.

In the co-design sessions, some participants expressed discomfort with the term "loneliness," describing it as "too strong" or "too negative." They proposed softer alternatives, such as "reflective state" or "well-being indicator." Others annotated their interface sketches with prompts like "How are you feeling today?" in place of system-generated loneliness labels. These design annotations suggest that users may prefer tools that prompt self-reflection, rather than systems that presume to define their emotional states on their behalf.

Algorithmic Assumptions and Multimodal Analysis

As discussed in the previous subsection, participants questioned the logic behind the algorithm used for loneliness detection. For instance, they expressed concern that feedback based solely on low physical activity might lead to false positives: "You're detected as being very still, but you're not lonely, you're just enjoying your book."

In response, researchers explained that the current system applies multimodal integration, combining physiological signals with behavioral data for a more comprehensive analysis. While participants appreciated this approach, they also asked whether the system could incorporate additional personalized factors to further improve detection accuracy: "If I'm motionless, and those factors you mentioned lead the system to assume I'm lonely, then I'm wondering, what other factors could be added?"

This desire for individualized calibration was also evident in the co-design artifacts. On the smart garment and furniture templates, some participants annotated notes such as "Don't assume lack of movement means I'm feeling low." Others, particularly older adults, proposed that the system should seek user confirmation before tagging as a loneliness event, effectively embedding emotional subjectivity into the algorithmic process.

Adoption, Applicability, and Ethical Futures

Adoption Among the Older Adults

While participants generally recognized the value of the systems in their later life, they also noted that those who might benefit most should be very old adults or individuals strongly invested in their independence (may be the least willing to adopt it). Factors such as psychological resistance and identity-related concerns were seen as major potential barriers to real-world implementation.

Most participants in both of the workshops were still socially active and engaged but reflected on family members who were socially isolated yet unwilling to engage with monitoring technologies or accept support:

> *My mum is very old and lives on her own. She's obviously lonely, but there's no way she'd get involved in something like this.*

Others expressed similar insight:

> *She won't accept any help. Yes, even though she's clearly spiraling because of it.*

These reflections highlight a tension between need, self-perception, and autonomy. The concept of "independent living" was both a source of pride and a practical barrier. Older adults may perceive acknowledging loneliness or using assistive technologies as a threat to their autonomy or even as an admission of vulnerability.

This resistance was also observed in the sensory ethnographic field notes. While most participants interacted with system components during the experience, a small number showed hesitation or disengagement when asked to wear the garment or respond to app prompts. Some made dismissive remarks such as: "This seems something for people who need looking after."

In co-design sessions, some participants openly stated that they found it a bit difficult to imagine themselves using such a system even hypothetically because it felt "irrelevant" or "only for people in worse situations." These views may reflect a desire to maintain a sense of competence and independence, even in the face of known risks or increasing social withdrawal.

Timing of App

During the focus group discussions, participants also reflected on when these technologies should be applied. Some participants thought it would be best to introduce the system before severe loneliness or functional decline occurs: "Maybe you need to catch people before they get to that point, so you can do it as a prevention rather than a late intervention."

Some participants thought that if people fall into severe isolation, their willingness to engage with new technologies may be significantly reduced: "By the time they need it, they may not want to learn it."

In addition, participants also mentioned that they may be more willing to use the system when they still feel in control, an insight that is consistent with the discussion in the Trust, Privacy, and Data Control section that trust is built through gradual voluntary participation rather than sudden or mandatory use.

Some participants proposed a "onboarding stage" during the co-design session, such as "Let me start with one feature first" or "Phase 1: Activity tracking only, no reminders yet." Others suggested setting up a "trial period" for the system so that users can experience it during this period without worrying about data being misunderstood or shared too early.

Expanded Health Monitoring

While loneliness detection was the primary aim of the system, many participants expressed strong interest in expanding its functionality to support broader physiological and behavior monitoring: "It's good to know the system can monitor so many different things, but could it also include more features?"

Some participants also highlighted their specific personal monitoring needs: "I often need to drink water, otherwise I get heart palpitations. could it tell me if I'm dehydrated?"

These ideas were further developed during the co-design activities, where participants added additional monitoring points to the smart garment framework diagrams. Suggestions included integrating electrocardiography and blood pressure tracking and hydration-level detection. Rather than replacing the core functionality related to loneliness, these suggestions were seen as complementary integrations that could increase the system's everyday utility and relevance by addressing users' broader well-being in a more holistic and meaningful way.

Linked Intervention

When participants reflected on the system's potential to monitor physiological and behavioral signals, the discussion naturally extended to scenarios involving health emergencies and critical incidents. Many raised concerns about automated alerts and connected interventions:

> *If you're in a state of severe loneliness or at some kind of risk, the next level of concern is whether social services would actually respond, whether your GP would be notified, or a nurse, or a district nurse would come out. That's the real worry.*

While many participants appreciated the system's potential to issue alerts or prompts, they expressed hesitancy about fully autonomous system actions, particularly in the context of emotional monitoring. Some expressed discomfort with the idea of automated triage, instead showing a preference for human-mediated intervention: "I would like a caregiver or clinician to review the data before contacting me."

In the co-design sessions, participants proposed customizable alert settings, including adjustable emergency thresholds, such as "Only trigger an alert if an abnormal signal persists for more than 10 minutes." and "Notify family members first, then professionals." These suggestions reflect a strong desire for tiered intervention logic, whereby users can define the severity of signals required to activate alerts as well as the order and type of recipients to be notified. This approach highlights the need for a personalized response, rather than a one-size-fits-all automation model.

Furthermore, although stakeholders such as care providers were not present in either workshop, participants actively imagined various relational configurations. Some participants preferred family members as first contacts, while others, particularly those living alone, favored designated professional care networks.

Discussion

Principal Findings

This study examined the acceptability and perceived usability of a novel smart loneliness monitoring system for older adults, comprising sensing garments, furniture, and a companion mobile app. Through user-centered evaluation and experience-based co-design, this study aimed to comprehensively explore users' practical, emotional, and ethical concerns to the system and to provide actionable design insights for future development. While

prior studies in pervasive computing and ambient-assisted living have focused on detecting behavioral correlates of social isolation, few have investigated how older adults themselves experience, interpret, and negotiate such monitoring systems [34-36]. Therefore, our findings contributed to bridging the gap between technical feasibility and user acceptability in the emerging field of smart mental health textiles.

Previous research has shown that older adults' acceptance of smart monitoring systems is heavily affected by perceived usefulness, particularly whether the data collected support meaningful or supportive interventions [17,56,57]. Given the practical and societal significance of loneliness monitoring, our prior research had explored older adults' initial design needs alongside stakeholder perspectives at the conceptual level [27]. Building on this foundation, this study combines smart textile design and sensing technology to develop prototypes that allow participants to physically experience, evaluate, and reimagine the system. This study identified 4 main domains affecting user acceptance and future design improvement, including wearability, usability and integration; trust, privacy and data control; limitations of loneliness monitoring; and future adoption, applicability, and ethical considerations.

Our findings highlighted the importance of adaptability and lifestyle compatibility in determining system acceptability, which are key aspects emphasized in previous research on wearable health technologies for older adults. Prior studies have shown that comfort, convenience, and discretion strongly influence engagement with wearable devices, particularly among older users who may have heightened sensitivities to fabric texture or skin contact [15]. In our study, although most participants were satisfied with synthetic materials for outerwear use, individual preferences and health history highlighted the value of personalized textile options. Participants appreciated the modular design and comfortable electronic textile integration, which enhanced wearability. However, unlike previous work that primarily assessed ergonomics or fit, our findings underscored the importance of emotional comfort and social invisibility. Participants expressed concerns about the visibility of sensing components and the potential stigma associated with being perceived as "monitored." This highlights an important extension of the current understanding of usability from physical comfort to psychosocial comfort. Additionally, the discussion around seasonal practicality and clothing preferences, such as the suggestion to adopt undergarment formats like vests or sports bras, introduces a novel consideration for thermal and social appropriateness and compatibility with individual everyday routines. While some previous smart garment research explored aesthetic design [58], our findings suggest that adaptability to seasonal routines and existing clothing habits is critical for long-term adoption. Moreover, the discomfort caused by rigid sensor modules further emphasizes the need for miniaturized and flexible electronics, a challenge also noted in emerging literature on e-textile scalability and integration [59,60]. Compared to sensing garments, sensing furniture was perceived as more comfortable, less obtrusive, and better aligned with habitual behaviors.

Trust, privacy, and data control were also key to user acceptance. Prior studies on digital health and remote monitoring technologies have consistently shown that trust and perceived data security are prerequisites for sustained engagement among older adults [61]. Our findings support these observations but extend them by revealing that participants' conditional trust depended not only on privacy assurances but also on the reliability, interpretability, and transparency of system feedback. These aspects highlighted in this study collaborated with previous studies on smart home and telehealth systems. However, unlike earlier work that primarily emphasized the role of institutional trust in health care providers [62], our participants focused on personal data sovereignty, and they want to see, understand, and adjust what the system infers about them in real time. While many older adults found the app's real-time feedback intuitive and easy to use, their past experiences with commercial wearables, such as smartwatches and fitness trackers, triggered skepticism regarding its accuracy when interpreting subtle emotional or behavioral changes. This echoes concerns in prior research that algorithmic opacity undermines user confidence in affective or well-being monitoring [63]. Our findings show that trust must be earned gradually through use and supported by transparent feedback mechanisms that allow users to confirm or challenge system outputs, which is an important element rarely addressed and discussed in earlier studies. Users have also shown a great preference to granular control over data sharing, allowing users to tailor access to different stakeholders such as family members, clinicians, or caregivers. While prior work on privacy in older adults has discussed consent management in general terms [64], our participants preferred a dynamic and contextual control that could match their current mental state and relationships. These insights extend the current literature by emphasizing that ethical acceptability is not achieved solely through initial consent, but through ongoing transparency, accountability, and user agency in data governance. Future development of wearable monitoring technologies should move beyond data protection compliance to include user-facing transparency features and active participatory data management frameworks.

Strengths and Limitations

The key strengths of this study lie in its multimethod integration of quantitative and qualitative approaches, combining structured questionnaires, focus groups, sensory ethnography, and experience-based co-design. This enabled a multifaceted understanding of older adults' experiences with the smart loneliness monitoring system and helped identify comprehensive user-driven directions for iterative improvement. However, several limitations also need to be acknowledged. First, all the participants were recruited from the United Kingdom, which may introduce a degree of regional bias and limit the generalizability of the findings to older adults in other geographic, cultural, or health care settings. In addition, the sample included relatively few male participants. Given that sex may influence perspectives on technology, privacy, and well-being, future research should aim to increase sex diversity to improve the representativeness of findings. Participants with diagnosed cognitive impairment were excluded during recruitment. Researchers applied the principles of the Mental Capacity Act (2005) to assess participants' capacity to understand the study and provide informed consent [40]. While

this ensured ethical participation and meaningful engagement with the system, the study does not include the perspectives of older adults living with cognitive impairment or dementia. Future work should explore how smart loneliness monitoring systems can be adapted or tailored for these populations, who may have different usability needs and vulnerabilities. Additionally, although participants met the inclusion criteria of being aged 65 years and older and having experienced loneliness, the majority of participants remained socially active, potentially limiting the generalizability of findings to more isolated or vulnerable populations. Moreover, the overall sample size was small. While small-scale qualitative studies can offer rich insight, findings should be interpreted as exploratory and hypothesis-generating rather than definitive. Finally, while the workshops were conducted in a controlled environment to allow in-depth interaction and observation, this setting may not fully capture the complexity of real-world use. To further strengthen the validity and practical relevance of the system, future research should involve longitudinal field testing in home or community settings. This would allow for continuous data collection over an extended period, enabling more robust analysis of behavioral and physiological patterns, as well as user engagement over time.

Conclusions

This study examined older adults' experiences with smart loneliness monitoring systems, including sensing garments, furniture, and a companion mobile app. Through immersive workshops combining structured questionnaires, focus groups, sensory ethnographic observation, and experience-based co-design, we investigated older users' practical, emotional, and ethical responses to the system, providing actionable design insights to inform future development. These findings indicate that while participants generally accepted the concept of monitoring via smart textile wearables and furniture, their willingness to adopt such systems over time is highly dependent on usability, personalization, lifestyle compatibility, and perceived control. Participants consistently emphasized the importance of adaptable design that respects bodily comfort, domestic routines, and personal identity. Moreover, the modular smart system developed in this study demonstrates strong potential as a discreet and passive sensing platform for psychological and social health indicators. However, continued user-centered iteration, broader real community testing, and deeper integration with health care infrastructure are required to ensure its future success in real-world applications.

Abstract

Background: As artificial intelligence (AI) becomes increasingly embedded in clinical decision-making and preventive care, it is urgent to address ethical concerns such as bias, privacy, and transparency to protect clinician and patient populations. Although prior research has examined the perspectives of medical AI stakeholders, including clinicians, patients, and health system leaders, far less is known about how medical AI developers and researchers understand and engage with ethical challenges as they develop AI tools. This gap is consequential because developers' ethical awareness, decision-making, and institutional environments influence how AI tools are conceptualized and deployed in practice. Thus, it is essential to understand how developers perceive these issues and what supports they identify as necessary for ethical AI development.

Objective: The objectives of the study were twofold: (1) to examine medical AI developers' and researchers' knowledge, attitudes, and experiences with AI ethics; and (2) to identify recommendations to enhance and strengthen interpersonal and institutional ethics-focused training and support.

Methods: We conducted 2 semistructured focus groups (60-90 minutes each) in 2024 with 13 AI developers and researchers affiliated with 5 US-based academic institutions. Participants' work spanned a wide variety of medical AI applications, including Alzheimer disease prediction, clinical imaging, electronic health records analysis, digital health, counseling and behavioral health, and genotype–phenotype modeling. Focus groups were conducted via Microsoft Teams, recorded, and transcribed verbatim. We applied conventional qualitative content analysis to inductively identify emerging concepts, categories, and themes. Coding was performed independently by 3 researchers, with consensus reached through iterative team meetings.

Results: The analysis identified four key themes: (1) AI ethics knowledge acquisition: participants reported learning about ethics informally through peer-reviewed literature, reviewer feedback, social media, and mentorship rather than through structured training; (2) ethical encounters: participants described recurring ethical challenges related to data bias, patient privacy, generative AI use, commercialization pressures, and a tendency for research environments to prioritize model accuracy over ethical reflection; (3) reflections on ethical implications: participants expressed concern about downstream effects on patient care and clinician autonomy, and model generalizability, noting that rapid technological innovation outpaces regulatory and evaluative processes; and (4) strategies to mitigate ethical concerns: recommendations included clearer institutional guidelines, ethics checklists, interdisciplinary collaboration, multi-institutional data sharing, enhanced institutional review board support, and the inclusion of bioethicists as members of the AI research team.

Conclusions: Medical AI developers and researchers recognize significant ethical challenges in their work but lack structured training, resources, and institutional mechanisms to address them. Findings of this study underscore the need for institutions to consider embedding ethics into research processes through practical tools, mentorship, and interdisciplinary partnerships. Strengthening these supports is essential to preparing the next generation of developers to design and deploy ethical AI in health care.

KEYWORDS

AI ethics; AI; artificial intelligence; ethics; focus group; medical

Introduction

Artificial Intelligence in Health and Medicine

Artificial intelligence (AI) is reshaping health care; AI tools are aimed at reducing costs [1], streamlining clinical workflow [2], and facilitating clinician and patient experiences [3]. Current AI applications may include assistance with clinical decisions, image-based diagnosis, self-diagnosis, mental health screening, and chronic disease management [2]. For example, electronic health records (EHRs) use natural language processing to support clinical decisions [4], and at-home AI monitoring systems assist older adults and those with long-term chronic illnesses, potentially alleviating caregiver burden [5]. Health care providers have started to use AI for medical imaging, diagnosis and disease screening, and prediction [6-9]. Furthermore, emerging scholarship demonstrates that AI has shown, to some extent, faster diagnostic speed and higher accuracy than human experts in image analysis and precision medicine [1,10]. The speed at which AI has been integrated and accepted into health care networks and its ease of access for users are unprecedented.

Despite these benefits, there are significant obstacles to AI implementation in clinical practice. Concerns about patient data security, privacy, clinician and patient autonomy, and decision-making may erode trust in AI outputs [11,12]. In addition, the pace of AI technology innovation often surpasses regulatory guidance at the federal and state levels [13]. Identifying and understanding ethical challenges may help establish practice and policy guidelines across health systems. Such mechanisms may ensure that AI developers and researchers, along with clinicians, patients, and health system leadership and administration, adapt and integrate AI that considers the needs and perspectives of all stakeholders. The purpose of this study was to explore AI developers' and researchers' understanding of and training in medical AI ethics.

Ethical Attitudes and Knowledge of Medical AI

Recent scholarship has shown rising ethical concerns among various stakeholders such as clinicians, patients, families, and policymakers who engage with medical AI [12,14-16]. Clinicians report that AI tools serve as a time-saving benefit in completing administrative tasks, which may effectively increase clinical productivity and patient engagement [6,17]. Yet, they are concerned with patient data privacy, the impacts on the clinician-patient relationship, and the possibility that the financial burdens of AI tools may heighten health inequities [7,17,18]. Patients and families voice similar concerns, focusing on patient autonomy and shared decision-making [19,20]. Patients articulate unease with the application of AI in treatment recommendations, medication administration, and surgical procedures [20].

Gap in Scholarship

The attitudes and perspectives of medical AI ethics among health care stakeholders are important. Yet, perspectives of other key stakeholders, such as AI developers and researchers, are underrepresented in research [12]. Previous studies demonstrate that ethical issues, including privacy and data security, fairness, transparency, and reliability of machine learning predictive analytics, are encountered by AI developers [21-23]. Yet, the perceived responsibility of developers and researchers to mitigate potential harms varies widely; some AI developers are cognizant of the broader societal impacts of AI (beyond technical considerations and optimization), while others feel disconnected and detached from direct patient and clinician outcomes [14,24,25]. Many AI developers report barriers to mitigating AI harms, including limited authority to make such decisions, and external pressures to deliver products quickly, all of which can hinder ethical reflexivity [26].

With a paucity of evidence-informed data on developers' AI knowledge and attitudes, further research is necessary to understand how AI ethics is addressed prior to deployment. Academic institutions play a central role in AI research and development, which lays the foundation for industry's AI design and application [14,24]. Academia has an important role in educating, training, and shaping the future generation of AI developers. This study presents a unique opportunity to guide policy, practice, and education efforts in research institutes that are aligned with the needs of AI developers and consider the deployment of ethical AI across health systems.

Research Rationale

AI developers and researchers work on algorithms that ultimately shape medical AI tools. Yet, clinicians often assume that AI tools used in clinical settings have been ethically scrutinized prior to deployment [27]. To understand ethical encounters of AI design, this study identifies the knowledge, attitudes, and training in medical AI ethics among AI researchers and developers. As an exploratory, pilot study, this work aims to offer an initial, in-depth understanding of how developers and researchers experience and navigate ethical challenges in medical AI. Rather than seeking generalizability, our goal was to capture diverse perspectives across academic contexts to illuminate key issues and inform the design of future large-scale, quantitative investigations on AI ethics training and institutional practices. Findings may inform strategies to facilitate AI ethics integration in development.

Methods

Recruitment and Sampling

The research team qualitatively explored perspectives of medical AI ethics among AI researchers and developers who were employed at academic institutions in the United States. Members of the research team had expertise in health communications,

AI and health promotion, and bioethics. Participants' inclusion criteria were (1) aged ≥18 years; (2) ability to read, understand, and communicate in English; (3) employed at an academic institution; (4) involved in medical AI research and development; and (5) consent to participate in a focus group. Participants were recruited through purposive sampling and chain referral methods to appropriately reach individuals who had an academic background in working with medical AI tools and the creation of algorithms. A study announcement and blurb were sent through listserv emails, through networks and contacts of the research team, and by word-of-mouth. Participants responded by email, and a focus group was scheduled that met participants' availability through an anonymous When2Meet Poll.

Data Collection

Focus groups (n=2; 60 minutes each) were held over Microsoft Teams and facilitated by the lead author. The facilitator had no pre-existing relationships with any participants. The lead author introduced herself to the research team and explained her background in clinical ethics, bioethics, and health scholarship prior to initiation. A semistructured interview guide was used in each focus group to reflect on participants' knowledge, attitudes, and encounters with AI ethics, and practical strategies to enhance or improve ethics education and training. Participants did not receive the interview guide prior to the scheduled focus group. Some example questions included the following: (1) What do you think is the extent of your AI ethics knowledge? (2) What is your prior experience with AI ethics? (3) What are the ethical concerns you have when conducting AI research? (4) How as a research team do you deliberate ongoing ethical issues you face? (5) In your current workplace, what training or learning opportunities are there with AI ethics? (6) What can your supervisor or the institution or university do to support you in understanding and identifying ethical issues in AI research? The interview guide was developed and piloted by members of the research team.

All focus groups (roughly 60-90 minutes each) were recorded and transcribed verbatim. No repeat interviews or focus groups were conducted. Transcripts were cleaned for errors and deidentified to protect participant confidentiality. Recordings and transcripts were stored on the university's secure password-protected server, and only members of the research team had access to the data. Thematic saturation was assessed through iterative review during and after the second focus group. At that stage, no substantively new themes emerged, and only minor variations of existing concepts were observed. We therefore determined that thematic saturation had been sufficiently achieved for the purposes of this pilot, exploratory study, and data collection concluded accordingly. In addition, members of the research team contacted different principal investigators within their respective academic units to enhance diversity in disciplinary backgrounds, institutional affiliations, and research areas. This strategy broadened the participant pool and helped capture a wider range of perspectives on AI ethics while maintaining the feasibility of this exploratory qualitative study.

Data Analysis

We applied conventional content analysis, an inductive qualitative approach used when limited theory or research exists on a topic [28]. Analysis occurs directly from the data without the use of preconceived frameworks or codebooks, allowing researchers to conduct in-depth exploration of raw data [28]. All focus group transcripts (roughly 70 pages of transcript data) were redacted and anonymized, and participants were given a specific numerical code to ensure the accuracy of responses. The 2 focus group transcripts were disseminated to 3 members of the research team (known as the coding team) to review independently from one another. Transcripts were reviewed, and data were coded inductively to form new insights and perspectives on medical AI ethics. Initial coding was conducted first to highlight exact words or phrases to denote emerging concepts. The whole research team met to discuss initial thoughts and impressions from the transcript and to develop a codebook. The transcripts were reviewed a few more times by the three independent coders to organize: (1) codes into categories, (2) categories into clusters, and (3) clusters into emerging themes. The coding team met frequently to finalize the codebook and to reach consensus on emerging themes and patterns from the data. Discrepancies in coding were discussed by the coding team to reach consensus. Codes were iteratively clustered into broader conceptual categories and then synthesized into higher-order themes that reflected shared meanings across participants. Throughout this process, the team also noted and discussed negative or divergent cases to ensure that contrasting perspectives were represented and that the final themes captured the full range of participant experiences. Once the codebook was finalized, the whole research team met to review findings and finalize themes. Rigor and trustworthiness were attained through peer debriefing with other AI and data science experts. The themes were grounded in participant data to capture their perspectives, thoughts, and insights on medical AI ethics.

Ethical Considerations

The study was approved by the Institutional Review Boards (IRBs) of Texas A&M University (approval number: IRB2023-0396D) and the University of Texas at Arlington (approval number: 2023-0234) prior to participant recruitment. Before the scheduled focus groups, participants received a copy of an informed consent form, which they signed and returned electronically. At the beginning of each focus group, the research team reviewed the consent information again orally, provided time for clarifying questions, and reiterated confidentiality limits and group norms. To protect the privacy and confidentiality of the participants, we transcribed the video recordings and removed all identifying information, including names, geographic location, or university affiliations. We conducted the data analysis based on the anonymized transcripts instead of videos. Each participant was paid US $20 in an Amazon gift card as compensation for their time.

Results

Overview

We interviewed a total of 13 participants employed in medical AI research and development. No participants declined or withdrew participation either before or during the focus group. Six (46%) participants were women, and 7 (54%) were men. Six (46%) participants identified as Chinese, and other participants identified as Asian Indian, Middle Eastern, Egyptian, Bangladeshi, Pacific Islander, or Taiwanese; only 1 participant identified as White. Participants held a range of positions, including research faculty (5/13, 38%), graduate students or research assistants (7/13, 54%), and programmer (1/13, 0.07%). Focus group participants represented 5 distinct academic institutes from different regions in the United States.

Participants' AI research included (1) disease or surgery outcomes prediction, (2) prediction and optimization of treatment, (3) analysis of electronic medical records or diagnostic imaging, (4) genetic analysis and genotype–phenotype correlation, (5) AI in counseling and behavioral health, and (6) AI in digital health and clinical trial work.

Four themes emerged from the analysis of focus group transcripts: (1) AI ethics knowledge acquisition that demonstrates how and where participants obtain AI ethics information, (2) ethical encounters that identify the main ethical issues that arise from algorithm development and design, (3) perceptions of ethical encounters to understand the implications of unresolved ethical encounters, and (4) recommendations and strategies to facilitate ethical deliberation and debrief in the workplace (Table 1).

Table 1. Themes and examples identified through conventional content analysis of focus groups on medical artificial intelligence (AI) ethics among US-based AI developers and researchers (2024).

Themes (innovation-decision process) and subthemes	Description	Quote
AI knowledge acquisition (knowledge)		
Peer-reviewed publications	Learning about AI ethics from published studies discussing bias, fairness, and responsible AI.	"So I was following up some publications, so I started to see the trend of new publications coming up and talking about like as I mentioned AI bias…"
Reviewers' feedback	Gaining awareness of ethical issues through reviewers' comments during the publication process.	"The first time I realized it was when I submitted my manuscript to Nature-like journals; most reviewers pointed it out, and that's when I started thinking about ethics seriously. "
Social media and AI policy updates	Following experts and organizations online to stay current with national and international AI ethics guidelines.	"I don't know if you've seen the recent news, like DeepMind's phone app for ChatGPT."
Informal mentorship and seminars	Receiving ethics training through informal networks, research supervisors, and academic workshops.	"Some competitions from big tech companies like Microsoft and Meta discussed these topics, and in our school, we also have weekly seminars about them."
Lack of formal training	Having little to no structured ethics education leads to uncertainty about ethical risks in AI research.	"I haven't received much training in AI ethics, so sometimes I don't even know what the problems are. Getting more training would help me recognize the issues and address them better."
Ethical encounters		
Data bias and fairness	Challenges related to underrepresentation in training data and unfair model outputs.	"Sometimes the data we use don't really represent everyone, so the model ends up being unfair to certain groups."
Privacy concerns	Issues with using patient data without proper consent or beyond the original intended use.	"Using patient data can be tricky; we're not always sure if we have full consent or if it's okay to reuse it for other purposes."
Use of generative AI	Concerns about researchers using tools like ChatGPT to fabricate or skip steps.	"Some people just ask ChatGPT to write sections for them, and that really blurs the line between help and fabrication."
Commercialization pressures	Ethical concerns regarding profit-driven deployment by tech companies over academic integrity.	"Once big companies get involved, the focus often shifts from research integrity to making profits."
Focus on accuracy over ethics	Some researchers prioritize performance over ethical considerations.	"Everyone talks about model accuracy, but barely anyone mentions the ethical side of it."
Reflections on ethical implications		
Model generalizability and explainability	Ethical concerns arise when models cannot be applied broadly or are not easily interpretable.	"Sometimes the model works great on one dataset but fails completely on another, and we don't really know why."
Impact on patient care	Researchers worry about AI models causing harm or failing to help diverse patient populations.	"If the model gives the wrong prediction, it could actually harm patients instead of helping them."
Clinician autonomy and displacement	Fears that AI may replace doctors or alter clinician-patient relationships.	"Some doctors worry that AI might start making decisions for them or replace parts of their job."
Technological pace vs evaluation speed	Difficulty in evaluating AI tools quickly enough to match their development speed.	"AI is moving so fast that our evaluation methods can't really keep up."
Ethical burden on researchers	Responsibility to address AI ethics falls heavily on developers without adequate support.	"We're the ones expected to think about ethics, but no one really gives us the tools or training to do it properly."
Strategies to mitigate ethical concerns (implementation and confirmation)		
Guideline communication	Improve access to updated ethical AI guidelines and standards.	"We really need clearer and more accessible guidelines on AI ethics; sometimes it's hard to even find the latest ones."
Ethics checklists and scenarios	Using predefined lists or cases to test and evaluate model ethics and bias.	"Having a checklist or real cases to go through would make it easier to see where our model might go wrong ethically."
Data collaboration and diversity	Partnering with other institutions to diversify datasets and reduce bias.	"If we could share data across more institutions, the models would be less biased and more reliable."
IRB[a] support and governance	Having AI-specific ethics experts within IRBs to guide responsible research.	"It would help a lot if IRBs had someone who actually understands AI to guide us on the ethical parts."

Themes (innovation-decision process) and subthemes	Description	Quote
Inclusion of bioethicists	Adding bioethics experts to AI teams to help identify and resolve ethical issues.	"Having a bioethicist on the team would make us think about these issues more seriously from the start."

[a]IRB: Institutional Review Board.

Medical AI Ethics Knowledge Acquisition

Participants discussed various avenues through which they sought AI ethics information and knowledge, including peer-reviewed publications, journal feedback, social media, and informal institutional learning. Several participants mentioned journal submission guidelines or peer review feedback that relayed information on AI ethics or included statements that mentioned AI use and plagiarism:

> *Although I had studied ethics during my medical school, I never paid attention during machine learning research. The first time I came to know was when I submitted my manuscript…the first thing they [reviewers] pointed out was about this [ethics]…most of the reviewers were concerned about it. So that's when I started thinking about it more seriously. I came to start thinking about ethics because if you publish in good journals, people will point out those things.* [P2]

Others observed a rise in publications on AI ethics and begun to read peer-reviewed articles for information: "I started seeing the trend of new publications coming up, talking about bias, fairness, and then AI ethics" (P5).

Other participants relied on social media to inform AI ethics knowledge:

> *I've been following [on X] anyone that has their hands in AI ethics or AI policy and checking all the guidelines, not just institutional levels, but national and international levels. It's hard to keep up with all the literature that's being pumped out right now. But it's important to at least familiarize yourself with some of the different pieces…and what the relevant concerns are that are transcending that international sphere.* [P6]

Social media was perceived as more current and relevant than peer-reviewed publications, able to keep up with fast-paced developments.

A small number of participants described that AI research ethics knowledge derived from informal discussions with supervisors or participation in university seminars or workshops:

> *I have really lucked out into having good people in my circle and training me. I think that's a huge resource in terms of understanding ethics and AI, and then also intentional engagement with current guidelines that are being put out.* [P6]

Yet, one participant remained silent during this discussion. When prompted, the participant stated having little to no knowledge about AI ethics:

> *I have received not too much training in AI ethics, so that is why I don't even know what the problems are. Even if I'm making some mistakes, I don't know if those are things that I should have been careful about.* [P2]

This participant's experience is important to elucidate, as it shows potential training gaps and impacts on students and researchers.

Ethical Encounters in AI Development

Participants reflected on ethical challenges encountered in their research environments, including concerns about data bias, privacy, commercialization, and the use of generative AI tools. Participants discussed the fabrication of data, in which the reliance on AI-generated tools, like ChatGPT, has enabled colleagues to skip steps through automated written responses. Yet, the primary ethical obstacle in medical AI research, as reported by participants, was bias and underrepresentation within training datasets. The ethical issues were consequences related to predictive modeling and fairness, especially how data omission could disproportionately exclude people of color. As a participant who worked on radiation therapy, observed:

> *When we build the predictive model, if our model is just purely based on the data we collected, it seems like it's not very fair for Black people or Asian people. That's the issue we are currently facing.* [P4]

Another participant agreed, stating:

> *Most of the data are coming from European [and] the therapeutics will be ultimately optimized for a certain group of people [so] it can't be generalized. If you are not careful with what kind of metric you're using to assess and evaluate that model, you're pretty much classifying everything as negative. And institutions like to incorporate these models into their systems. If you put more weight on them [the positive cases] you might be identifying the white skin tone but not the darker skin tone.* [P1]

There were also concerns of data security and the risk of breaching patient data privacy:

> *If you're using patient data without their proper consent or you use data that trains a model that is then used for something else that's not within the previously defined scope, that is not ethical.*

A participant discussed that privacy was also the "need to test it [the model] and then be transparent to the community and [provide] the proper instructions of the model's performance degree" (P10) to ensure that the model is explainable and interpretable to key stakeholders.

Participants deliberated on the dangers of the commercialization of AI technologies and limited regulations:

> *What I am really concerned with is that these big tech companies are pushing very hard to deploy their AI model into the hospital system. It's linked to profit, a very profitable market; if those big tech companies want to push their product, I don't know whether they will do it with the same level of checks and balances because it's profit-driven, and they can promise a lot of money, and we cannot make that promise.* [P9]

The overall ethical concern related to commercialization was the fast-paced development of AI and the time sensitivity of implementing AI into health care spaces; for-profit companies will be selected over evidence-informed AI research programs.

> *The perceived competitiveness between big tech corporate research and also academic research and I feel like they are not playing by the rules because they can skirt and essentially do things that we have to abide by like privacy issues and so forth.* [P8]

In contrast, there were participants who did not perceive these as ethics issues but rather as an accuracy issue: "I'm not really focused on ethics. I tend to focus more on accuracy, something that will make the model better but not actually the ethics" (P3).

Reflections on Ethical Implications

Participants described how the ethical encounters stated above influenced research design and modeling choices and raised broader concerns about patient care, clinician roles, and the future of health care. For example, issues related to fairness and bias influenced generalizability:

> *from a data scientist perspective, it's an issue; you cannot have a very accurate model with very high bias. You can build your model, but we want the model to have higher generalizability; we need to take this issue from a data scientist perspective.* [P4]

Participants noted that limits to explainability of AI impeded solutions to resolve ethical issues:

> *with so much advancement in AI technology, there is still no standard correct ways of evaluating my model because I haven't understood my data or the distribution of the data yet.* [P1]

Other participants considered ways ethical issues in AI development may impact patient care and physician interactions. For example, participants who worked on large language models deliberated on how AI tools can generate clinical notes for the patient and questioned the accuracy of how "clinical notes could be to the specific patient…. we don't know how that benefits the patients" (P7). Questions related to predictive modeling also drew fears of perpetuating patient harms:

> *How do we balance advancing healthcare to truly help patients in this unprecedented way, but also make sure that we're not exploiting them or using models that aren't appropriate for them?* [P6]

Participants reported that physician autonomy and patient-physician relationships were another important area to identify the ethical implications of AI deployment in health care. One participant asked, "whether AI is going to replace certain jobs and tasks and maybe even eventually replace doctors; that's a conversation I have about my research" (P8). The timing to evaluate technology was an added concern that could impact patient care:

> *By the time you come up with a standard metric that you need to satisfy your AI model to be deployed in a healthcare facility…maybe the technology has completely changed by then. I don't know what the solution would be, but clinicians, researchers, lawmakers, you know, everybody needs to be on board because they can no longer take that long to evaluate a technology.* [P1]

The perceived impacts of AI ethics placed added burdens and responsibilities on AI researchers and developers. Heightened attention on AI ethics placed more obligations on AI developers and researchers to resolve these issues, yet without training or learned mitigation strategies.

Strategies to Mitigate Ethical Concerns

Participants described a range of strategies to address AI ethics in research, including individual practices, team-based approaches, and institutional-level interventions. Participants suggested individual and team-based approaches that foster transparent communication and knowledge mobilization. For example, a participant emphasized the need for

> *…good communication about the latest guidelines that are available from different communities. If that becomes available to use as students and even as faculty that will be more helpful to make us more compliant with those regulations.* [P5]

Guidelines, in turn, can assist in the design and development of checklists or critical scenarios to mitigate biased models. One participant stated

> *…maybe we can have a checklist on what we need to see before doing something that's more concrete. I know it's difficult to do that in AI ethics because we don't directly use it for patient outcomes right now. But I think it will be a good starting point to have some kind of checklist on what we should be careful about.* [P2]

Another participant wanted the actual model to counteract biases:

> *The first check should be done on the data and how the data biases have been handled by the AI models. And last, what are the abusive ways this model can be used? We should have some critical scenario by which we can test our model, like some exerted test on the product to see whether this product is stable up to two years…whether it is up to our expectation.* [P1]

Participants advocated for organizational and institutional strategies to support ethical AI development. One approach mentioned was multi-institutional collaboration to improve data quality and diversity and mitigate bias by increasing access to larger, more representative datasets. One participant said: "Where you don't have enough data to support the deep learning [models], we have to collaborate with other institutes to not

only expand the sample size but also introduce diversity into the data" (P4). Participants also called for ethics consortiums to foster ethical awareness and skill development. For instance, a participant said: "I feel like getting more training will help me more to even identify what the problems are and then address them" (P2).

An added strategy was to equip the IRB with AI-specific guidance or AI ethics expertise on regulatory committees to enhance regulation through a uniform approach and facilitate adherence to best practices. IRB involvement could promote a more consistent approach to oversight and improve adherence to best practices. However, several participants expressed frustration that current assistance or guidance sought from the IRB often resulted in confusion rather than clarity:

> *We have those IRB boards and maybe some better governance…to have somebody also on AI ethics and being responsible for sharing that awareness as well as ensuring that we are going through the guidelines and sticking through the regulations.* [P5]

Finally, for some participants, a bioethicist or ethics expert should be involved as a potential interdisciplinary member of the research team:

> *When you don't have a bioethicist at your beck and call or infused in the research in some degree, that makes it really tricky too because you might not have the checks and balances that are appropriate in maybe expanding your research or getting into the right market.* [P6]

Discussion

Overview

The integration of medical AI in preventive care and clinical decision-making means that researchers, data scientists, and those involved in the design and development of AI need to start becoming attuned to its clinical impacts. This study aims to address gaps in scholarship by examining AI researchers' ethics perspectives. Academic institutions, such as universities and research institutes, play a central role in educating the future generation of AI developers on AI ethics and design.

Findings from the study inform how medical AI may be diffused into health care settings and how its use communicated effectively between physicians, staff, and patients. The themes from this study may be adapted into Rogers' diffusion of innovation framework [29]. Rogers maps a 5-stage decision-making process to evaluate and adopt AI innovation into practice. The series of stages is as follows: (1) knowledge (gains understanding), (2) persuasion (reflect on attitudes), (3) decision (activities and experiences that lead to choice), (4) implementation (its actual use in practice), and (5) confirmation (to avoid dissonance and conflict).

Our findings ought to be conceptualized within the diffusion of innovation framework to understand how perspectives of AI researchers and developers offer insight into the steps, attitudes, and barriers that influence the decision-making of medical AI adoption and integration. Findings from this study may inform policy, practice, and education efforts to readily prepare AI researchers and developers to identify and examine ethical encounters in their work and to illustrate how medical AI attitudes, perceptions, and support may influence adoption or rejection [29].

AI Ethics Knowledge Acquisition

In the knowledge stage of individual decision-making, participants in this study received information about AI ethics from a multitude of sources, including social media, peer review journal commentary and publications, and voluntary workshops and seminars. Students' particular focus on social media as an access point for AI knowledge may be an important consideration to assess (1) the type of accuracy of messaging received and (2) the ethical issues being described and disseminated. Knowledge garnered through social media may filter into how students understand and evaluate their own research and ethical encounters, including how early adopters may rely more on social media than on peer-reviewed sources. For example, participants who described issues as rooted in accuracy rather than ethics may benefit from conversations and messaging that deciphers ethical issues from technical issues; the ability to understand how to identify and label issues as ethical (rather than solely technical) could enhance medical AI ethics knowledge and lead to a more nuanced and robust deliberation on how ethics may impact medical AI design, development, and deployment.

Ethical Encounters and Resolution Strategies

Past research experiences of participants impacted their attitudes and perspectives of medical AI. Bias and fairness were central ethical challenges identified by participants, particularly the underrepresentation of people of color in training datasets. Such omissions risk reinforcing structural inequities and limiting the generalizability of medical AI systems. To address these issues, future research should prioritize diversifying medical datasets and integrating fairness auditing across development, supported by multi-institutional collaborations and community engagement to ensure representativeness, transparency, and accountability [30-32]. Together, these efforts can help mitigate the disproportionate exclusion of marginalized groups and promote more equitable AI-driven health outcomes to address negative attitudes toward medical AI innovation.

Extant scholarship echoes the current study's findings by demonstrating that AI developers possess some awareness of key ethical principles, such as fairness, data security, transparency, and reliability [14], that may persuade their decision-making in adoption. Nichol et al [14], for example, conducted semistructured interviews with 40 employees from AI organizations. Participants in the study identified potential impacts of ethical issues, such as violation of patients' privacy, misdirected health care practices, and disrupted health care systems. Other studies have similarly shown that some AI developers are sensitive to broader societal impacts of ethical AI [24,25], beyond technical issues and optimization of their algorithms [33,34].

Although participants in this study were able to identify emerging ethical issues and had thoughtfully evaluated how

these issues would impact patient and clinician experiences, there were limited resolution strategies. These experiences impacted AI researchers' decision-making, including not knowing whether to adopt or reject innovations in their work. For participants, ethical encounters were often left unresolved with no clear direction on how to proceed. The lack of informed decision-making was rooted in a lack of clarity from institutions and left participants feeling that AI researchers and developers held an undue burden in deploying ethical AI tools without further scrutiny or analysis. The added pressure on AI developers and researchers to perform was perceived as a challenge, and our findings suggest that other key stakeholders (including physicians or clinicians and health systems) ought to contribute to ethical decision-making when AI is used in practice. Thus, findings from this study show that decisions of whether to adopt or reject AI ought to include diverse perspectives to allow for more information, to identify problems, and to have support [29].

AI models must continue to be questioned and analyzed by stakeholders even after deployment. With AI technologies changing so rapidly, participants struggled to balance the fast-paced development of AI algorithms with the ethical concerns that arose. This led participants to articulate that medical AI tools ought to be continuously reviewed and evaluated.

The barriers and limited support indicate that implementation and confirmation, the final stages in the innovation-decision process, may be difficult to reach. Participants described that in the development of medical AI innovation, they often evaluated long-term impacts on patients and families and desired further support from mentors, supervisors, and organizational leadership. The perspectives of participants show that there continue to be conflicting messages and dissonance among researchers and developers regarding the adoption and use of medical AI in practice settings. Further organizational practices and policies ought to be considered to assist in decision-making activities to facilitate a more robust and comprehensive adoption process.

This study's findings echo prior work wherein AI developers voiced confusion regarding their own roles and responsibilities in mitigating the potential harm of their tools, compounded by perceived limited authority, external pressures to produce, and the difficulty of balancing productivity and ethical considerations [26,33]. Algorithm development is highly complex and iterative, making it difficult for researchers to predict its ethical impact and apply oversight in the process. As participants in this study noted, transparency and explainability were key ethical issues, and a gap in accessible checklists or guidelines heightened obstacles to elucidating datasets and explaining patterns to clinicians and patients who may rely on these algorithms for diagnosis and treatment. The issue here is that resolving ethical encounters requires additional time and energy from AI developers, which may be an added challenge in a high-stress environment that is at odds with the fast-paced development of commercial AI tools [14]. The capacity to build collaborative environments, hold ethics consortiums, and have a robust network of people and resources to support AI ethics awareness, knowledge, and action is critical to support AI developers and researchers. Relieving some of the burdens on AI developers and researchers with institutional mechanisms can model an environment that supports ethical rigor and deliberation and lead to reinforcement and confirmation of medical AI technologies in practice settings.

As pointed out by Mittelstadt [35], compared with medicine, the field of AI research is much more heterogeneous, without defined common aims, fiduciary duties, or historical professional norms. The constant changes and shifts related to AI policy and procedure create difficulties in outlining consistent guidelines or measures to follow. Additionally, AI developers typically have backgrounds in computer science with limited training in ethics. The relative unfamiliarity with ethical principles and their implications could add further barriers to ethical medical AI development, potentially leading to ethically flawed AI products that could impose unintended harm to patients [34]. Thus, multisite collaborations, interdisciplinary communication, and IRB guidance and best standards may help to reduce the burden on AI developers, create more teachable moments, and establish more thoughtful and intentional mechanisms for deliberating ethical encounters, along with clear resolution pathways to facilitate implementation and confirmation.

Bioethics-Informed Guidance

The inclusion of bioethicists on research teams, as stated by participants, has been suggested in prior theoretical scholarship. For example, McLennan et al [36] proposed the concept of "embedded ethics," a collaborative approach that creates interdisciplinary research teams whereby AI developers and ethicists can anticipate, identify, and address ethical issues as they arise in the development process. Other studies have suggested a practical ethics checklist for AI developers [37] that recognizes ethical and social responsibility within AI development [38] or ethics guidelines and review processes specifically designed for AI developers [39,40] to support research design and analysis. These efforts offer improvements by having a refined focus on the practicality of how to use ethics recommendations and an emphasis on frontline AI developers, who can help mitigate ethical issues prior to AI deployment and use. This study's findings demonstrate that AI developers are interested in gaining knowledge about AI ethics, are already deliberating on the ethical encounters in their design and development, and are thoughtful about the longer-term practical implications of their work in health systems. Future research ought to consider strategies to mitigate ethical encounters and to advocate for heightened ethics knowledge, training, and conversations specifically targeted for AI developers and researchers. Foundational seminars on how to identify and label an issue as ethical (as opposed to technical) are a critical first step in training to ensure all developers and researchers can recognize these encounters in practice. Supervisors and managers must consider ways to encourage ethical dialogue and empower students and faculty to seek ways to mitigate ethical concerns and bridge their work to practice. This may involve bringing in bioethicists or other ethics experts who can speak diligently, thoughtfully, and comprehensively about these topics. AI developers and researchers should not be working in siloes but rather placed in communities with other medical AI stakeholders to heighten ethical dialogue and theorize novel

mitigation strategies. Additionally, to enhance the actionability of these recommendations, institutions could develop sample ethics checklists (eg, addressing data representativeness, model explainability, and patient privacy), workflow templates that map ethical review points within the AI development process, and metrics to evaluate ongoing compliance. Such practical tools can help translate ethical principles into consistent, operational practices for research offices and AI teams. These steps may facilitate the diffusion of innovation processes to allow for an easier and more transparent decision, implementation, and confirmation process that can lead to ethical adoption of medical AI. It is clear that ethical conflict and encounters of ethical dilemmas in the development and deployment of medical AI have stark impacts on the diffusion of innovation and the ability to effectively implement and reinforce the decision to adopt. Future research may seek to understand how this process may infiltrate the decision-making and ethical attitudes and perspectives of other key stakeholders, including physicians, allied health workers, health care administrators, patients, and families.

Limitations

This is one of the first studies in North America to examine AI developers' knowledge, encounters, and recommendations of medical AI ethics. Yet, there are several limitations. The small and relatively homogenous sample limits the diversity and generalizability of the findings. Future research should pursue broader and more inclusive investigations that capture perspectives from a wider range of disciplines, institutions, and demographic backgrounds across the United States. The representation of only 5 academic institutions may narrow the findings and may overlook other ethical concerns that emerge in distinct research areas. This was also a qualitative focus group study, and, thus, participants may have had concerns regarding privacy and confidentiality, reputation, and status in responses, and the emergence of potential power imbalances with student participants. Furthermore, as with most focus group studies, participants may have provided more socially desirable responses due to the group setting or the presence of peers, which could have influenced the depth or candor of some discussions. The focus group facilitator mitigated any ethical concerns by setting group norms, ensuring privacy and confidentiality, and piloting focus group questions and prompts. Future research may consider an anonymous survey to broadly examine ethical encounters in medical AI research.

Conclusions

As an exploratory pilot study, the current findings provide preliminary insights that can guide future empirical and institutional efforts. Findings from this study are important to determine the next steps to facilitate ethical decision-making among medical AI developers and researchers. There ought to be strategies to effectively deliberate about AI ethics across research teams and create opportunities for multisite collaboration, IRB debriefs and guidelines, protocol checklists and testing mechanisms, and the involvement of key stakeholders in deliberation, including bioethicists, clinicians, patients, and hospital leadership or administration with AI research teams. These initial insights lay the groundwork for larger-scale, multi-institutional investigations that can further validate and expand on the patterns identified here. The perspectives of key stakeholders may inform stages in the innovation-decision process and gain insight into barriers, supports, and resources necessary to ethically adopt medical AI into practice.

Abstract

Background: Bleeding complications are a major contributor to adverse drug events among older inpatients, particularly in those treated with antithrombotic agents. Timely and accurate detection of bleeding events is essential for improving drug safety surveillance and clinical risk management.

Objective: The study aimed to develop and validate automated algorithms for detecting major bleeding (MB) and clinically relevant nonmajor bleeding (CRNMB) events from electronic medical records (EMRs) by combining structured data-based rule models and a natural language processing (NLP) approach, and to evaluate their performance and generalizability against a manually reviewed gold standard and an external dataset.

Methods: We conducted a multicenter retrospective study using routinely collected EMR data from 3 Swiss university hospitals. Patients 65 years or older who received at least one antithrombotic agent and were hospitalized between January 2015 and December 2016 were included. To detect MB and CRNMB events, rule-based algorithms were developed using structured data (*International Statistical Classification of Diseases, 10th Revision, German Modification* [*ICD-10-GM*] codes, laboratory values, transfusion records, and antihemorrhagic prescriptions), with variables and cutoff values defined according to adapted International Society on Thrombosis and Haemostasis definitions and expert consensus. In parallel, a supervised NLP model was applied to discharge summaries from one hospital. A manual review of 754 EMRs served as the reference standard for internal validation, and the algorithm performance of the structured data algorithms (SDA), NLP, and their combination (SDA+NLP) was evaluated against this manually reviewed gold standard using standard performance metrics. External validation was performed on an independent dataset from the Lausanne University Hospital to assess model robustness and generalizability.

Results: Among 36,039 inpatient stays, SDA identified 8.26% (n=2979) as MB and 15.04% (n=5419) as CRNMB cases. *ICD-10-GM* codes alone detected 28.5% (n=849) of MB and 31.48% (n=1706) of CRNMB cases, while laboratory data contributed most to event detection (n=1994, 66.94% for MB and n=3663, 67.60% for CRNMB). Integrating SDA with NLP improved detection, identifying 12.2% (920/7513) of MB and 27.4% (2062/7513) of CRNMB cases at 1 hospital. The combined model achieved the best performance (sensitivity 0.84, positive predictive value 0.51, F_1-score 0.64). External validation on Lausanne University Hospital 2021 - 2022 data (n=24,054 stays) confirmed the algorithms' reproducibility; the prevalence of MB decreased while CRNMB increased, reflecting evolving clinical practices and antithrombotic use patterns.

Conclusions: Our integrated approach, combining SDA with NLP, enhances the detection of hemorrhagic events in older hospitalized patients treated with antithrombotic agents, suggesting its potential usefulness for drug safety monitoring and clinical risk management.

Introduction

Over 16% of older inpatients experience at least 1 adverse drug event (ADE) during their hospital stay [1], often with more severe consequences than in younger patients [2]. Among the medications most frequently implicated, antithrombotic agents, widely prescribed in older adults for the prevention and treatment of cardiovascular disease, stand out as a major cause of bleeding-related ADEs [1,3]. Hemorrhagic complications represent a substantial share of drug-related harm in this population and are associated with longer hospital stays, higher readmission rates, and increased mortality. Continuous and accurate measurement of these events is therefore essential to inform prevention strategies, strengthen pharmacovigilance, and promote safer antithrombotic use in clinical practice.

Various approaches have been developed to detect ADEs in hospital settings, each with advantages and limitations. Spontaneous reporting systems, though simple to implement, notoriously underestimate the true frequency of ADEs due to underreporting [4]. Systematic chart reviews of electronic medical records (EMRs), often considered the reference standard, provide detailed clinical information but are too resource- and time-intensive for routine surveillance [5]. To overcome these constraints, automated detection methods using routinely collected EMR data have emerged. These approaches leverage both structured data, such as diagnostic codes, medication records, laboratory results, and vital signs, and unstructured clinical narratives, including discharge summaries, progress notes, and consultation reports. Structured data are accessible and standardized, supporting large-scale analyses but may lack contextual nuances needed to capture complex clinical events such as bleeding [6-8]. Conversely, textual data, although unstructured, often contain richer clinical detail but require advanced computational methods for analysis. Recent advances in machine learning (ML) and natural language processing (NLP) have markedly improved the ability to extract this information and are increasingly applied to pharmacovigilance and ADE detection [9]. Integrating both structured and textual data appears particularly promising for identifying bleeding events, potentially enhancing accuracy and completeness [10].

Despite growing interest in automated ADE detection to support drug safety monitoring, important knowledge gaps remain, particularly in the Swiss context. Most existing studies focusing on bleeding events have relied exclusively on either structured or unstructured data [11-15], have prioritized prediction rather than detection [8,16], or have focused on specific bleeding types or patient groups [7,10,17-19]. Furthermore, clear operational definitions distinguishing major bleeding (MB) from clinically relevant nonmajor bleeding (CRNMB) are often lacking, limiting comparability across studies [20]. To date, no study in Switzerland has comprehensively evaluated the combined contribution of structured and textual data for ADE detection in a general inpatient population receiving antithrombotic therapy. To address this gap, we conducted a multicenter study integrating rule-based algorithms and NLP to detect MB and CRNMB events among older inpatients treated with antithrombotics. We hypothesized that combining structured and textual EMR data would improve the accuracy and completeness of bleeding event identification compared with using either data source alone. The study aimed to develop rule-based algorithms for bleeding detection from structured data sources (diagnoses, laboratory results, transfusions, and antihemorrhagic prescriptions) based on international definitions; design and train an NLP model to identify bleeding mentions in discharge summaries; assess and compare the diagnostic performance of structured data algorithms (SDA), NLP, and their combination (SDA+NLP) against a manually reviewed gold standard; and evaluate the generalizability of the best-performing models through external validation on an independent dataset.

Methods

Study Design

We conducted a multicenter cross-sectional study using retrospective data covering the period from January 1, 2015, to December 31, 2016. Data were obtained from 4 large Swiss hospitals: Lausanne University Hospital (CHUV; approximately

1500 beds [21]), Geneva University Hospital (HUG; approximately 2000 beds [22]), both located in the French-speaking region and serving the cantons of Vaud and Geneva, respectively, Zürich University Hospital (USZ; approximately 900 beds [23]) serving the Zurich metropolitan area, and Baden Cantonal Hospital (KSB; approximately 400 beds [24]) serving the canton of Aargau in the German-speaking region. This study was conducted in accordance with the SRTOBE (Strengthening the Reporting of Observational Studies in Epidemiology) statement (Checklist 1).

The 2015 - 2016 dataset was used for algorithm development as it was the most recent period with harmonized, high-quality structured and unstructured EMR data across all hospitals. Later years were excluded due to EMR vendor transitions, database restructuring, and new data-governance restrictions limiting access to deidentified text. A more recent CHUV dataset (2021 - 2022) was used for temporal and external validation to test algorithm robustness under evolving clinical practices and documentation standards.

Study Participants and Hospital Stays

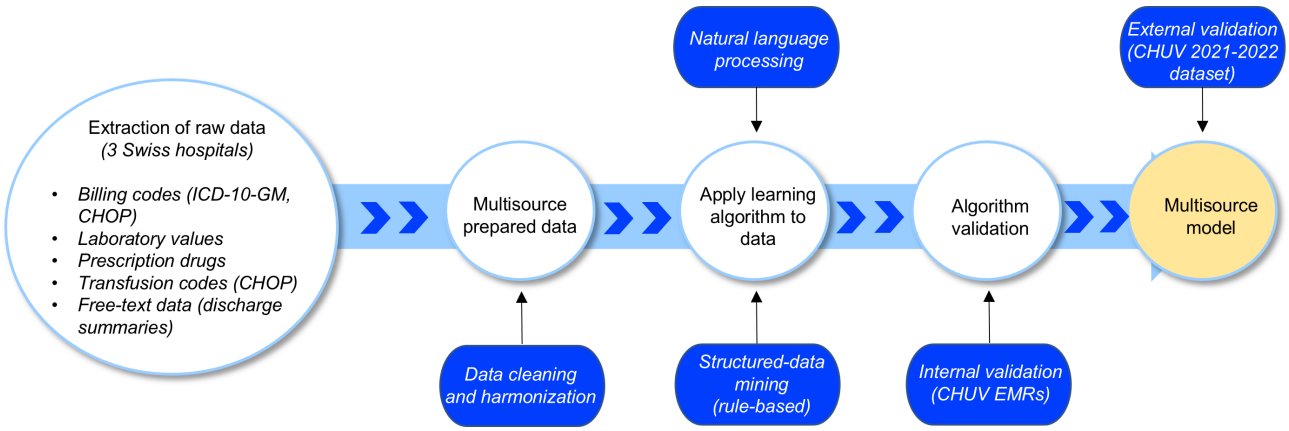
Eligible participants were Swiss residents 65 years or older treated with at least 1 antithrombotic agent during their hospital stay. Antithrombotic agents included vitamin K antagonists, heparins, platelet aggregation inhibitors, direct thrombin inhibitors, direct factor Xa inhibitors, or fondaparinux. Hospitalizations had to last at least 24 hours and to occur between January 2015 and December 2016 (test dataset). For the external validation, an additional dataset from CHUV covering January 2021 to December 2022 was used (validation dataset). Only patients who had provided explicit consent for the reuse of their health data for research purposes, as indicated by the signature of the general consent form, were eligible for inclusion. Hospital stays lasting less than 24 hours were excluded from the analysis.

Data Sources and Preprocessing

Each participating hospital extracted relevant clinical data from its institutional data warehouses for all inpatient stays meeting the inclusion criteria. The extracted datasets included both structured and unstructured data. Structured data comprised administrative information, patient movements within the hospital, key clinical and laboratory parameters, and prescribed medications coded using the anatomical therapeutic chemical classification. Diagnostic codes were drawn from the *International Statistical Classification of Diseases, 10th Revision, German Modification* (*ICD-10-GM*), and procedures were coded according to the Swiss Classification of Surgical Procedures (CHOP). Diagnoses and procedures were obtained from the hospital billing records associated with each inpatient stay. Unstructured data included discharge summaries. Further details on data extraction and handling are available in the published study protocol [25].

Prior to analysis, structured data were cleaned, harmonized, and verified for consistency at each site, then locally deidentified before being transferred to a centralized database hosted at CHUV. Unstructured data were deidentified and, where necessary, converted into machine-readable formats, but were stored locally on secure hospital servers to comply with data governance policies. Due to the extent of missing and inconsistent information, such as discrepancies in data structure, coding systems, variable definitions, and extensive missing values, reliable harmonization of KSB data with the other hospitals was not feasible, and data from KSB were excluded from the analysis. In addition, only unstructured data from CHUV were analyzed, as full deidentification of textual data from the other sites could not be ensured. The same preprocessing workflow was applied to the 2021 - 2022 CHUV dataset used for external validation. An overview of the data processing workflow is provided in Figure 1.

Figure 1. Overview of the data extraction and preprocessing pipeline for structured and unstructured electronic medical record (EMR) data. CHOP: Swiss Classification of Surgical Procedures; CHUV: Lausanne University Hospital; *ICD-10-GM*: *International Statistical Classification of Diseases, 10th Revision, German Modification*.

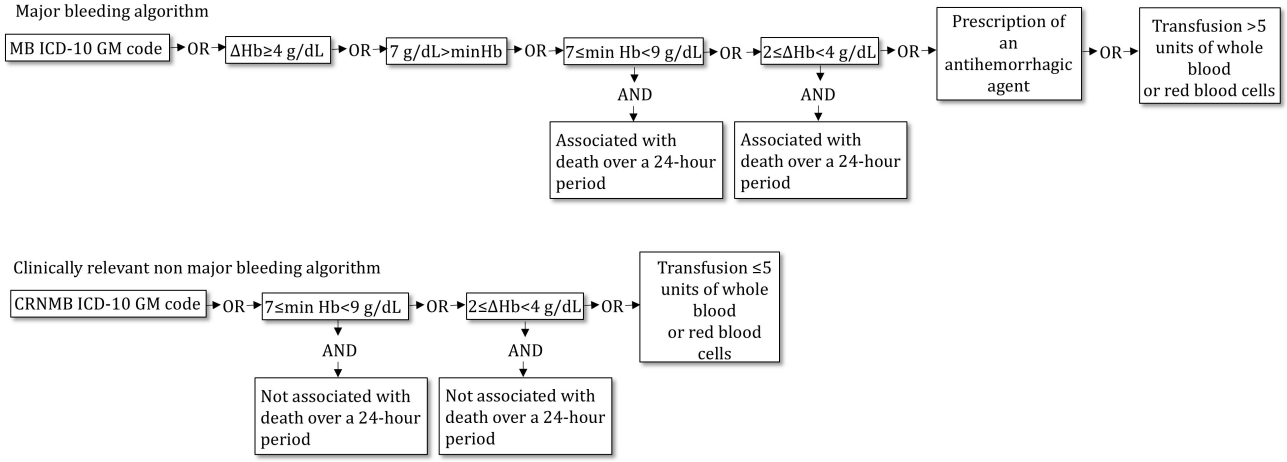


Bleeding Detection Algorithms

We selected variables of interest and cutoff values for our algorithms based on an adaptation of the International Society on Thrombosis and Haemostasis (ISTH) definitions of MB [26] and CRNMB [27], informed by an extensive review of international guidelines (Multimedia Appendix 1). MB was defined as a hemoglobin drop of 4 g/dL or more within 48 hours, a 2 to 4 g/dL drop associated with death within 24 hours, a hemoglobin level less than 7 g/dL, a hemoglobin level between 7 and 9 g/dL associated with death within 24 hours, or a transfusion of more than 5 units of blood or red blood cells. CRNMB was defined as a hemoglobin drop of 2 to 4 g/dL within

48 hours not associated with death or a hemoglobin nadir between 7 and 9 g/dL without subsequent death. The ISTH hemoglobin thresholds were adapted to improve specificity in older inpatients and to reduce the risk of misclassifying nonhemorrhagic anemias. The 5-unit transfusion threshold was pragmatically chosen due to the limited granularity of CHOP procedural codes. Additional structured indicators were also integrated to refine case classification: the prescription of antihemorrhagic agents (idarucizumab, andexanet alfa, prothromplex, octaplex, and beriplex) was considered indicative of MB. MB-related in-hospital mortality was defined as any hospital stay involving at least 1 MB event followed by death during the same admission. We then developed rule-based algorithms using Boolean logic to detect MB and CRNMB cases from structured data (Figure 2).

Figure 2. Algorithmic framework for detection of major bleeding (MB) and nonmajor clinically relevant bleeding (CRNMB) cases using structured data. Antihemorrhagic agent: idarucizumab, andexanet alfa, prothromplex, octaplex, and beriplex. ΔHb: drop in hemoglobin levels within 48 hours; *ICD-10-GM*: *International Statistical Classification of Diseases, 10th Revision, German Modification*; Min Hb: minimum hemoglobin value during the stay.



The *ICD-10-GM* list comprised 12 codes for MB and 41 codes for CRNMB (Table 1). We defined an MB in-hospital mortality case as a stay containing an MB occurring during hospitalization followed by death of the patient during the same hospitalization period. We measure the prevalence of bleeding cases, corresponding to inpatient stays with at least 1 MB or CRNMB event, either present on admission or occurring during hospitalization. We quantified the relative and absolute contribution of each structured data source (diagnoses, laboratory, transfusions, and medications), both individually and in combination, in terms of overall detection capacity and proportion of identified bleeding events.

Table . Lists of deficient systems/organs and distribution of *ICD-10-GM*[a] chapters and codes identifying MB[b] and CRNMB[c] cases.

Types of hemorrhagic events	*ICD-10-GM* codes
MB

[b]MB: major bleeding.

[c]CRNMB: clinically relevant nonmajor bleeding.

Natural Language Processing Model

To complement structured data detection, we developed a supervised ML model to identify MB, CRNMB, and past bleeding cases documented in discharge summaries.

A dataset of 400 discharge summaries from CHUV was randomly divided into a training set (n=280) and a test set (n=120), including 100 summaries with MB, 100 with CRNMB, and 200 with no bleeding. Three independent physicians manually annotated the 400 discharge summaries using 4 mutually exclusive labels: (A) 'presence of CRNMB,' (B) 'presence of MB' (as previously defined), (C) 'history of bleeding' (when a discharge summary mentioned bleeding in the EMR before the hospital admission), and (D) 'absence of any bleeding.' Preprocessing steps included tokenization, lemmatization, and sentence segmentation using the French spaCy model (v3.0) [28]. The classification pipeline combined logistic regression and support vector machine models, selected for their interpretability and robustness with limited training data. We deliberately used a classical supervised ML model rather than deep learning architectures to ensure interpretability, reproducibility, and computational efficiency, which are essential for clinical validation and routine pharmacovigilance applications. This approach also better suited the relatively small, annotated corpus, allowing transparent feature weighting and easier auditability across institutions. The model was trained using the scikit-learn library (Python v3.9.1). The classification pipeline proceeded in 3 stages: step 1: binary classifier to identify bleeding-relevant versus irrelevant sentences; step 2: multiclass classifier to distinguish between *irrelevant*, *antecedent bleeding*, and *active bleeding*; step 3: binary classifier to further differentiate between MB and CRNMB within sentences flagged as active bleeding. Sentence-level predictions were aggregated to assign a final label to each document. Rules were prioritized as follows: MB>CRNMB>history of bleeding>no bleeding. This ensured a conservative classification hierarchy, favoring the identification of more severe bleeding cases when multiple labels were present. Further methodological details are available in the study proposal previously published [25], the related article [29], and summarized in Figure 3.

Figure 3. Natural language processing workflow from raw text input to final classification output. Validation of the Bleeding Detection Algorithms

Internal Validation Using CHUV 2015-2016 Data

To validate the SDA and SDA combined with NLP (SDA+NLP) models, we conducted a manual review of 754 EMRs from CHUV's 2015 - 2016 dataset. The sample size for validation was determined using a test result-based sampling method [30]. Assuming a 7% MB, a 10% CRNMB accuracy, and a sensitivity of 0.7, at least 704 EMRs had to be reviewed, and 754 EMRs were effectively reviewed. Four physicians independently reviewed the records to compare algorithm-detected with clinician-identified MB and CRNMB cases. The review process followed a structured protocol aligned with ISTH definitions [26,27] and adapted for retrospective application to routinely collected hospital data. Reviewers assessed each inpatient stay according to 4 key criteria: (1) evidence of active bleeding, (2) severity of the event (eg, hemodynamic instability), (3) need for therapeutic intervention (eg, transfusion volume, administration of antihemorrhagic agents), and (4) temporal relationship to hospital admission (present on admission versus occurred during stay). A complete list of synonyms used to identify MB and CRNMB cases during manual chart review is provided in Multimedia Appendix 2. Two binary classification scenarios were evaluated: (1) MB versus all other cases (CRNMB or no bleeding), and (2) CRNMB versus no bleeding (excluding MB). Algorithm performance was evaluated at the inpatient-stay level using standard binary classification metrics (sensitivity, specificity, positive predictive value [PPV], negative predictive value, accuracy, and F_1-score), with manual chart review as the gold standard. Comparisons between SDA, NLP, and combined models were descriptive, and sensitivity was prioritized due to the study's patient safety focus. Interrater

reliability among reviewers was evaluated using Fleiss κ on a subset of 40 cases, with agreement levels interpreted according to Landis and Koch [31] (>0.80: *almost perfect*; 0.61 - 0.80: *substantial*; 0.41 - 0.60: *moderate*; 0.21 - 0.40: *fair*; 0.00 - 0.20: *slight*; <0.00: *poor*). A *P* value associated with the Fleiss κ coefficient was also calculated, with a *P* value less than .05 indicating statistically significant agreement. Additional details and results are provided in Multimedia Appendix 3. In a subanalysis, a causal relationship between antithrombotic therapy and each bleeding event was also assessed during the manual review, using a structured tool based on temporal association, biological plausibility, and alternative explanations. Cases were rated as *certain*, *probable*, *possible*, or *unclassified*, in relation to antithrombotic exposure, according to the WHO-Uppsala Monitoring Center scale [32]. The methodology, sample size calculation, and findings of the causality assessment of the subanalysis are presented in Multimedia Appendix 4.

External Validation Using CHUV 2021-2022 Data

An external validation was performed using CHUV data from 24,054 inpatient stays between January 2021 and December 2022. We applied the same detection algorithms (SDA and SDA+NLP) to this independent dataset to evaluate their performance, robustness, and reproducibility. Results were compared to those from the 2015 - 2016 CHUV dataset.

Statistical Analysis

Descriptive statistics were used to summarize population characteristics. Comorbidity was assessed using the Charlson and Elixhauser indexes [33,34], which are validated tools for risk adjustment and mortality prediction based on administrative health data. Comparisons of patient characteristics between hospitals were conducted using a 1-way analysis of variance on ranks (Kruskal-Wallis test) for continuous variables and Pearson χ^2 test for categorical variables. Hyperparameters of the NLP classifier were optimized through 5-fold cross-validation on the training set, and final performance was estimated on an independent test set. All performance metrics were reported with 95% CIs calculated using the Wilson method. Analyses were conducted using StataCorp. 2021. Stata Statistical Software: Release 17. College Station, TX: StataCorp LLC software for structured data and Python (v3.9.1) for NLP development.

Ethical Considerations

Human Subject Ethics Review Approvals or Exemptions

This study was conducted in accordance with the *Declaration of Helsinki* and Swiss federal regulations governing research on human data. Ethical approval was obtained from all relevant cantonal ethics committees, coordinated by the lead committee of the Canton of Vaud (CER-VD No. 2018 - 00272). As the study involved secondary analysis of routinely collected, deidentified hospital data, it qualified for a simplified review under Swiss Human Research Act article 2, paragraph 2(c).

Informed Consent

The study relied exclusively on existing clinical data that were deidentified before analysis. According to Swiss regulations and institutional data governance policies, informed consent was waived for patients who had not explicitly objected to the use of their medical data for research purposes. All participating hospitals operate an institutional opt-out procedure, allowing patients to refuse the secondary use of their data for research.

Privacy and Confidentiality

All data were deidentified at source before analysis. Structured data were transferred through secure institutional channels to a restricted-access research environment hosted at CHUV. Unstructured textual data remained stored locally on hospital servers and were processed within each institution's secure infrastructure to comply with data protection requirements. No directly identifiable information was accessible to the investigators.

Compensation Details

No compensation was provided to patients, as the study involved secondary analysis of preexisting, routinely collected data and did not include direct contact with participants.

Protection of Identifiable Information in Figures and Supplementary Materials

No image, document, or figure contains any identifiable patient information. Consequently, no individual consent for image publication was required.

Ethics Approval

Approved by the Cantonal Ethics Committee of Vaud, Switzerland (CER-VD No. 2018 - 00272); informed consent was waived for patients who did not opt out of research data use.

Results

Study Population Characteristics

A total of 36,039 inpatient stays, involving 24,991 unique patients, were included in the analysis: 7677 stays (5754 patients) at CHUV, 18,015 stays (11,356 patients) at HUG, and 10,347 stays (7881 patients) at USZ. Patient characteristics are detailed in Table 2. The median age at admission was 78 (IQR 65 - 99) years, with a balanced sex distribution (51.40% male). Comorbidity was generally low across the cohort, with a median Charlson index and Elixhauser index of 0.0; USZ patients had the lowest overall comorbidity burden.

Table . Baseline patient characteristics and treatments: overall and by university hospital.

Characteristics	All hospitals (n=36,039)[a]	CHUV[b] (n=7677)	HUG[c] (n=18,015)	USZ[d] (n=10,347)

[a]n: total number of recorded measurements for the respective parameter.

[b]CHUV: Lausanne University Hospital.

[c]HUG: Geneva University Hospital.

[d]USZ: Zürich University Hospital.

[e]Not available (missing or nontransferred data).

[f]UI: unit of blood component.

Distinct prescribing patterns were observed across hospitals: HUG had the highest use of vitamin K antagonists (n=4943, 27.44%), CHUV had the highest prescription rate of antiplatelet agents (n=4354, 56.71%), and USZ reported the highest use of direct factor Xa inhibitors (n=1220, 11.79%) and heparins (n=7821, 75.59%). Hypertension (n=18,316, 50.82%), chronic renal dysfunction (n=8418, 23.36%), anemia (n=7624, 21.15%), and cancer (n=6776, 18.80%) were among the most prevalent comorbidities. Overall, in-hospital mortality was 3.93% (n=1416).

Bleeding Detection Using SDA

SDA detected 8748 (24.27%) overall bleeding cases, of which 2979 (8.26%) were MB cases and 5419 (15.04%) were CRNMB cases (Table 3). Fatal MB occurred in 1.0% (n=350) of all stays. MB prevalence varied across hospitals, with the highest proportion observed at CHUV (n=769, 10.0%), followed by USZ (n=998, 9.6%) and HUG (n=1212, 6.73%). CRNMB prevalence was highest at USZ (n=1682, 16.26%). Missing values for each variable used to identify MB and CRNMB events are presented in Multimedia Appendix 5.

Table . Prevalence of bleeding cases detected by SDA[a], overall and by university hospital[b].

	All hospitals, n (%)	CHUV[c], n (%)	HUG[d], n (%)	USZ[e], n (%)	*P* value[f]
Nonbleeding-related	27,641 (76.70)	5822 (75.84)	14,152 (78.56)	7667 (74.10)	<.001
CRNMB[g]	5419 (15.04)	1086 (14.15)	2651 (14.72)	1682 (16.26)	<.001
MB[h]	2979 (8.26)	769 (10.0)	1212 (6.73)	998 (9.6)	<.001
MB in-hospital mortality	350 (1.0)	119 (1.6)	137 (0.8)	94 (0.9)	<.001
Total	36,039	7677	18,015	10,347	—[i]

[a]SDA: structured data algorithms (ie, rule-based algorithm for structured data).

[b]Bleeding cases: number of stays for patients treated with at least 1 antithrombotic agent during which at least 1 bleeding episode occurred.

[c]CHUV: Lausanne University Hospital.

[d]HUG: Geneva University Hospital.

[e]USZ: Zürich University Hospital.

[f]Using Pearson χ^2 test.

[g]CRNMB: clinically relevant nonmajor bleeding.

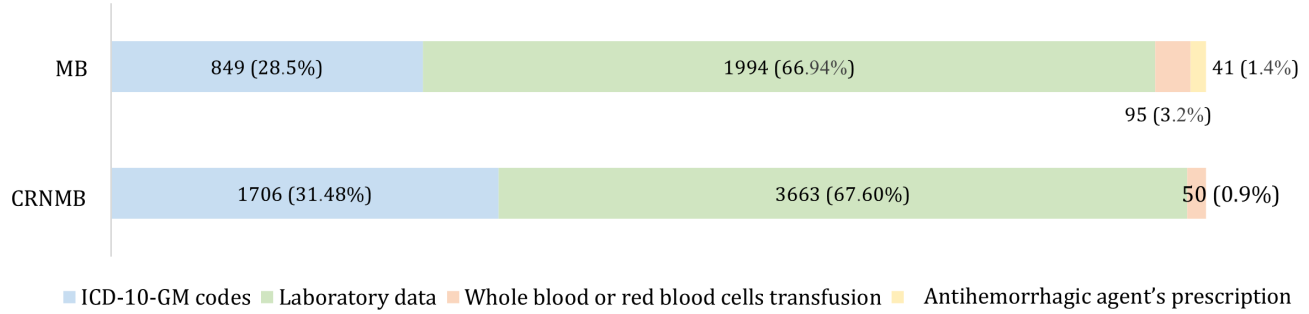
[h]MB: major bleeding.

[i]Not applicable.

Relative and Absolute Contribution of Structured Data Sources

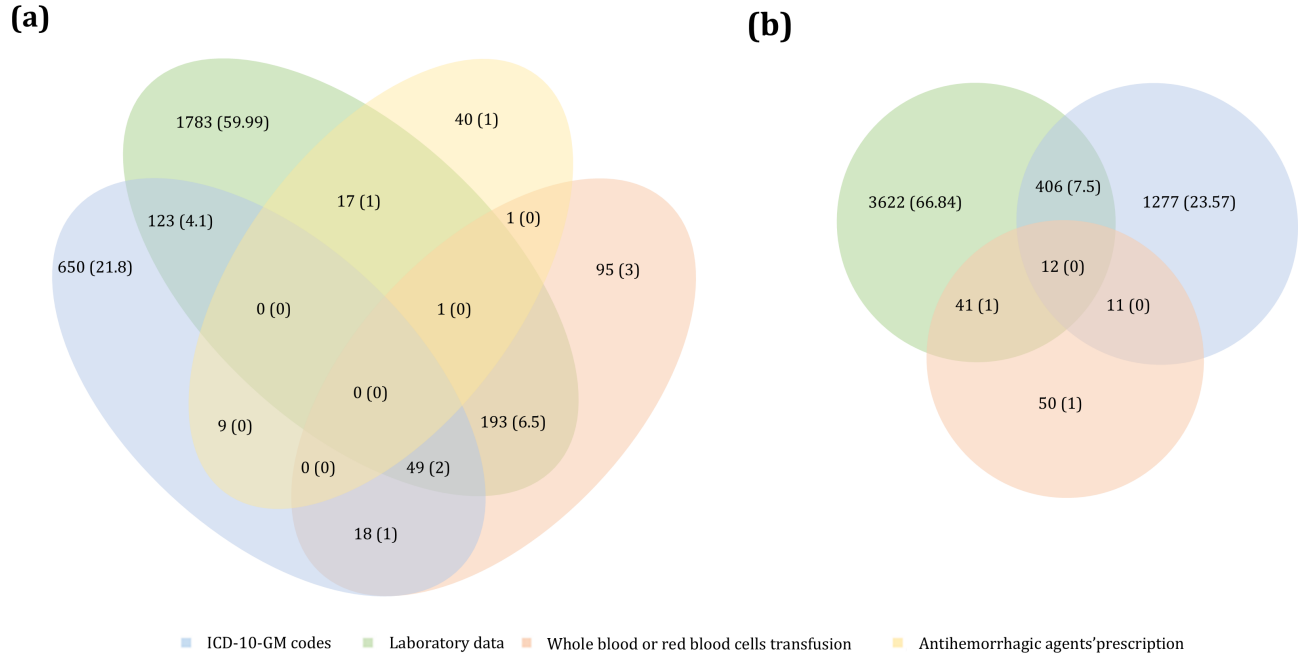
Laboratory data were the most influential source for detecting both MB and CRNMB, contributing to two-thirds of identified cases, while *ICD-10-GM* codes contributed to approximately one-third. Prescriptions for antihemorrhagic agents had a minimal added value for MB detection, while transfusion data contributed modestly. Figure 4 illustrates the relative contribution of each data source.

Figure 4. Relative contribution of structured data sources (laboratory data, *ICD-10-GM* codes, prescription of antihemorrhagic agents, and transfusions) to the detection of major bleeding (MB) and clinically relevant nonmajor bleeding (CRNMB). *ICD-10-GM*: *International Statistical Classification of Diseases, 10th Revision, German Modification*.



Overlap between data sources was limited. Only 12.1% (n=361) of MB stays and 8.7% (n=458) of CRNMB stays were identified by 2 data sources, while detection by all 4 sources occurred in 0% of MB cases and only 0% (n=12) of CRNMB cases (Figure 5). This limited overlap highlights the complementarity, but also fragmentation, of structured data signals.

Figure 5. Absolute contribution of structured data sources (laboratory data, *ICD-10-GM* codes, prescription of antihemorrhagic agents, and transfusions) to the detection of (A) major bleeding and (B) clinically relevant nonmajor bleeding. *ICD-10-GM: International Statistical Classification of Diseases, 10th Revision, German Modification*.



Combined Detection Using SDA and NLP (CHUV Only)

Among 7513 CHUV stays with discharge summaries, combining SDA and NLP increased case detection: In total, 39.69% (n=2982) of hemorrhagic cases were detected: 12.2% (n=920) were identified as MB and 27.45% (n=2062) as CRNMB.

For MB cases, 56.6% (n=521) were detected by SDA alone, 19.8% (n=182) by NLP alone, and 23.6% (n=217) by both. For CRNMB cases, 35.1% (n=724) were detected by SDA alone, 48.2% (n=994) by NLP alone, and 16.7% (n=344) by both.

Classification discrepancies were observed between SDA and NLP: 217 cases identified as MB by SDA were reclassified as CRNMB by NLP, and conversely, 81 CRNMB cases by SDA were reclassified as MB by NLP. NLP also enabled the detection of a history of bleeding in 8.5% (n=642) of cases, improving the temporal resolution of hemorrhage onset.

Internal Validation Using CHUV 2015-2016 Data

The manual review of 754 EMRs identified 276 bleeding cases: 144 MB and 132 CRNMB. Structured laboratory data showed the highest sensitivity (0.58, 95% CI 0.52 - 0.64), while *ICD-10-GM* codes had the highest PPV (0.89, 95% CI 0.83 - 0.98), and F_1-score (0.60). SDA outperformed NLP in sensitivity (0.77 vs 0.61), but NLP had higher PPV (0.70 vs 0.51) and F_1-score (0.65 vs 0.62). The best performance was achieved by the combined *ICD-10-GM*∪NLP algorithm, with a sensitivity of 0.71 (95% CI 0.66 - 0.76), PPV of 0.72 (95% CI 0.66 - 0.87), and F_1-score of 0.72. Algorithms combining SDA and NLP yielded the highest sensitivity (0.84), confirming the benefit of multimodal approaches. However, intersection-based algorithms (eg, SDA∩NLP) demonstrated higher specificity at the cost of reduced sensitivity.

Performance metrics for MB and CRNMB subgroups followed similar trends, with reduced sensitivity but high specificity for

ICD-10-GM–based detection. Table 4 presents a comprehensive summary of all performance metrics, including sensitivity, specificity, PPV, negative predictive value, accuracy, and F_1-score.

Table . Performance metrics of bleeding detection algorithms compared to manual electronic medical records review (gold standard; n=754)[a].

[a]It should be noted that no patient record contained the variable antihemorrhagic agent for the detection of MB. Consequently, the performance for this variable was not included in the table.

[b]Sensitivity: proportion of bleeding cases that have been correctly identified.

[c]Specificity: proportion of nonbleeding-related cases that have been correctly identified.

[d]PPV: positive predictive value; proportion of bleeding cases among all those classified as bleeding cases by the algorithm.

[e]NPV: negative predictive value; proportion of nonbleeding-related cases among all those classified as nonbleeding-related cases by the algorithm.

[f]Accuracy: overall prediction accuracy (ie, the proportion of bleeding and nonbleeding-related cases that the algorithm has correctly identified.

[g]F_1-score: harmonic mean of the precision and recall (ie, F_1-score = 2 × [recall × precision]/[recall + precision]).

[h]MB: major bleeding.

[i]CRNMB: clinically relevant nonmajor bleeding.

[j]*ICD-10-GM*: *International Statistical Classification of Diseases, 10th Revision, German Modification*.

[k]SDA: structured data algorithm.

[l]NLP: natural language processing.

Interrater reliability for manual review of 40 EMRs showed substantial agreement: Fleiss' Kappa was 0.65 for bleeding detection and 0.61 for MB versus CRNMB classification. Of 276 manually reviewed inpatient stays with bleeding events, 17% (n=48) were attributed to antithrombotic agents. The causal relationship was classified as "certain" in 25% of cases (n=12), "probable/likely" in 23% (n=11), and "possible" in 52% (n=25).

External Validation Using CHUV 2021-2022 Data

Application of the SDA and SDA+NLP algorithms to the CHUV validation dataset (24054 stays) demonstrated generalizability. The prevalence of MB cases significantly decreased from 10.0% in the 2015 - 2016 period to 5.55% (n=1336) in the 2021 - 2022 period, while the prevalence of CRNMB cases increased significantly from 14.15% to 16.63% (n=4000). MB in-hospital mortality also rose, from 1.6% to 2.6% (n=616).

Patient characteristics differed significantly between cohorts (Multimedia Appendix 6). Direct oral anticoagulant prescriptions increased from 7.8% to 22.7%, while vitamin K antagonist use decreased from 17.2% to 7.6%. The incidence of elevated INR values >4 declined from 3.3% to 1.8%. Both Charlson and Elixhauser scores increased, reflecting higher comorbidity. Transfusions involving ≤5 units of blood rose from 1.3% to 8.8%. Notably, the proportion of patients receiving ≥3 antithrombotic agents during hospitalization increased fivefold (from 6.7% to 35.0%).

Discussion

Principal Findings

To our knowledge, this is one of the first multicenter studies assessing the feasibility and effectiveness of combining structured and unstructured EMR data to detect bleeding cases in older inpatients treated by one or more antithrombotic agents. Across 3 large university hospitals, our SDA identified 8.26% of MB and 15.4% of CRNMB cases. Laboratory variables contributed most to event detection, while *ICD-10-GM* codes alone captured only about one-third of cases, achieving a sensitivity of 0.84 when both data sources were combined. These findings confirm the feasibility of automated bleeding surveillance in real-world hospital data and demonstrate the added value of leveraging free-text information to complement structured data sources.

Comparison to Prior Work

Our estimated bleeding rates (MB: 8.26% and CRNMB: 15.04%) are consistent with prior hospital-based studies in older adults, which reported MB incidences ranging from 1.8% to 11.3% [35,36] and CRNMB from 3.5% to 13.0% [35,37]. These findings confirm that antithrombotic-related bleeding remains a major cause of ADEs in older populations, associated with increased hospitalization length, morbidity, and mortality [38], highlighting the need for targeted preventive strategies.

The algorithms' performance varied across structured data sources and aligns with prior research. *ICD-10-GM* codes detected only one-third of MB and CRNMB cases, consistent

with previous evidence of underreporting anticoagulant-related bleeding events [39,40]. Yap et al [15] found similarly low sensitivity (16% - 24%) but very high PPV (>0.97), indicating that diagnostic codes are reliable confirmatory markers but poor screening tools. The inclusion of laboratory data markedly improved sensitivity in our SDA model, consistent with findings by Dyas et al [6] and Shung et al [10]. The modest decline in PPV was likely due to false positives generated by hemoglobin thresholds, a limitation noted in earlier work [15].

Detection of CRNMB was more challenging than MB, partly due to broader definitions and lower specificity of *ICD-10-GM* codes and transfusion data, echoing the moderate performance reported by Yap et al [15] (sensitivity 50% - 56%, PPV 43 - 50%).

The NLP model contributed substantially to overall detection, with a sensitivity of 61% and PPV of 70%, in line with earlier NLP-based models for bleeding and ADE detection [10,41]. Importantly, only about 20% of events overlapped with those captured by structured data, demonstrating that text analysis retrieves unique clinical insights often missing from coded data. NLP also enhanced temporal resolution by identifying prior bleeding episodes in 8.5% of cases, information generally unavailable from structured data alone. The combined SDA+NLP model achieved high sensitivity (0.84), thereby minimizing the risk of missed events, with only 16% of cases being false negatives. Although this proportion is relatively low, it still represents missed hemorrhagic events that could impact the accuracy of retrospective surveillance and safety signal detection. However, our detection algorithm provides a notable proportion of false positives (49%), which could contribute to alert fatigue in clinical practice and increase the workload associated with unnecessary chart reviews. For real-world deployment, performance thresholds depend on the intended use: for surveillance or signal detection, a sensitivity above 0.80 with PPV above 0.50 is generally acceptable, as false positives can be secondarily reviewed; for clinical decision support, stricter thresholds (eg, PPV≥0.70) are needed to prevent alert fatigue. Improving true positive detection to 70% would strengthen reliability and clinical applicability, potentially through prioritization or triage of clinically significant cases.

External validation revealed a decline in MB prevalence and a concurrent increase in CRNMB and MB-related mortality in the validation dataset (2021 - 2022), compared to the CHUV 2015 - 2016 dataset. These trends may reflect evolving prescribing patterns, such as increased use of direct oral anticoagulants and reduced use of vitamin K antagonists, and a shift in clinical profiles, with higher comorbidity scores and greater treatment complexity in the more recent cohort. These observations are consistent with the known bleeding risk profiles of antithrombotic agents, direct oral anticoagulants being more frequently associated with gastrointestinal bleeding (CRNMB), and vitamin K antagonists with intracranial bleeding (MB) [42], and underscore the need for dynamic algorithmic models capable of adjusting for changing treatment patterns and patient characteristics [43].

Strengths and Limitations

This study has several notable strengths. It is one of the first multicenter initiatives to integrate structured and unstructured EMR data for ADE detection in older hospitalized patients. The inclusion of 3 university hospitals provided a large, diverse dataset, while the harmonization of over 1 million clinical variables ensured robust data quality. Algorithms were developed using internationally accepted definitions of MB and CRNMB and validated through manual chart review, ensuring clinical credibility. External validation on a temporally distinct dataset further reinforced reproducibility and robustness.

Several limitations should also be considered.

First, the test dataset (2015 - 2016) was relatively dated and spanned only 2 years, reflecting mostly the time-consuming extraction and harmonization process required to merge data from three hospitals before data interoperability infrastructures were implemented. Consequently, it may not entirely capture current clinical practices. Nevertheless, this limitation was mitigated by validating our pipeline on an independent and more recent dataset.

Second, NLP development and validation were performed using CHUV data only and did not take into consideration interinstitutional variations in coding practices, hospital information system architecture and interoperability, clinical documentation standards, or local prescribing patterns, which may limit the generalizability of our findings. To mitigate this, the model was trained on a balanced, manually annotated corpus reviewed by 3 independent physicians. Future studies should externally validate the NLP model on datasets from other French-speaking institutions to confirm its performance and enhance its applicability.

Third, data from 1 hospital (Baden hospital) were excluded due to missing information and harmonization challenges, and CHOP codes could not be extracted from the USZ hospital; this could have led to underestimation of certain bleeding events. Recent efforts have been undertaken to improve data harmonization across sites, which now largely mitigate the harmonization challenges previously encountered.

Fourth, while *ICD-10-GM* code selection was based on international guidelines and expert review, some misclassification may have occurred. This limitation was partly mitigated by manual validation. However, the adoption of a standardized bleeding classification would help overcome this limitation and harmonize bleeding-event categorization across studies.

Fifth, causality assessment between bleeding cases and antithrombotic agents was not formally assessed by our algorithms, as this requires strict criteria and necessitates a comprehensive EMR review. Causality was manually evaluated using the WHO–Uppsala Monitoring Center framework, which provided valuable contextual insights but is resource-intensive. Future work should investigate semiautomated causal-inference tools to scale this process efficiently.

Sixth, structured data were insufficient to capture the timing of bleeding cases prior to admission, as such information is

documented in discharge summaries, underscoring the need for unstructured data in ADE detection.

Finally, all participating hospitals were tertiary academic centers with strong data infrastructures and comprehensive documentation practices. While this ensured data reliability and methodological consistency, it may limit the generalizability of our findings to other contexts, such as secondary or community hospitals, or to health systems with different digital maturity levels. Compared to many international settings, Swiss university hospitals operate within a decentralized but highly standardized health care system, characterized by universal coverage and well-developed inpatient services. Future research should evaluate these algorithms in more diverse hospital types and countries to assess their adaptability and scalability beyond tertiary Swiss institutions.

Future Directions

This study illustrates the value of combining structured and unstructured clinical data to improve the detection of bleeding events in older inpatients exposed to antithrombotic therapy. This integrated approach can enhance pharmacovigilance systems, reduce underreporting, and support timely clinical interventions. Future efforts should expand algorithm coverage to additional unstructured sources (eg, nursing notes and consultation letters), improve clinical documentation practices, and incorporate semiautomated causality assessment tools. Combining these detection models with multivariate risk stratification that integrates patient-specific factors (age, comorbidities, comedications, and clinical service) could enable prioritization of clinically meaningful alerts. Finally, embedding such tools within common data models and privacy-preserving data-sharing infrastructures, such as those promoted by the Swiss Personalized Health Network, could facilitate cross-institutional learning health systems and accelerate artificial intelligence-supported pharmacovigilance in real-world clinical practice.

Acknowledgments

The authors thank all contributors to data extraction and processing across participating sites, with special appreciation to Walid Gharib-Blanc and Alexandre Wetzel. We gratefully acknowledge Tapio Niemi, Marie Bettex, and Patrick Taffé (Unisanté, Department of Epidemiology and Health Systems, University of Lausanne, Switzerland).

The SwissMADE collaborators are Bernard Burnand, Department of Epidemiology and Health Systems, Unisanté and University of Lausanne, Lausanne, Switzerland; Pierre Olivier Lang, Geriatric Medicine and Geriatric Rehabilitation Division, Department of Medicine, University Hospital of Lausanne, Lausanne, Switzerland; Nicola Colic, Dalle Molle Institute for Artificial Intelligence Research, Università della Svizzera Italiana, Lugano, Switzerland; Angela Schulthess-Lisibach, Institute of Primary Health Care, University of Bern, Bern, Switzerland; Christophe Gaudet-Blavignac, Division of Medical Information Sciences, Geneva University Hospitals, Geneva, Switzerland and Department of Radiology and Medical Informatics, University of Geneva, Geneva, Switzerland; Nathalie Casati, Clinical Data Science Group, Lausanne University Hospital, Lausanne, Switzerland; Jean-Philippe Goldman, Faculty of Letters, Department of Linguistics, University of Geneva, Geneva, Switzerland; and Vasiliki Foufi, Division of Medical Information Sciences, University Hospitals of Geneva, Geneva, Switzerland and Faculty of Medicine, University of Geneva, Geneva, Switzerland.

Funding

This study was partially supported by the Swiss National Research Fund (project 167381). The funder had no role in study design, data collection, data analysis, data interpretation, or writing of the report.

Data Availability

Requests for access to the anonymized dataset and study materials should be directed to the corresponding author and will be considered on a case-by-case basis in accordance with institutional policies and applicable data protection regulations.

Authors' Contributions

MALP and C Csajak designed the study; MALP, FG, and C Csajak wrote and submitted the proposal. CL, Christophe Gaudet-Blavignac, Bernard Burnand, FR, ML, Pierre Olivier Lang, and PEB contributed to the development of the study proposal and participated in its revision. CL, PEB, Christophe Gaudet-Blavignac, Nicola Colic, ML, and FR contributed to data extraction and curation. C Coumou, MALP, C Csajak, and FG conducted the study and designed the rule-based algorithms. C Coumou, MALP, C Csajak, FG, and MZ performed the formal analysis. LA contributed to the conceptualization of the rule-based algorithms. MZ and EB designed and implemented the natural language processing algorithms. C Coumou has written the original draft of the manuscript. MALP, C Csajak, FG, and LA contributed to the conceptualization, supervision, and review and editing of the manuscript. The SwissMADE collaborators were consulted on methodological aspects throughout the study. All authors have read and approved the final version of the manuscript.

Conflicts of Interest

PEB reports having received fees and funding from AstraZeneca for matters unrelated to the present study. All other authors declare no competing interests.

Abstract

Background: While artificial intelligence (AI) holds significant promise for health care, excessive trust in these tools may unintentionally delay patients from seeking professional care, particularly among patients with chronic illnesses. However, the behavioral dynamics underlying this phenomenon remain poorly understood.

Objective: This study aims to quantify the influence of AI trust on health care delays through integrated survey-based mediation analysis and real-world research, and to simulate intervention efficacy using agent-based modeling (ABM).

Methods: A cross-sectional online survey was conducted in China from December 2024 to May 2025. Participants were recruited via convenience sampling on social media (WeChat and QQ) and hospital portals. The survey included a 21-item questionnaire measuring AI trust (5-point Likert scale), AI usage frequency (6-point scale), chronic disease status (physician-diagnosed, binary), and self-reported health care delay (binary). Responses with completion time <90 seconds, logical inconsistencies, missing values, or duplicates were excluded. Analyses included descriptive statistics, multivariable logistic regression (α=.05), mediation analysis with nonparametric bootstrapping (500 iterations), and moderation testing. Subsequently, an ABM simulated 2460 agents within a small-world network over 14 days to model behavioral feedback and test 3 interventions: broadcast messaging, behavioral reward, and network rewiring.

Results: The final sample included 2460 adults (mean age 34.46, SD 11.62 years; n=1345, 54.7% female). Higher AI trust was associated with increased odds of delays (odds ratio [OR] 1.09, 95% CI 1.00-1.18; *P*=.04), with usage frequency partially mediating this relationship (indirect OR 1.24, 95% CI 1.20-1.29; *P*<.001). Chronic disease status amplified the delay odds (OR 1.42, 95% CI 1.09-1.86; *P*=.01). The ABM demonstrated a bidirectional trust erosion loop, with population delay rates declining from 10.6% to 9.5% as mean AI trust decreased from 1.91 to 1.52. Interventions simulation found broadcast messaging most effective in reducing delay odds (OR 0.94, 95% CI 0.94-0.95; *P*<.001), whereas network rewiring increased odds (OR 1.04, 95% CI 1.04-1.05; *P*<.001), suggesting a "trust polarization" effect.

Conclusions: This study reveals a nuanced relationship between AI trust and delayed health care–seeking. While trust in AI enhances engagement, it can also lead to delayed care, particularly among patients with chronic conditions or frequent AI users. Integrating survey data with ABM highlights how AI trust and delay behaviors can strengthen one another over time. Our findings indicate that AI health tools should prioritize calibrated decision support rather than full automation to balance autonomy, odds, and decision quality in digital health. Unlike previous studies that focus solely on static associations, this research emphasizes the dynamic interactions between AI trust and delay behaviors.

Introduction

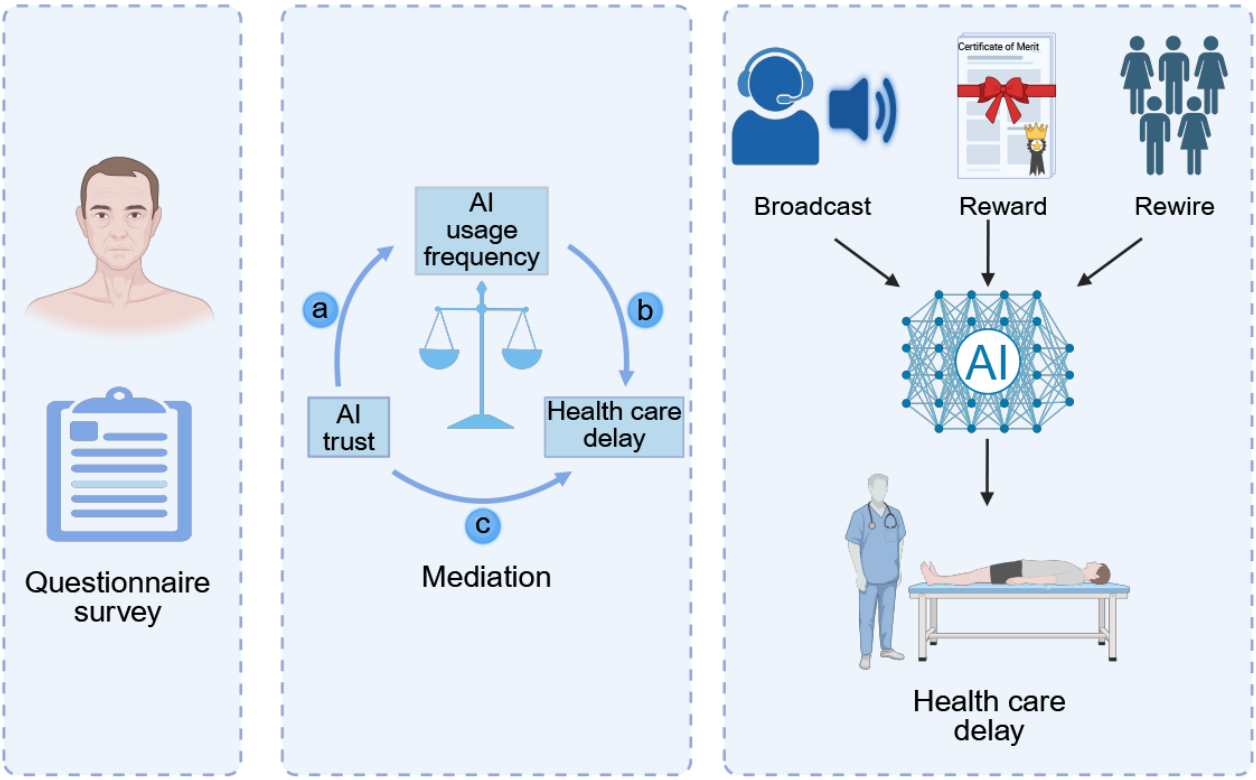
Background

With the rapid development and widespread adoption of artificial intelligence (AI) in the medical field, AI has emerged as a pivotal tool across multiple domains, including health management, disease prediction, and clinical decision support [1,2]. Its potential to enhance health care efficiency, assist in disease diagnosis, optimize treatment strategies, and facilitate personalized health management is substantial [3,4]. However, this promise is tempered by growing concerns about its psychosocial and behavioral effects. The prevailing view of AI as an unequivocal force for good is being challenged by evidence that human-AI interaction can lead to new cognitive and behavioral issues [5,6]. In particular, AI's capacity to provide health recommendations and interventions based on extensive data analysis marks a significant breakthrough [7,8]. However, this ability may alter traditional health decision-making processes. Trust is a key concept for adopting technology, involving aspects such as performance, process, and purpose. A growing body of research indicates that while AI offers convenient access to health-related information, excessive reliance on these tools may lead to detrimental health behaviors, such as overreliance on automated suggestions and disregarding clinical intuition [9-11].

Traditional health decision-making models typically depend on professional medical judgment and individuals' self-awareness of their health status [12]. The advent of AI is reshaping this framework by providing automated diagnostic recommendations and personalized health guidance [13]. While such "digital health advice" can enhance confidence in medical decision-making in the short term, it may foster excessive dependence on AI tools over the long term. Patients with chronic diseases, who require ongoing health management and exhibit relatively stable symptoms, may be particularly susceptible to this shift [14]. This population often practices prolonged self-management, leading to frequent use of digital tools [15]. The relative stability of their conditions can create a sense of security, in which they may consider AI-generated reassuring feedback adequate. This dependence on AI could lead to delays in pursuing health care, as patients with chronic disease tend to give priority to AI-generated symptom evaluations and treatment options rather than traditional medical advice [16]. Consequently, they might overlook complex diagnostic and therapeutic needs that AI cannot fully assess [17]. Moreover, biases in medical AI can persist throughout its life cycle, potentially leading to serious repercussions in clinical decision-making. If these biases are not addressed, they can result in inaccurate medical judgments and exacerbate existing health care disparities [18]. While existing research has shed light on the potential risks of AI reliance in health care, a comprehensive framework that formally analyzes the complex relationship between AI trust and health behavior, particularly in the context of chronic disease, is still lacking. Additionally, few studies have used computational simulation to assess how various public health intervention strategies might mitigate this system-level risk.

This study aims to systematically analyze the interrelationships among AI trust, AI usage frequency, chronic disease status, and delayed health care–seeking behavior. The analysis was conducted through a cross-sectional online survey from December 2024 to May 2025. We propose that AI trust and frequency of use jointly contribute to the odds of delayed medical care through a behavioral feedback mechanism, particularly pronounced among patients with chronic conditions. High levels of AI trust may inadvertently lead individuals to postpone health care–seeking by increasing usage frequency, highlighting a complex interaction between trust and behavior. To investigate these dynamic interdependencies, we use an agent-based modeling (ABM) framework to simulate the trust-behavior feedback over time. By embedding individuals within social networks and allowing trust and delay behaviors to evolve together, the ABM enables us to examine how microlevel decisions accumulate into population-level odds. This includes issues such as collective delays or systemic trust collapse, which are often difficult to capture using conventional cross-sectional data. A schematic overview of the study design is provided in Figure 1.

Figure 1. Schematic overview of the study design and methodology. Based on online questionnaires, the analysis framework includes mediation analysis to explore the relationship between artificial intelligence (AI) trust, usage frequency, and delayed health care–seeking behavior. Additionally, agent-based modeling was used to model the dynamic feedback loops over a 14-day period, incorporating 3 intervention strategies: broadcast, reward, and rewire. These strategies aimed to evaluate how the interventions affected trust and delay behavior within the population. Image created in Biorender by WL [19].



Objective

This study not only addresses a theoretical gap in understanding the impact of AI on delayed health care–seeking but also offers a fresh perspective on optimizing the design of AI-based health tools. A key challenge in future medical applications of AI will be achieving the right balance between fostering user trust and ensuring accuracy and timeliness in health care–seeking. We aim to provide theoretical support for designing AI-driven health interventions. Additionally, we seek to inform more effective public health strategies, ensuring that technological advancements promote rather than hinder appropriate health care decisions.

Methods

Survey Design and Data Collection

This study was conducted in 2 integrated phases: a cross-sectional survey and an ABM simulation. To ensure comprehensive and transparent reporting, the methods are reported following the Journal Article Reporting Standards guidelines under relevant subheadings [20,21]. A cross-sectional online survey was conducted between December 1, 2024, and May 20, 2025. The 21-item questionnaire was conducted in Mandarin Chinese and developed based on a systematic literature review and focus-group discussions. It underwent refinement through 2 rounds of expert review by 4 specialists in public health and AI, and was finalized after a pilot test involving 5 target participants. The full survey questionnaire (English translation) is provided in Multimedia Appendix 1.

Eligible participants were adults aged 18-75 years who had resided in mainland China for the past 12 months and were able to read Chinese. The age range was selected to include the digitally engaged adult population while excluding minors and the very old people, who may exhibit different health-seeking patterns. The 12-month residency criterion ensured consistent exposure to the local health care, minimizing confounding from recent immigration or transient populations. The survey was disseminated via WeChat (Tencent) and QQ (Tencent), and the patient-education portals of collaborating hospitals using convenience sampling. Participants accessed the questionnaire after reading an electronic informed consent form and selecting “Agree.” All items were mandatory, and skip logic was applied to minimize irrelevant questions. Responses were transmitted over HTTPS and encrypted at rest on the institution’s private server, accessible only to authorized investigators.

To ensure the validity and interpretability of the logistic regression and mediation models, which require complete-case data, we performed rigorous data cleaning. Questionnaires completed in under 90 seconds, or those containing logical inconsistencies, missing values, or duplicate entries (only the first complete entry was retained), were excluded. Given the limited amount of missing data and the potential risk of introducing bias through imputation, listwise deletion was considered the most appropriate and conservative approach. To examine the mechanism of missingness, we conducted Little’s

missing completely at random (MCAR) test using the *mice* package in R software (versions 4.2.3; R Foundation for Statistical Computing). Descriptive statistics were used to summarize the data (frequencies, percentages, means, and SDs), and multivariable logistic regression was conducted to examine the association between AI usage frequency and delayed health care–seeking behavior. Likert-type scales ranging from 1 to 5 (or 0 to 5 for AI usage and trust items) were used to assess frequency, trust level, and willingness to recommend.

Chronic disease was defined as any physician-diagnosed condition lasting 6 months or longer, including chronic allergic rhinitis, asthma, hypertension, diabetes, chronic skin diseases, etc. The variables included demographic characteristics (eg, age, sex, and occupation), AI usage behaviors (eg, frequency and exposure), trust perceptions, and health care–seeking outcomes.

Self-reported health care delay was assessed using a single binary item specifically targeting AI-influenced delay behaviors. Participants were asked: "Has advice provided by ChatGPT ever caused you to postpone or cancel seeking medical care?" with response options 0=no and 1=yes. This measure captures intentional delay or avoidance of health care that participants attributed directly to ChatGPT's recommendations, rather than delays caused by logistical or accessibility barriers. This operationalization aligns with behavioral delay frameworks used in prior studies and reflects clinically meaningful patterns of health care–seeking behavior.

Ethical Considerations

The study protocol was approved by the Institutional Review Board of Xiangya Third Hospital, Central South University (approval number 2025255). All procedures complied with the Declaration of Helsinki and the Personal Information Protection Law of China. Electronic informed consent was obtained from all participants. After reading a digital information sheet that outlined the study's purpose, procedures, risks, benefits, and their rights (including voluntary participation and withdrawal), participants indicated their agreement by selecting "Agree" before proceeding to the questionnaire. All collected data were deidentified. No personally identifiable information (eg, name, ID number, and contact details) was stored with the response data. Data were transmitted securely via HTTPS and stored in encrypted form on a private, access-controlled institutional server. Results are reported in aggregate to prevent any possibility of individual identification. Participants did not receive any financial or material compensation for their involvement in this study. The manuscript and its supplementary materials do not contain any images, videos, or textual data that could lead to the identification of an individual participant. Therefore, specific consent for the publication of identifiable information was not applicable.

Key Predictors of Delayed Care: Logistic Regression Analysis

We used logistic regression models to evaluate key predictors of delayed health care–seeking behavior. Initially, univariate logistic analyses were conducted to estimate the association between each candidate variable and the outcome, with results reported as odds ratios (ORs) accompanied by 95% CIs. Variables demonstrating potential significance were subsequently included in a series of hierarchical multivariate models (models 1-4). These models progressively incorporated individual characteristics, intervention exposure, AI usage patterns, and social influence to assess their independent contributions to delay behavior. This approach allowed us to identify the relative importance of each factor in influencing health care–seeking delays.

The data collection period encompassed the public release of DeepSeek, a major large language model in China, which occurred in early 2025 [22]. This event represented a significant shock to public awareness toward AI. To test the robustness of our core findings against this potential confounding effect, we performed a stratified analysis by dividing the sample into pre- and post-DeepSeek release subgroups. The cutoff date was set to February 1, 2025, allowing a sufficient time frame for the model's public impact to materialize within our survey window. We then reran the univariate logistic analyses within each subgroup to assess the consistency of the associations between AI trust, usage frequency, and health care delays.

Mediation Analysis: Indirect Effect of AI Trust via Usage Frequency

To examine whether AI trust influences delay behavior indirectly through AI usage frequency, we conducted mediation analysis using 2 approaches. First, following the traditional Baron and Kenny framework with the Sobel test, we estimated path *a* (the association between AI trust and usage frequency) via linear regression, and paths *b* and *c'* (the associations of usage frequency and AI trust with delay behavior) via multivariable logistic regression. The significance of the indirect effect ($a \times b$) was assessed using the Sobel *z* test. Second, to obtain robust CIs and significance estimates, we performed nonparametric bootstrap resampling (n=500). In each iteration, we reestimated paths *a* and *b*, calculated the product $a \times b$, and derived the empirical distribution of the indirect effect. The 95% bootstrap CI and *P* value were computed accordingly. All models were adjusted for age, gender, and chronic disease status.

Moderation by AI Recommendation Exposure: Stratified and Interaction Models

To further examine whether the level of AI recommendation exposure moderates the relationship between AI trust and delayed health care–seeking behavior, we conducted stratified logistic regression and interaction modeling. Participants were divided into low and high exposure groups based on their reported frequency of receiving AI recommendations (≤2 vs >2). Separate multivariable logistic regression models were fitted for each group, adjusting for age, gender, chronic disease status, and AI usage frequency. ORs and 95% CIs were reported to assess effect heterogeneity across exposure levels.

Additionally, we introduced an interaction term between AI trust and recommendation exposure into the full model. The interaction coefficient was used to calculate the interaction OR and the corresponding 95% CI. Predicted probability curves were plotted to visualize how the relationship between AI trust and delay behavior varies by exposure group, providing insights

into the moderating effect of AI recommendation exposure on health care–seeking behavior.

Moderation by Recommendation Willingness: Stratified Trust-Delay Associations

To evaluate whether individuals' willingness to recommend AI tools moderates the relationship between AI trust and delayed medical care, we conducted stratified logistic regressions and interaction analysis. Participants were grouped based on their scores (1-5) regarding the likelihood of recommending AI: those scoring ≤2 were classified as the "low recommendation intensity" group, and those scoring ≥3 as the "high recommendation intensity" group. Multivariable logistic regression models were fitted within each stratum, adjusting for age, gender, chronic disease status, and AI usage frequency. ORs and 95% CIs were calculated for AI trust in each group.

Subsequently, a full model including an interaction term between AI trust and recommendation intensity was constructed. We estimated the interaction effect (OR, 95% CI, and *P* value) and generated a prediction grid with standardized covariates to visualize the predicted probability of delayed care across AI trust levels in each group. Interaction plots were created to illustrate potential effect modification, enhancing our understanding of how willingness to recommend AI tools influences the relationship between AI trust and health care–seeking behavior.

Scenario-Based Modeling: Joint Effects of AI Behavior Factors on Delay

To theoretically evaluate the potential impact of various intervention strategies on delayed health care–seeking behavior, we conducted a scenario-based simulation analysis using logistic regression. A multivariable logistic model was initially constructed with AI trust, frequency of use, and chronic disease status as predictors. ORs, 95% CIs, and *P* values were reported for each explanatory variable.

Based on this model, the following six intervention scenarios were simulated: (1) baseline (trust=3, frequency=3, no chronic disease); (2) increased AI trust (set to 5); (3) increased frequency of AI use (set to 5); (4) chronic disease status switched to "yes"; (5) combined trust + frequency increase; and (6) combined trust + frequency + chronic disease. For each scenario, predicted probabilities of delay were computed across all individuals and averaged to reflect group-level effects.

The results were visualized using a bar plot displaying the mean predicted probability of delay under each strategy. Annotations highlighted the ORs and significance levels of the 3 key predictors, facilitating an intuitive understanding of their relative contributions to delay behavior. This comprehensive approach allowed us to identify the most effective interventions for reducing delays in health care–seeking.

ABM: Broadcast, Reward, Rewire

To evaluate the impact of different intervention mechanisms on delayed health care–seeking behavior, we used an ABM framework. ABM is a computational simulation approach particularly suited for studying complex systems, where population-level outcomes emerge from the interactions of autonomous, diverse individuals ("agents") operating within a defined environment and set of rules [23-25]. This method is particularly appropriate for our research question for 3 main reasons. First, AI trust is not a static trait; it is a dynamic belief influenced by personal experience and social factors, which ABM is designed to capture. Second, the decision to delay care involves weighing personal trust against the behaviors of peers, a scenario well modeled by embedding agents within a social network where attitudes and actions spread [26,27]. Third, ABM allows us to test the "trust-delay" feedback loop, a causal chain that cannot be directly identified from our cross-sectional survey data but can be explored through simulation [28].

To improve the transparency and reproducibility, the ABM model is described following the overview, design concepts, and details (ODD) protocol [29]. The purpose of the simulation was to examine how AI trust, peer influence, and intervention strategies jointly shape delayed health care–seeking behavior over time. Each agent represented 1 survey respondent and was initialized using the individual's empirical AI trust (1-5), AI usage frequency (1-5), and chronic disease status. Agents were embedded in a Watts-Strogatz small-world social network (n=2460; average degree=4; rewiring probability=0.2), which captures realistic social clustering and intermittent long-distance ties. The simulation progressed in daily cycles for 14 days, during which agents first computed a probability of delay using a logistic model derived from the survey data, then made a probabilistic delay decision, and subsequently updated their trust and usage behaviors according to personal outcomes, peer context, and intervention conditions. A total of 100 repetitions were performed for each scenario.

The model incorporated key design concepts of agent-based systems. Interaction occurred exclusively through local network neighbors; both average neighbor trust and neighbor delay behaviors influenced an individual's own updates. Stochasticity was present in network initialization, delay decisions, and trial-level replications. Agents adapted their trust and usage frequency over time, increasing them when surrounded by high-trust peers or after not delaying care, and decreasing them when neighbors frequently delayed or after personally delaying care. No explicit learning mechanism was included; behavioral dynamics emerged entirely from rule-based adaptation. Model outputs consisted of daily population-level delay rates and comparative effects of intervention strategies relative to baseline.

Detailed implementation followed ODD guidelines [29]. At initialization, agents with an empirically predicted baseline delay probability above 0.20 were assigned a 1-point reduction in trust and usage frequency to represent structural vulnerability. During each daily update, delaying care reduced trust by 0.2 and usage frequency by 0.3, whereas not delaying increased trust by 0.1; all values were bounded between 1 and 5. A total of 3 intervention strategies were embedded into this baseline framework. In the broadcast condition, trust was reduced daily by a small fixed penalty to reflect exposure to trust-eroding messages. The reward condition increased trust and usage frequency for agents who consistently sought timely care, with rewards provided every 2 days. In the rewiring condition, network edges were periodically redirected toward the highest-trust agents to model opinion leader amplification. All

intervention rules were implemented on top of the core behavioral update mechanism. Finally, 1-way sensitivity analyses were conducted by varying initial trust levels (means of 2.5, 3.0, and 3.5), broadcast penalty intensities (0.05-0.20 per day), reward magnitudes (0.03-0.10), and rewiring frequencies (intervals of 2-10 days). Each parameter set was simulated in 100 trials, and the resulting delay trajectories were compared to assess model robustness.

Results

Demographic Characteristics, AI Use, and Health Decision Outcomes

Of 2785 initial submissions, 325 (11.7%) responses were excluded based on prespecified criteria (completion time <90 seconds, logical inconsistencies, duplicate entries, or missing values in key variables). Specifically, 136 (4.9%) exclusions from the initial sample were due to missing values. Little's MCAR test indicated that the data were MCAR (χ^2_{14}=12.87; *P*=.54), supporting the use of complete-case analysis. Consequently, a total of 2460 valid responses were retained, predominantly female (n=1345, 54.7%), with an average age of 34.46 (SD 11.62) years. Occupations included students (n=825, 33.5%), technology workers (n=715, 29.1%), other professions (n=640, 26%), and health care personnel (n=280, 11.4%). A significant majority (n=2215, 90%) reported being aware of generative AI tools, and 62% (n=1525) had previously used AI for health advice. Regarding the frequency of AI-based advice use, 38% (n=935) of participants never used it, while 16.2% (n=398) used it weekly (1-2 times) and 15.7% (n=385) monthly. Trust in AI-generated advice varied, with 38% (n=935) never using it, and the remaining participants distributed across differing trust levels (Table 1).

In terms of health care decision outcomes, 11.6% (285/2460) of participants deferred or canceled health care due to AI advice, while 18.9% (465/2460) changed their health care decisions based on it. Additionally, 16.9% (415/2460) adopted alternative therapies following AI recommendations. The primary source of health information was physicians (1203/2460, 48.9%), followed by search engines (465/2460, 18.9%) and generative AI tools (375/2460, 15.2%). Perceived influence of online discussions varied, with 19.7% (485/2460) considering it very likely to impact their decisions. Lastly, 30.1% (740/2460) of participants reported having a chronic disease (Table 2).

Table 1. Demographic characteristics and artificial intelligence (AI) use (n=2460).

Variable	Values
Sex, n (%)

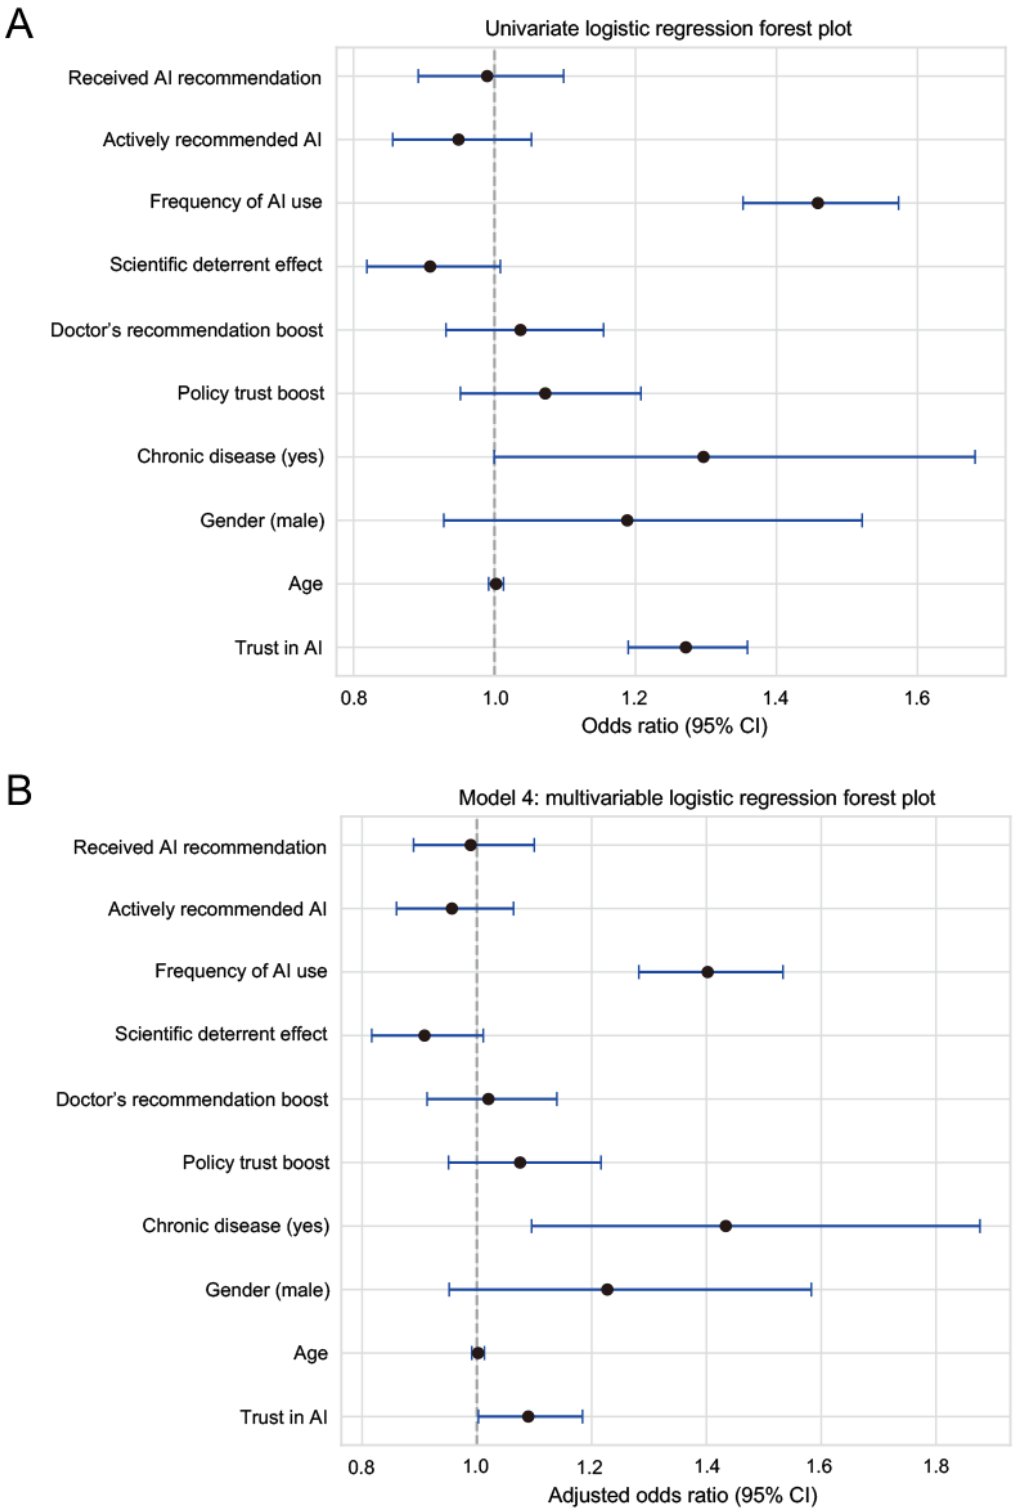
[a]AI: artificial intelligence.

AI Trust and Usage Frequency Are Key Predictors of Delay

In the univariate logistic regression, higher AI trust was positively associated with delayed health care–seeking behavior, with an OR of 1.27 (95% CI 1.19-1.36; *P*<.001; Figure 2A). Similarly, the frequency of AI use also showed a significant positive correlation with delay (OR 1.41, 95% CI 1.18-1.69; *P*<.001; Figure 2A). Although not statistically significant, trends were observed in the effects of receiving AI recommendations (OR 0.95, 95% CI 0.81-1.11) and actively recommending AI (OR 0.92, 95% CI 0.781.09; Figure 2A), both suggesting a potential reduction in delay. In the fully adjusted model (model 4), AI trust remained a significant predictor (OR 1.09, 95% CI 1.00-1.18; *P*=.04; Figure 2B). Frequency of AI use exhibited the strongest association with delay (OR 1.39, 95% CI 1.14-1.68; *P*<.001; Figure 2B), indicating that more frequent users had higher odds of postponing medical visits. Additionally, chronic disease status demonstrated a persistent positive association with delay (OR 1.43, 95% CI 1.10-1.88; *P*=.009; Figure 2B). Detailed analyses for univariate and multivariate logistic regression can be found in Tables S1 and S2 in Multimedia Appendix 2.

To address potential confounding from a major AI market event, we stratified the analysis by the DeepSeek release period. The results confirmed the robustness of our primary findings. The association between AI usage frequency and delayed health care–seeking remained nearly identical in both direction and magnitude in the pre- and postrelease periods (prerelease: OR 1.41, 95% CI 1.17-1.70; *P*<.001; postrelease: OR 1.41, 95% CI 1.27-1.56; *P*<.001). For AI trust, while the positive association was slightly attenuated and not statistically significant in the prerelease period (OR 1.05, 95% CI 0.89-1.25; *P*=.56), it was significant in the postrelease period (OR 1.10, 95% CI 1.00-1.21; *P*=.046). This suggests that the fundamental behavioral mechanism linking AI trust and usage to delay is robust. The DeepSeek release may have slightly amplified the measurable effect of AI trust, possibly due to increased public reliance on AI tools. Detailed results of this stratified analysis are available in Table S3 in Multimedia Appendix 2.

Figure 2. Association between artificial intelligence (AI) trust, usage frequency, and delayed health care–seeking behavior. (A) Univariate logistic regression and (B) fully adjusted multivariable model evaluating key predictors of delayed health care–seeking behavior.



AI Trust Influences Delay via Frequency: Evidence of Mediation

We further evaluated the indirect effect of AI trust on delayed health care–seeking through AI usage frequency, supporting a partial mediation model. In the linear regression analysis, AI trust significantly predicted usage frequency (path *a*: β=.5754; *P*<.001). In the multivariable logistic model, usage frequency was also significantly associated with delay (path *b*: OR 1.40, 95% CI 1.28-1.55; *P*<.001). The product term (indirect effect $a \times b$) was calculated to be 0.1949, and the Sobel test yielded a significant result (*P*<.001), indicating a statistically robust mediation path (Table 3). To further validate these findings, a nonparametric bootstrap analysis with 500 replications was conducted. The mean indirect effect was found to be 0.2152 (OR 1.24, 95% CI 1.20-1.29), with a bootstrap *P* value of <.001.

This confirms that AI trust contributes to delay behavior partly through increased frequency of AI usage. The direct effect of AI trust on delay remained statistically significant after adjusting for the mediator (path *c'*: OR 1.09, 95% CI 1.00-1.18; *P*=.04), supporting the conclusion of a partial mediation model (Table 3). A diagram illustrating this mediation relationship can be found in Figure 3.

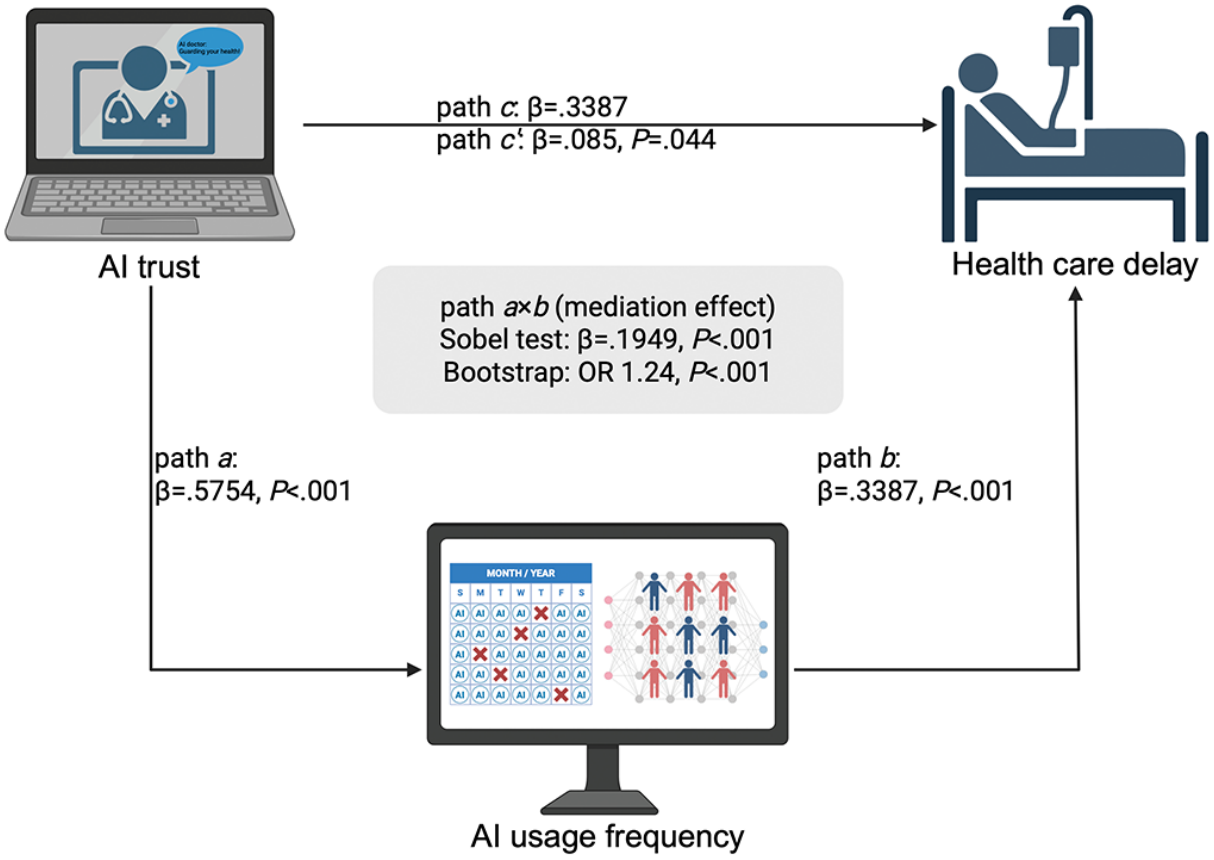
Table 3. Mediation effect of artificial intelligence (AI) trust on health care delay behavior.

Path	β (log OR[a])	OR (95% CI)	SE	*P* value	*P* value (Sobel)
a (AI trust-AI frequency)	.5754	N/A[b]	0.014	<.001	N/A
b (AI frequency-delay)	.3387	1.4031 (1.28-1.53)	0.0455	<.001	N/A
a × *b* (indirect)	.1949	N/A	0.0266	N/A	<.001
c (AI trust-delay, total effect)	.2473	1.2806 (1.20-1.37)	N/A	N/A	N/A
c' (AI trust-delay, direct effect)	.085	1.0887 (1.0-1.18)	0.0423	.04	N/A

[a]OR: odds ratio.

[b]N/A: not applicable.

Figure 3. Mediation model demonstrating how artificial intelligence (AI) trust influences delayed health care–seeking through increased frequency of AI usage. Path *a* shows the significant effect of AI trust on usage frequency, while path *b* indicates the association between usage frequency and delay. The indirect effect (*a* × *b*) and direct effect (*c'*) are also represented, highlighting the statistical significance of the mediation pathway. Image created in Biorender by WL [30]. OR: odds ratio.



No Significant Moderation by Recommendation Exposure Level

In the stratified analysis by recommendation exposure, AI trust was significantly associated with delayed health care–seeking in the high exposure group (OR 1.11, 95% CI 1.01-1.23; *P*=.03), but not in the low exposure group (OR 1.04, 95% CI 0.88-1.22; *P*=.67). Notably, frequency of AI use was consistently associated with delay across both groups (low: OR 1.47, 95% CI 1.24-1.73; *P*<.001; high: OR 1.38, 95% CI 1.24-1.53; *P*<.001), suggesting a stable effect regardless of exposure level (Table 4). In the full model with interaction terms, the AI trust × recommendation exposure interaction was not statistically significant (interaction OR 0.97, 95% CI 0.83-1.14; *P*=.75; Figure 4A; detailed stratified analyses can be found in Table S4 in Multimedia Appendix 2). As shown in the predicted probability plot, the slopes of AI trust

on delay were similar between groups, with overlapping CIs, supporting the absence of a significant interaction (Figure 4A).

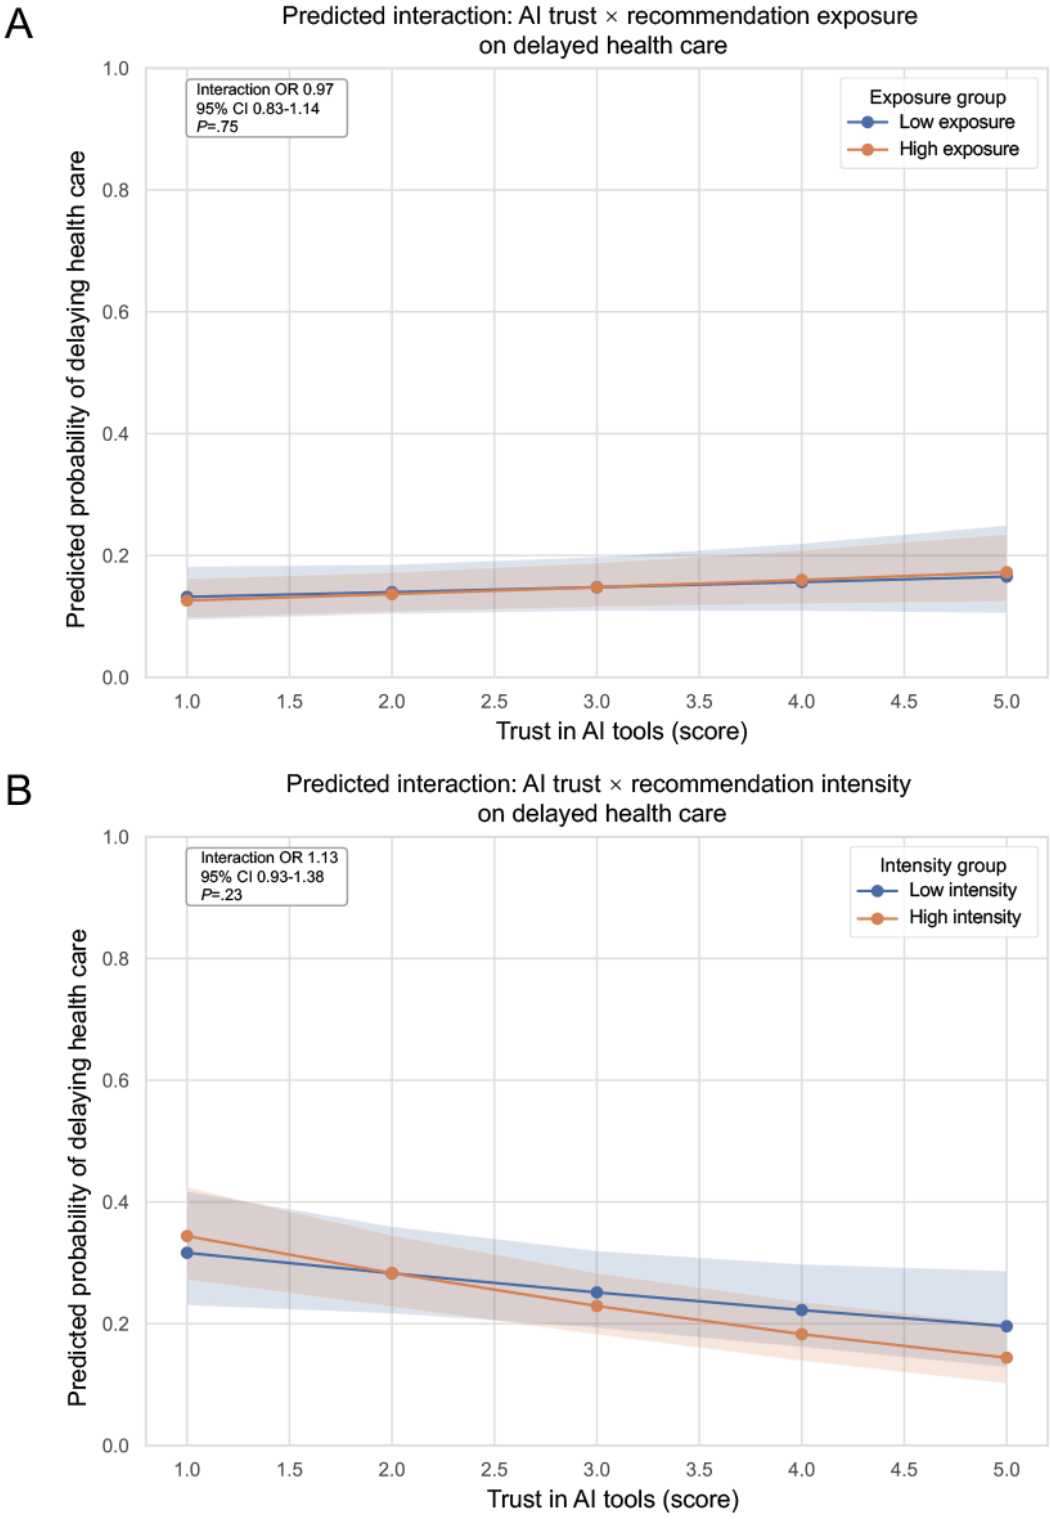
In summary, although AI trust showed a stronger association with health care delay in the high exposure group, the overall model did not indicate a statistically significant moderation effect. This suggests that while recommendation exposure may influence the magnitude of the trust-delay relationship, it does not alter its fundamental nature.

Table 4. Stratified analysis by recommendation exposure for the artificial intelligence (AI) trust-health care delay associations.

Outcome and variable	OR[a] (95% CI)	*P* value
Low recommendation exposure		
Trust in AI	1.04 (0.88-1.22)	<.001
Frequency of AI use	1.47 (1.24-1.73)	.67
Chronic disease (yes)	0.80 (0.47-1.37)	<.001
Age	1.01 (0.99-1.04)	.42
Gender (male)	1.35 (0.84-2.19)	.16
High recommendation exposure		
Trust in AI	1.11 (1.01-1.23)	.21
Frequency of AI use	1.38 (1.24-1.53)	<.001
Chronic disease (yes)	1.78 (1.30-2.44)	.03
Age	1.00 (0.99-1.01)	<.001
Gender (male)	1.17 (0.87-1.58)	<.001

[a]OR: odds ratio.

Figure 4. Stratified logistic regression and interaction modeling between artificial intelligence (AI) trust and recommendation exposure. Moderating effect of (A) AI recommendation exposure and (B) recommendation intensity on health care–seeking behavior. OR: odds ratio.



Limited Moderation by Recommendation Willingness Intensity

When stratified by willingness to recommend AI tools, AI trust was significantly associated with higher odds of health care delay in the low-intensity group (OR 1.16, 95% CI 1.00-1.34; *P*=.047), but not in the high-intensity group (OR 1.06, 95% CI 0.96-1.17; *P*=.27). Frequency of AI use remained a significant predictor of delay across both strata (low: OR 1.35, 95% CI 1.15-1.57; *P*<.001; high: OR 1.43, 95% CI 1.28-1.60; *P*<.001; Table 5). In the interaction model, the interaction term between AI trust and recommendation intensity was not statistically significant (interaction OR 1.13, 95% CI 0.93-1.38; *P*=.23; Figure 4B; detailed stratified analyses can be found in Table S5 in Multimedia Appendix 2). The interaction plot showed that the predicted probability of delaying care decreased with

increasing AI trust in both groups, with overlapping CIs, indicating no significant moderation effect (Figure 4B).

In summary, while AI trust appears to be more strongly associated with the odds of health care delay in the low-intensity group, recommendation intensity did not significantly moderate this association statistically. Its influence may reflect subtle variation in effect size rather than a true interaction.

Table 5. Stratified analysis by recommendation intensity for the artificial intelligence (AI) trust-health care delay associations.

Outcome and variable	OR[a] (95% CI)	*P* value
Low recommendation intensity		
Trust in AI	1.16 (1.00-1.34)	.047
Frequency of AI use	1.35 (1.15-1.57)	<.001
Chronic disease (yes)	1.53 (0.94-2.48)	.09
Age	1.00 (0.98-1.02)	.75
Gender (male)	1.07 (0.68-1.68)	.79
High recommendation intensity		
Trust in AI	1.06 (0.95-1.17)	.27
Frequency of AI use	1.43 (1.28-1.60)	<.001
Chronic disease (yes)	1.41 (1.02-1.95)	.04
Age	1.00 (0.99-1.02)	.71
Gender (male)	1.30 (0.96-1.77)	.09

Scenario Simulations Reveal Combined Risk of AI Trust, Frequency, and Chronic Disease

In the multivariable logistic regression analysis, all 3 key predictors—AI trust, frequency of use, and chronic disease status—were significantly associated with health care delay. Specifically, each unit increase in AI trust was linked to 9% higher odds of delay (OR 1.09, 95% CI 1.00-1.18; *P*=.04). Frequency of AI use demonstrated an even stronger association (OR 1.40, 95% CI 1.28-1.53; *P*<.001), and chronic disease status significantly increased the odds of delay as well (OR 1.42, 95% CI 1.09-1.86; *P*=.01; Table 6).

Table 6. Multivariable logistic regression analysis for the associations between key predictors and health care delay.

Variable	OR[a] (95% CI)	*P* value
Trust in AI[b]	1.09 (1.00-1.18)	.04
Frequency of AI use	1.40 (1.28-1.53)	<.001
Chronic disease (yes)	1.42 (1.08-1.86)	.01

[a]OR: odds ratio.

[b]AI: artificial intelligence.

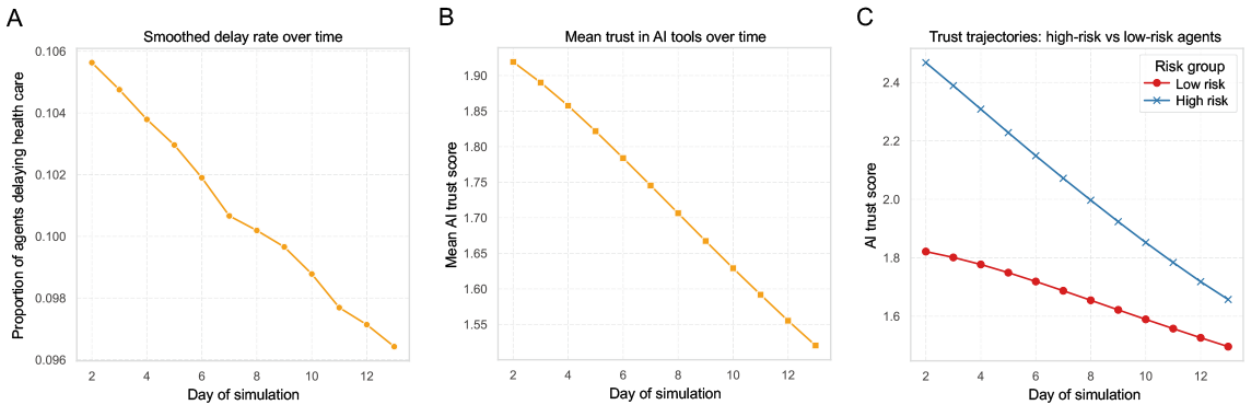
Scenario simulations indicated that, compared to a baseline of moderate trust and usage without a chronic condition (predicted probability=11.6%), increasing either AI trust (13.97%) or frequency (25.2%) alone raised the likelihood of delayed health care. The effect was most pronounced with frequency increases. When chronic illness was present alone, the predicted delay probability rose to 14.1%. Combining high trust and high frequency led to a delay probability of 30.5%, and when all 3 factors—high trust, high frequency, and chronic illness—were present, the probability escalated to 35.8%. These findings suggest that while increased trust and usage may enhance engagement with AI, they may paradoxically elevate the odds of behavioral delay due to potential overreliance or false reassurance. Therefore, intervention strategies should carefully balance cognitive trust with medical decision accuracy to mitigate potential adverse outcomes.

Agent-Based Simulation Reveals Bidirectional Feedback Between Trust and Delay

Simulation results demonstrated a consistent decline in the overall rate of health care delay, decreasing from 10.6% on day 1 to 9.5% by day 14 (Figure 5A). This trend reflects behavioral feedback, where agents who experienced delays reduced their AI usage frequency, ultimately lowering delay probabilities at the population level. Concurrently, the mean AI trust score declined steadily from approximately 1.95 to 1.49 over the 14-day period (Figure 5B). This indicates a natural erosion of trust in the absence of external reinforcement, suggesting a feedback loop where behavioral delays contribute to progressive trust deterioration. When stratifying agents by their predicted baseline delay probability, both high-risk and low-risk groups exhibited declining trust; however, the high-risk group experienced a steeper decline (from 2.55 to 1.74) compared to

the low-risk group (from 1.84 to 1.53; Figure 5C). This suggests that high-risk individuals may fall into a "high expectation-high disappointment" loop, accelerating trust collapse and reinforcing delay behavior. Detailed analyses for ABM can be found in Table S6 in Multimedia Appendix 2.

Figure 5. Agent-based modeling for the bidirectional feedback between artificial intelligence (AI) trust and delay behavior over a 14-day simulation period. (A) The overall rate of delayed health care. (B) The mean AI trust score. (C) AI trust score for the high-risk and low-risk groups.

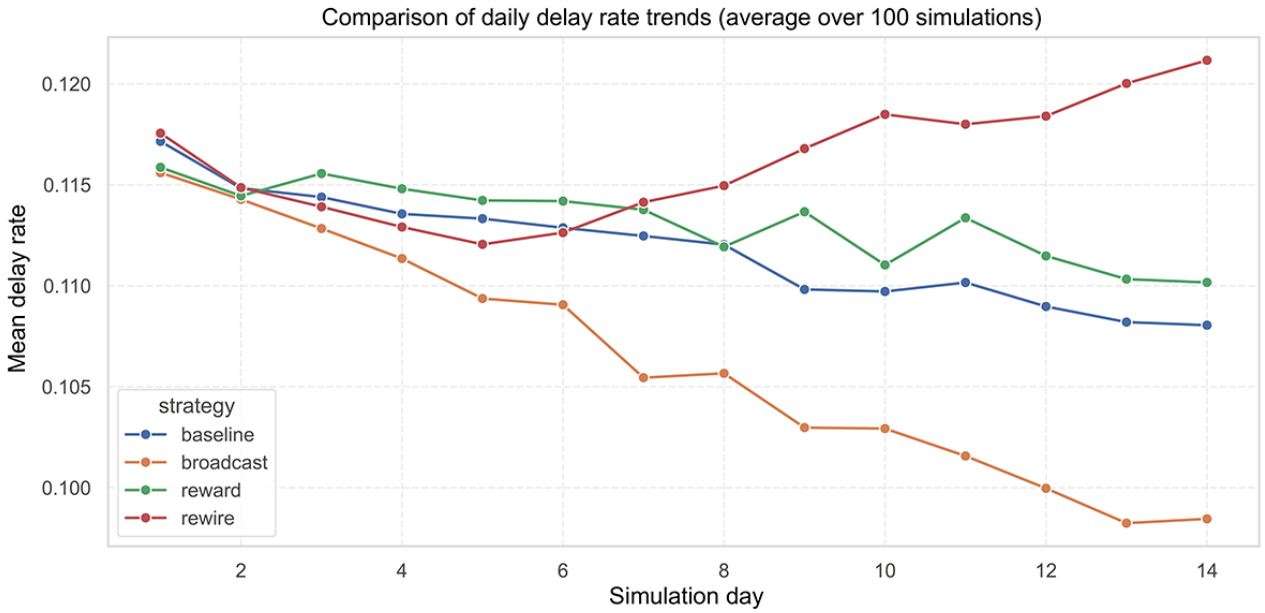


Overall, these simulations demonstrate the reciprocal feedback between trust and behavior, with individual heterogeneity compounding over time. The findings highlight the potential need for risk-stratified interventions or strategies designed to counteract trust erosion to prevent systemic trust breakdown.

Strategy Comparison: Broadcast Is the Most Effective, While Rewire May Backfire

Across 100 simulation trials, we examined the temporal effects of 4 intervention strategies on delay behavior. The broadcast strategy resulted in the most significant reduction in delay rates, reaching approximately 9.7% by day 14 (Figure 6). The reward strategy showed a moderate effect, with a slight downward trend compared to the baseline (Figure 6). In contrast, the rewire strategy led to an upward trend in delay rates after day 7, ultimately surpassing the baseline group, which suggests a potential amplification of trust polarization (Figure 6).

Figure 6. Comparison of 4 intervention strategies on delay behavior using artificial intelligence simulations. Strategies include baseline, broadcast messaging, behavioral reward, and network rewiring.



Logistic regression further quantified these effects (Table 7). Compared to the baseline, the broadcast strategy significantly reduced the odds of delay (OR 0.94, 95% CI 0.94-0.95; *P*<.001). The reward strategy indicated a slight increase in the odds of delay (OR 1.01, 95% CI 1.01-1.02; *P*<.001), while the rewire strategy demonstrated the most substantial increase in odds (OR 1.04, 95% CI 1.04-1.05; *P*<.001), indicating that this approach may exacerbate delay behavior under certain conditions. In summary, the broadcast strategy emerged as the most effective in reducing delay behavior within the current simulation framework, highlighting the potential advantages of proactive information signaling and group-level risk awareness alerts.

Table 7. Logistic regression analysis for the intervention strategies on health care delay.

Strategy	OR[a] (95% CI)	*P* value
Broadcast	0.94 (0.94-0.95)	<.001
Reward	1.01 (1.01-1.02)	<.001
Rewire	1.04 (1.04-1.05)	<.001

[a]OR: odds ratio.

To validate the robustness of the simulation across varying intervention configurations, we performed sensitivity analyses on 4 key parameters: initial trust level, broadcast penalty intensity, reward magnitude, and rewiring frequency. When varying the initial trust level (2.5, 3.0, and 3.5), higher values led to significantly increased rates of health care delay over time, suggesting that excessive trust may backfire despite its general benefits (Figure S1A in Multimedia Appendix 3). For broadcast penalty intensity, tested at values of 0.05, 0.1, and 0.2, the delay trajectories remained nearly identical, indicating minimal impact of penalty strength on intervention stability (Figure S1B in Multimedia Appendix 3). Similarly, altering the reward magnitude (0.03, 0.05, and 0.10) produced overlapping delay curves, demonstrating the strategy's robustness and absence of nonlinear effects (Figure S1C in Multimedia Appendix 3). In the case of rewiring frequency (2, 5, and 10 days), more frequent rewiring only slightly reduced early-stage delays, with long-term outcomes remaining consistent across intervals (Figure S1D in Multimedia Appendix 3). Overall, these results confirm that the simulation framework is stable, with behavioral outcomes staying similar across a range of parameters, highlighting the broader relevance and effectiveness of the modeled interventions.

Discussion

Principal Findings

This study is the first to systematically investigate the joint influence of AI trust, AI usage frequency, and chronic disease status on predicting delayed health care–seeking from the perspective of a behavior-trust feedback mechanism in China. Our findings demonstrate that both AI trust and usage frequency are significant predictors of health care delay. Importantly, AI trust not only indirectly elevates the odds of delay through increased usage frequency but also exerts a significant direct association when controlling for usage frequency, indicating a partial mediation pathway. Of note, individuals with chronic conditions inherently exhibit a predisposition toward delayed care. These odds are further exacerbated by the combined effects of high AI trust and frequent AI use. These results expand the current understanding of delayed health care behaviors. They emphasize the complex and dynamic interplay between technological trust and health-related decision-making. Additionally, they highlight that enhanced trust in AI may inadvertently contribute to adverse behavioral outcomes among patients with chronic diseases.

To investigate the psychological mechanisms underlying the "AI trust-frequent AI use-health care delay" pathway, we propose that cognitive bias and overreliance are key driving factors [31,32]. On one hand, patients with chronic conditions often experience stable and slowly progressing symptoms. They are more likely to view AI's reassuring suggestions as indicators of safety. As a result, they may underestimate the seriousness of their own symptoms. This sense of "false reassurance" is particularly pronounced among individuals with high levels of trust in AI [33]. Previous studies have shown that excessive trust in health AI recommendations can result in users neglecting bodily warning signs, ultimately leading to delays in health care–seeking [5]. On the other hand, frequent AI usage does not necessarily reflect higher health literacy. It also does not always indicate better self-management capacity [34]. Instead, it may suggest a psychological tendency to avoid traditional health care services. This tendency is especially common when medical care is expensive, time-consuming, or perceived as untrustworthy [35]. This form of "instrumental dependence" may drive individuals to rely on AI as a substitute source of advice when experiencing discomfort, instead of seeking timely professional care [36]. Therefore, this study emphasizes that the behavioral consequences of AI trust and usage frequency should not be interpreted simply as empowerment. Instead, it is important to explore the underlying psychological and behavioral mechanisms. This is essential for accurately assessing the true impact of technological interventions on health care behavior.

Although we further investigated the moderating effects of AI recommendation exposure and recommendation willingness on the "AI trust-health care delay" pathway, the interaction terms were not statistically significant. This indicates that these factors have a limited influence on the primary effect pathway. Subgroup analyses revealed some trend-level differences; for instance, individuals with higher recommendation willingness showed a slight reduction in delay behavior [37], but these effects did not achieve statistical significance. We speculate that a nonlinear threshold effect may be present. Once recommendation exposure reaches a certain frequency, its impact may plateau. This could result in a failure to further enhance trust or promote behavioral change. Another possibility is that the effectiveness of recommendations is highly context dependent. They may exert influence primarily when users experience high health anxiety, evident symptoms, or a strong sense of urgency [38,39]. Additionally, AI trust may be inherently unstable among individuals, easily influenced by emotional states, prior experiences, or public opinion [40]. These factors may further diminish the practical effectiveness of recommendations. While recommendation behaviors have the potential for positive influence, their underlying mechanisms appear more complex [41]. They may not adequately address the fundamental contradiction between AI trust and health care delay. Therefore, future interventions should not concentrate solely on increasing recommendation frequency or willingness.

Instead, it is crucial to address system-level design issues. This includes enhancing decision transparency and improving users' perceived control over health-related choices. Additionally, developing prompting strategies that better align with users' psychological models is essential. Such improvements are essential for facilitating meaningful and lasting behavioral change.

Scenario-based simulations further confirmed that the combination of high AI trust, frequent AI usage, and chronic disease status results in the greatest odds of delayed health care–seeking. This finding underscores the behavioral risks inherent in the trust feedback mechanism. Using behavioral decision theories, particularly the dual-process model, helps illuminate the psychological underpinnings of this phenomenon [42]. In high-trust situations, individuals tend to rely more on the intuitive system for decision-making, leading to quick, automatic judgments rather than thorough risk evaluations [43]. This "intuitive trust" is especially evident among patients with chronic illnesses, who often feel a sense of safety due to the relatively stable nature of their symptoms. When coupled with high trust in and frequent reliance on AI, these individuals are more likely to accept AI-generated suggestions without critically assessing their health status or seeking professional medical advice [44]. This can create a "false reassurance" effect, significantly heightening the risk of delayed health care. These findings serve as a cautionary note for the future design of AI-based health tools. Simply pursuing user trust is insufficient; it is essential to strike a balance between fostering trust and maintaining risk awareness. Both clinical practitioners and AI developers need to consider how to enhance user experience while mitigating the unintended consequences of overreliance [45]. Future AI systems should be designed to promote rational judgment, especially among high-risk groups with chronic conditions. Incorporating interactive features that provide calibrated risk reminders may be necessary to prevent the unconscious shift from trust to delayed health care behavior.

Our ABM offered a dynamic and systems-level understanding of how AI trust and delay behavior coevolve over time. Unlike traditional regression models that provide static snapshots [23], ABM captures how small differences in initial trust and exposure can compound through individual learning and social influence. Over a 14-day simulation period, we observed a steady decline in both trust and health care–seeking behavior, indicating a reciprocal erosion loop: delayed health care leads to dissatisfaction or unmet expectations, which in turn diminishes trust and further health care delay [46]. Importantly, agents stratified by predicted baseline odds (above vs below 20%) showed divergent trust trajectories. High-risk individuals began with higher trust but experienced a sharper decline—suggesting a "high expectation-high disappointment" loop. This highlights how perceived safety in chronic illness, when coupled with excessive AI reliance, may paradoxically lead to trust collapse and amplified delay behavior. Such patterns would be difficult to detect using empirical data alone, underlining the value of simulation modeling in behavioral health research. Beyond reproducing observed behaviors, ABM also allowed us to simulate system-wide interventions and uncover nonlinear responses to trust regulation strategies. Of the 3 mechanisms tested, broadcast messaging consistently reduced delay by maintaining population-level risk awareness. In contrast, network rewiring unexpectedly increased delay, likely due to the formation of echo chambers among high-trust individuals, a phenomenon we term "trust polarization" [47]. This emergent property demonstrates that even well-intentioned peer-based reinforcement may backfire under certain trust dynamics. Overall, these simulations underscore the importance of viewing AI trust not merely as an individual attribute, but as a collective behavioral variable that evolves across time, context, and networks [48]. While the ABM provides valuable insights into potential system dynamics and the comparative theoretical performance of different strategies, these findings serve as a proof of concept. Their real-world effectiveness and causal impact must be rigorously tested in future randomized controlled trials or natural experiments.

Simulation-based evaluations of 3 intervention strategies indicate that broadcast messaging is the most effective for reducing delayed health care behavior. This suggests that public health interventions delivering wide-reaching, consistent risk reminders may be the most cost-effective approach [49]. Conversely, the reward-based strategy was less effective, likely due to insufficient incentives or limited reach, which hindered meaningful behavior change at the population level [50]. Unexpectedly, the network rewiring strategy not only failed to reduce delays but exacerbated them. We hypothesize that this may result from the formation of information echo chambers among high-trust individuals [51]. In these tightly connected groups, AI trust can become mutually reinforced, amplifying the "AI trust-health care delay" pathway and leading to what we term trust polarization. These findings underscore the need to prioritize intervention strategies that broadly disseminate risk information and continuously enhance risk awareness. Future health interventions should focus on scalable and sustainable communication mechanisms rather than relying on individual "opinion leaders" or short-term incentives. This approach provides valuable insights into integrating AI and health behavior, while also offering empirical evidence to inform public health policy development.

Limitations

Despite proposing a novel "trust-behavior" feedback mechanism and validating various intervention strategies through simulation, this study has several limitations. First, the cross-sectional and observational nature of our survey data precludes definitive causal inference. While we controlled for several demographic and health factors, the potential for omitted variable bias remains. Unmeasured confounders, such as general health literacy and prior negative experiences with the health care system, could independently influence both AI trust and the propensity to delay care. To establish causality, future research should use randomized controlled trials that investigate participants' trust in AI. This approach would enable more conclusive mediation and moderation analyses and would represent a critical continuation of our future research efforts. Second, measurements of AI trust and usage frequency were based on self-reported data. This approach may introduce recall bias, social desirability effects, or subjective judgment. Consequently, these factors could potentially affect the accuracy

of the findings. Although we introduced a group-based behavioral simulation model to address the static nature of cross-sectional data, this model simplifies the complex dynamics of trust evolution in real-world contexts. Future research could incorporate reinforcement learning or dynamic trust modeling approaches to better capture human cognitive and behavioral trajectories [52]. Third, the generalizability of our findings may be limited by the specific sociotechnical context of China. Our recruitment relied on dominant Chinese digital platforms (WeChat and QQ). The observed relationships between AI trust, usage, and health care delays are likely influenced by China's unique health care system, technology ecosystem, and cultural norms. Therefore, caution is warranted when extending these results to other countries with different health care policies, technology adoption patterns, and cultural attitudes toward AI in medicine. Fourth, our recruitment via social media and hospital portals, while enabling broad access, prevents precise quantification of response rates from each channel. Although we estimate that most responses came from WeChat and QQ, with a smaller proportion from hospital portals, the anonymous nature of the survey precluded channel-specific stratification. Additionally, this approach likely oversampled individuals who are more digitally literate or proactively engaged with health care information. This may limit the generalizability of our findings to populations with limited digital access or lower health literacy. Fifth, the questionnaire did not collect data on rural or urban residence or socioeconomic status, limiting our ability to examine these potential sociodemographic influences on the trust-delay pathway. Future studies would benefit from incorporating these variables. Sixth, our sample contained a slightly higher proportion of female participants (1345/2460, 54.7%), which may influence generalizability. However, we adjusted for gender in all analyses and found no evidence of significant effect modification. Finally, we advocate for the development of AI health tools with stratified trust management functions [53]. Such systems should provide tailored risk alerts for high-risk patients with chronic conditions, promoting rational trust for genuine health empowerment rather than fostering passive dependence.

Conclusions

This study identifies a nuanced relationship between AI trust and delayed health care–seeking behavior. While trust in AI tools can enhance user engagement, it may also be associated with delayed health care, particularly among individuals with chronic conditions or higher levels of AI use. By integrating survey data with ABM, our study moves beyond static associations and illustrates how AI trust and delay behaviors may interact and reinforce one another over time. This dynamic perspective highlights how individual-level trust processes can accumulate into system-level patterns, including trust polarization and collective delay. Our findings suggest that the design of AI health tools should prioritize calibrated decision support rather than full automation. Encouraging a balanced interaction between user autonomy and technological assistance may help mitigate delay-related risks and improve decision quality in digital health contexts. Beyond individual-level tool design, these insights may also inform population-level strategies for trust governance and risk communication in AI-driven health care systems.

Abstract

Background: Digital parenting programs offer a promising way to disseminate evidence-based parenting knowledge and support early childhood development. They help reduce costs while improving scalability and fidelity. However, their successful implementation is context-dependent, and existing research offers limited guidance on how the implementation of digital parenting interventions unfolds across diverse settings.

Objective: This study aims to identify the shared and unique facilitators and barriers affecting each dimension of implementation, as well as differentiated mechanisms that support the effective implementation and institutionalization of such interventions across diverse settings.

Methods: Using a multiple-case study design, this research compared the implementation of a digital (chatbot-led) parenting program across 2 distinct settings in China: urban educational and rural health care contexts. The intervention content remained consistent, while the contexts and formats of local human-led support differed. Guided by the RE-AIM framework, this study examines the program's reach, adoption, implementation, and maintenance in both settings. Data sources included program documents, field observations, semistructured interviews, and focus group discussions with 83 stakeholders. Thematic analysis was conducted using ATLAS.ti until thematic saturation was reached.

Results: Data were collected from 83 stakeholders, and findings are based on an analysis of 18 interviews and 4 focus groups with caregivers, village doctors, and health officials from the rural health care setting, and 29 interviews and 4 focus groups with caregivers, teachers, social workers, and managers from the urban educational setting. Regarding reach, strong relationships between parents and implementers and the credibility of program developers were shared facilitators in both settings. Parenting conservatism and limited understanding of the program were shared barriers. In rural health care settings, parents' perception of village doctors as lacking parenting expertise posed an additional challenge. For adoption, trust between managers and program developers, program alignment with organizational functions, and organizational empowerment supported implementation are shared facilitators in both settings. At the individual level, task-driven motivation helped, while time constraints hindered adoption in the health care setting. Teachers adopted the program due to its relevance to their roles in the educational setting, unlike village doctors, who did not see it as part of their core duties. For implementation, supportive management and clear guidelines were shared facilitators in both settings, while a lack of purpose and psychological pressure acted as barriers. Rural implementation was aided by scheduling during off-seasons and standardized workflows, whereas flexible workflows were essential in the educational setting. Regarding maintenance, alignment with organizational functions and internal resources facilitated sustainability in both settings, while overreliance on government authorization posed challenges. Educational settings required contextual adaptation, while health care settings needed more content adaptation.

Conclusions: Implementing digital parenting programs is a complex process, influenced by multilevel facilitators and barriers that vary across regions (rural vs urban) and settings (educational vs health care). This study highlights the importance of context-specific implementation strategies and proposes differentiated delivery models tailored to local structures and needs.

Introduction

Early childhood is a critical period for long-term educational, emotional, and economic development [1]. Globally, more than 43% of children younger than 5 years of age are at risk of not reaching their full developmental potential, with children in low- and middle-income countries (LMICs) being disproportionately affected [2]. The failure to achieve developmental potential during early childhood has far-reaching consequences, not only for individual well-being but also for societal progress, which leads to losses in human capital and increased risks of social instability [3]. These challenges underscore the critical importance of investing in effective strategies that support ECD.

Among the most influential predictors of positive ECD outcomes is the quality of parenting [4,5]. Improving parenting practices, especially in under-resourced settings, is therefore a key priority in global ECD efforts. Parenting interventions, which are typically grounded in social learning and attachment theories, aim to equip parents with the knowledge and skills necessary to enhance parenting quality and to foster home environments that promote children's health and development [6-8]. Such programs have been shown to improve ECD outcomes, enhance positive parenting practices, reduce the use of harsh or violent discipline, and improve caregivers' mental health [9,10]. Meta-analytic findings indicate that such interventions in LMICs yield greater improvements in children's cognitive, language, and motor development, highlighting the potential for large-scale benefits in resource-limited settings [10].

Traditional parenting interventions, delivered through home visits or small-group sessions, are resource-intensive and face barriers such as time constraints, geographic distance, and limited personnel [3,11]. These limitations make conventional delivery methods difficult to scale and sustain, particularly in low-resource settings [12,13]. Nowadays, the growing accessibility of the internet and the widespread ownership of mobile phones present a promising opportunity to overcome these challenges by leveraging digital technology [14]. Digital parenting programs provide a cost-effective way to deliver evidence-based parenting support, particularly in low-resource settings, by enhancing scalability while maintaining high fidelity [12,15]. They reduce costs associated with time and travel and increase accessibility to high-quality parenting resources [16,17]. Emerging evidence indicates that digital parenting interventions can positively influence multiple outcomes, including child development, parental confidence, parenting stress, and children's behavioral problems [18-20]. These programs are particularly effective when complemented by human-led support, either in person or remotely [21].

The success of social and behavioral interventions hinges not only on the inclusion of key components designed to facilitate behavior change, but also on the fidelity and quality of their implementation in real-world settings [22]. While the body of research demonstrating the effectiveness of digital parenting interventions in promoting child development is growing, limited attention has been given to their implementation processes. This gap in knowledge poses significant barriers to the replication, adaptation, and scale-up of such interventions, particularly in diverse and resource-constrained contexts [23,24].

Implementation research seeks to uncover what works, how it works, and why it works in everyday settings beyond the confines of controlled trials [25]. It emphasizes identifying contextual factors that influence successful implementation, such as characteristics of the delivery environment, community context, interorganizational partnerships, and intervention delivery mechanisms [26,27]. The RE-AIM (Reach, Effectiveness, Adoption, Implementation, and Maintenance) framework is a widely recognized model that offers a comprehensive approach for evaluating the implementation and public health impact of interventions [28]. It helps researchers and practitioners identify the strengths and barriers in intervention implementation, thereby facilitating the optimization and broader dissemination of public health practices [28-30]. This approach also offers insights into how short-term programs can be transformed into sustainable, institutionalized practices within organizations and service systems [31]. While existing studies applying the RE-AIM framework have examined digital interventions in various health domains, such as diabetes management, psychotherapy, vaccination, and health behavior promotion [32-35], there is a notable gap in research on the implementation of digital parenting programs, especially across different settings. This gap is especially evident in LMICs, where such interventions remain underexplored and underdeveloped.

Guided by the RE-AIM framework, this study addresses these gaps by evaluating the implementation of a digital parenting program, "Keyushiguang", in 2 distinct service delivery systems in China: an urban educational setting and a rural health care setting. In China, where significant early childhood development gaps and resource disparities persist, there is an urgent need for scalable, context-sensitive parenting support models [36,37]. This study, therefore, examines the program's reach, adoption, implementation, and maintenance to identify shared and setting-specific facilitators and barriers. By comparing these 2 delivery models, the study aims to provide new insights into

the differentiated mechanisms required for scaling and sustaining digital parenting support in diverse, low-resource contexts. The program's impact evaluation will be reported separately.

Methods

Study Design and Context

A multiple-case study approach was used to facilitate a deeper understanding of individual cases while also identifying overarching patterns. A case study is an empirical research method used to investigate contemporary phenomena within their real-world context. By analyzing a specific case in depth, researchers gain insights into the background, processes, and influencing factors, which is especially valuable for studying complex social phenomena or contexts [38]. Case studies can be categorized into single-case and multiple-case studies, depending on the number of cases analyzed. The multiple-case study approach was adopted to enhance the validity of findings from different cases, leading to more robust and reliable conclusions [39]. This method allowed us to identify commonalities and differences in the facilitators and barriers to implementation across different contexts.

Theoretical Underpinnings: RE-AIM

This paper focuses on 4 key dimensions of the RE-AIM framework: Reach, Adoption, Implementation, and Maintenance. Effectiveness was assessed using quantitative methods and will be presented separately.

Reach refers to the total number, proportion, and representativeness of individuals who are willing to participate in a given initiative, intervention, or program [28]. It primarily focuses on understanding the factors that influence individuals' decisions to engage—or not engage—with the program. Adoption refers to the absolute number, proportion, and representativeness of settings and intervention agents (people who deliver the program) who are willing to initiate a program, as well as the reasons behind their decisions [28]. Implementation primarily focused on the program's fidelity, which is the extent to which the program is delivered as intended, and examined how this fidelity was achieved throughout the delivery process [40]. Maintenance at the setting level of a program refers to its institutionalization or integration into routine practices and policies [30].

This paper evaluated each of these dimensions across the 2 distinct settings, analyzing the factors that were perceived to facilitate or hinder participation in the programs, as well as the differences in these factors between the 2 settings.

We also reported a descriptive overview of reach, adoption, and implementation. Reach was calculated by the ratio of participants who consented to participate relative to the total number of eligible individuals in both settings. The recruitment criteria for both programs were similar, with the primary requirement being that the caregivers of children be the primary caregivers. Adoption at the staff level is calculated by dividing the number of staff who agreed to participate in program implementation by the total number of staff eligible to participate in the program within the organization. In addition, we assessed the implementation based on the fidelity checklists of implementers.

Case Selection

The selection of cases in this research was guided by the study objectives. This paper examines the implementation of the digital (chatbot-led) parenting intervention in 2 distinct settings in China: an urban preschool (educational) setting and 2 rural health centers (health care) settings. Intervention delivery in both settings was led by local implementation partners, with support from the research team that developed the digital intervention. Consequently, the intervention's digital delivery method and content remained highly consistent across the 2 settings, with only minor adaptations made for the rural health care setting, such as colloquial expressions used, without altering the core parenting principles.

Case boundaries were defined as follows. The urban educational case referred to the implementation within one preschool in Xinyu city, Jiangxi Province, while the rural health care case referred to the implementation within the village-level public health system, supported by the county-level Maternal and Child Health Department and 2 township-level Health Centers in Huining County, Gansu Province. The analysis covered the full pilot implementation period: the preschool intervention that ran from March 2024 to June 2024, and the health care intervention that ran from October 2024 to January 2025. Stakeholders included in the case analysis were those directly engaged in program implementation—caregivers, teachers, social workers, village doctors, program managers, and local government officers. Broader community members who were not directly involved in program delivery were excluded.

The digital parenting program "Keyushiguang" was culturally adapted from the Parenting for Lifelong Health's ParentText chatbot for parents of children aged 2 to 9 years by a local research team [41]. Delivered via a rule-based chatbot on WeChat, the program covers 8 key parenting topics, each consisting of 3 to 6 modules depending on the child's age. Each module includes an introduction, quizzes, core parenting tips (in video or text format), and home exercises. The chatbot sends one parenting module every 23.5 hours, allowing parents to gradually develop their parenting skills and apply them in daily situations. Designed to integrate smoothly into parents' daily routines, the chatbot enables flexible engagement at convenient times, such as after work, during breaks, or before bedtime. This gradual approach encourages parents to apply the learned skills in real-life scenarios, such as managing child behavior or establishing daily routines. By offering relevant, practical, and easily accessible support, the chatbot helps parents stay engaged consistently, enhancing the program's long-term impact (Detailed program description can be seen in Multimedia Appendix 1).

The main distinctions between the 2 implementations lay in the format of additional human-led parenting support and were driven by the unique implementation contexts and available resources in each setting. In the urban educational setting, chatbot-led digital delivery was supplemented by message-based WeChat group interactions via web, held once or twice per week, and facilitated by headteachers and trained social workers.

In contrast, the rural health care setting incorporated biweekly 40-minute individual home visits conducted by village doctors to reinforce the content delivered online and foster engagement.

The choice between group-based and individual-based human-led parenting support models was based on a comprehensive assessment of the target population and implementation environment [42]. In China, rural areas typically face greater challenges to child development than urban areas [43]. Therefore, the program was designed as a universal intervention (available to all families regardless of child development status) in the urban setting, while in rural areas, it was implemented as a selective intervention (targeted at high-risk families). Additionally, resource feasibility and cultural acceptance also informed program design. For example, most rural families have access to village doctors, whereas urban preschools face teacher shortages. In addition, rural parents are more receptive to home visits [44]. Therefore, we adopted a group-based WeChat interaction model for the urban preschool setting and a combined individual and group home visit model for the rural health care setting to better suit local needs and contexts. The comparison of the 2 pilot implementations is provided in Multimedia Appendix 2.

The rationale for selecting these 2 cases was that by controlling for similarities in program content, the study could minimize the impact of content-related differences and more precisely analyze the result variations arising from differing implementation contexts (ie, urban education vs rural health care settings).

Data Collection

We used data triangulation to enhance the comprehensiveness and validity of our findings. Multiple sources of data were used, including program documentation (such as program manuals and materials), field observation notes (such as the behaviors of stakeholders in the process of program pre-preparation, implementation, and evaluation), semistructured individual interviews, and focus group discussions (FGDs). Our triangulation involved 2 levels. First, we conducted within-case triangulation by integrating these diverse data sources to validate findings within each of the 2 settings. For example, we compared implementers' subjective perceptions of their implementation fidelity with parents' feedback (as reflected in the fidelity checklist) and triangulated these with our field observation records. This approach allowed us to more accurately interpret and evaluate the perspectives expressed by stakeholders. Following this, we conducted between-case triangulation (ie, a cross-case analysis). This second level systematically compared the validated themes from the urban educational setting against those from the rural health care setting to identify the overarching facilitators, barriers, and divergent patterns presented in our results.

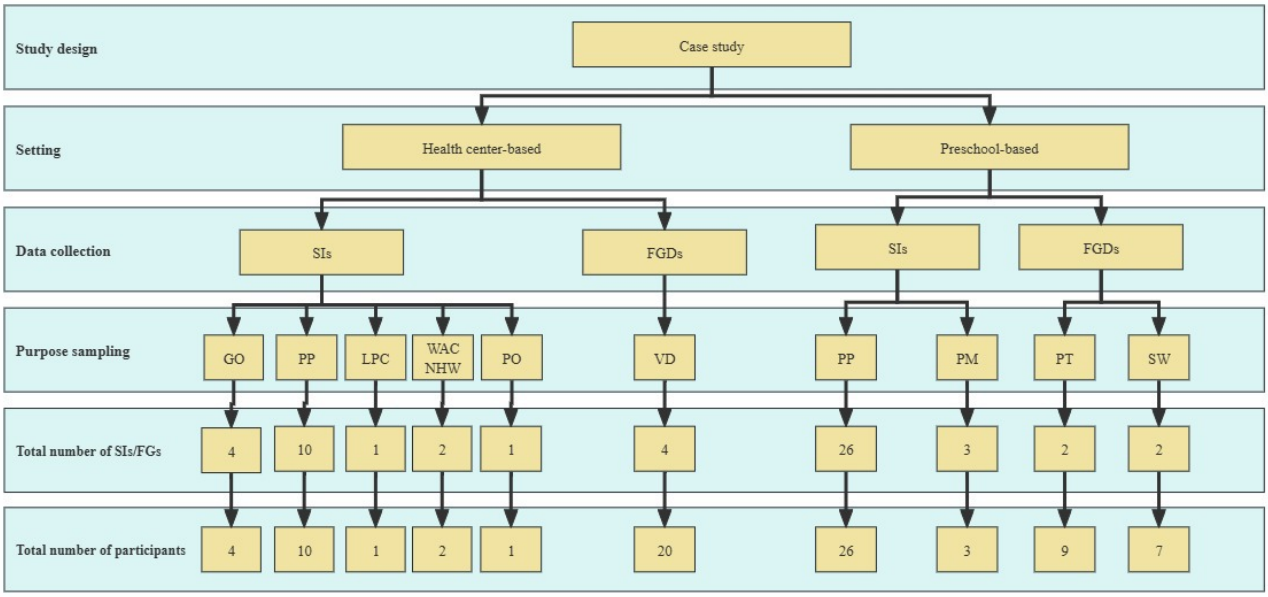
Program-related documents retained since the program's inception were collected and analyzed. These included program proposals, curriculum designs, daily implementation records, and training materials, which served as foundational resources for understanding the intervention. All documents were reviewed systematically, and key implementation details were extracted for analysis. In addition, as members of the research team, the authors were actively involved in and directly observed the implementation processes in both settings, providing them with in-depth insights into the contextual dynamics and operational realities of the program delivery.

Field observations related to stakeholders' behaviors, program structure, and implementation processes. We observed the behavior and actions of stakeholders throughout the program and recorded those, which allowed for a more accurate understanding of the viewpoints they expressed.

We adopted a purposive sampling strategy, which is consistent with qualitative research practices that emphasize differentiation (Figure 1). Participants were deliberately selected to reflect diversity in roles, experiences, and contextual backgrounds. This approach allowed us to explore the phenomenon under investigation in a more nuanced and comprehensive manner. Specifically, participants were categorized into 5 key stakeholder groups: program officers, local leadership, local program managers, program implementers, and program participants. The final sample included 1 program officer from the health care setting; 7 local program leaderships (ie, 3 preschool leaderships and 4 government officers from the health care setting); 3 local program managers (ie, 2 Women's and children's health workers and 1 local program staff from the health care setting); 36 program implementers (ie, 9 preschool teachers and 7 social workers from the preschool setting, and 20 village doctors from the health care setting); and 36 program participants (ie, 26 caregivers from the preschool setting; and 10 caregivers from the health care setting).

The figure 1 illustrates the overall structure of data collection. As detailed in the Methods section, the implementation and data collection were conducted sequentially (urban case first, followed by the rural case). FGD: focus group discussion; GO: government officers from the healthcare setting; LPC: local program coordinator; PM: preschool managers; PO: program officer; PP: program participants; PT: preschool teachers; SI: semistructured interview; SW: social worker; VD: village doctor; WACHW: Women's and Children's Health Worker.The interview and FGD guides were developed based on the RE-AIM framework, incorporating a structured set of open-ended questions. Data related to the "Reach" dimension were primarily obtained from program participants, while "Implementation," "Adoption," and "Maintenance" were explored through interviews and focus groups with program donors, local leadership, local program managers, and program implementers. Each FGD lasted approximately one hour, and individual semistructured interviews averaged 40 minutes in duration. Prior to data collection, informed consent was obtained from all participants. With participants' permission, all interviews and FGDs were audio-recorded. Recordings were subsequently transcribed, reviewed for accuracy, and anonymized to ensure confidentiality.

Figure 1. Stakeholder sampling and data collection design for the 2 cases.



Data Analysis

Data were coded using ATLAS.ti (version 8; Lumivero). A thematic analysis was conducted using a hybrid inductive-deductive approach to identify patterns across the dataset [45]. As data collection was conducted at different times, we first collected and analyzed data from the urban educational setting following a stepwise thematic analysis procedure. After completing data collection in the rural health care setting, we applied the same analytical process. To ensure consistency and mitigate the risk of bias from this sequential design, the same coders applied the same predefined RE-AIM framework to both datasets independently. Only after both independent analyses were complete were the results from the 2 settings formally compared to identify similarities and differences. The coding process was conducted by 2 researchers (XS and RR) and followed the steps outlined by standard thematic analysis [45,46]. Thematic analysis was conducted through a structured 5-step process—data familiarization, initial coding, theme development, collaborative review, and final theme definition—guided by the RE-AIM framework to identify facilitators and barriers to program implementation (Figure 2). During the coding process, we continuously compared new data with existing codes and themes. We considered thematic saturation to be achieved when no new codes or themes emerged from subsequent interviews and FGDs. Given the diversity of stakeholders included—parents, teachers, village doctors, local managers, and government officers—the data provided a comprehensive reflection of perspectives across both settings.

Finally, as the capstone of our cross-case analysis, we synthesized the shared and setting-specific facilitators and barriers identified through the RE-AIM framework. This synthesis allowed us to construct the differentiated implementation models presented as the final component of our Results.

Figure 2. The process of data analysis.

Ethical Considerations

Ethics approvals were obtained from Beijing Normal University (approval numbers: SSDPP-HSC-2024003 and BNU202410100062) and the University of Oxford (SPI_DREC_24_006). We provided participants with a detailed introduction to the program and obtained their informed consent voluntarily. All data is stored in a secure database and is used only for research purposes by the researchers.

Positionality Statement

We acknowledge that our dual roles as program designers and researchers may have influenced data interpretation. To mitigate this, we applied both personal and methodological reflexivity throughout the study.

Our research team has diverse academic backgrounds, including evidence-based social intervention, child development and protection, public administration, education, and social work. These perspectives shaped how we approached the research: team members with social intervention and public administration backgrounds tended to focus on macro-level structures and policies, while those with child development, education, and social work backgrounds were more attuned to participants' lived experiences. To minimize potential biases from these disciplinary differences, the team engaged in ongoing reflexive discussions, considering multiple perspectives at all stages of analysis.

Methodologically, 2 researchers (XS and RR) independently coded different portions of the dataset and cross-checked each other's work. A third researcher (ZF) reviewed the coding, provided feedback, and helped resolve discrepancies through iterative discussion until consensus was reached. This collaborative process ensured rigor and consistency in the analysis.

In addition, practical measures were taken to reduce researcher influence during data collection. Data collectors were trained to use semistructured interview guides with open-ended, nonleading questions, fostering a neutral environment that encouraged participants to share their authentic experiences.

Results

Overview

To ensure methodological rigor and transparency, the reporting of this study followed the iCHECK-DH: Guidelines and Checklist for the Reporting on Digital Health Implementations (Checklist 1) [47]. Descriptions of interview participants can be seen in Multimedia Appendix 3.

Case Context and Stakeholder Profiles

The Urban Educational Setting: A Preschool in Xinyu City

This pilot was implemented in a preschool located in Xinyu City, an urban, medium-income area in eastern China. The preschool provides early childhood education before primary school, with parenting integrated into daily activities. The main participants were parents, most of whom hold stable jobs; their participation time was influenced by their work schedules. Key implementers included teachers who hold educational credibility and trained social workers who offered professional parenting support and assisted teachers in carrying out the program. The preschool leadership's primary motivation was to enhance the school's educational quality and reputation.

The Rural Health Care Setting: 2 Townships in Gansu Province

This pilot took place in health centers across 2 townships in Huining County, Gansu Province, a low-income rural region in western China. The centers are responsible for public health services, and promoting early childhood development was one of their key goals. The main participants were parents recruited from rural communities, most of whom engage in agricultural work. Their participation was shaped by the agricultural calendar and seasonal migration for work. The key implementers were village doctors who were trusted in their communities with strong local knowledge but generally older and less experienced in parenting. The health care leaderships were primarily motivated by fulfilling national public health directives. We labeled the interview data based on the source and role of the interviewees. The initial letters in each label represent the interviewee's role, as illustrated in Figure 1. HB and SB denote data from the hospital-based program and preschool-based program, respectively. The last 3 digits of each label indicate the document number, and each number corresponds to a unique interviewee or focus group.

Reach—Facilitators and Barriers

Overview

In total, 541 (81.4%) caregivers (402 [74.3%] were mothers, 135 [25%] were fathers, and 2 [0.3%] were grandparents) of the 665 eligible families consented to participate in both the program and the research.

In contrast, the township central health center–based program aimed to recruit 120 parents of children aged 24 - 59 months from 2 pilot townships, out of approximately 795 eligible families. A total of 83 out of the targeted amount of 120 were able to participate (69.2%).

Shared Facilitators to Reach

The main motivations for participation in the program include its strong emphasis on child development, strong relationships between program implementers and caregivers, the perceived credibility of the program developers, and the convenience of learning through a chatbot.

A primary motivation in both settings was a recognized need for practical parenting skills. In the rural health care settings, caregivers expressed that they faced ongoing challenges in daily parenting and felt that their current knowledge was insufficient. They recognized the need to learn practical parenting skills to better support their children. In the urban educational setting, parents expressed similar concerns.

> *We don't know much about how to support our children's growth or deal with their emotional problems. This program gives us a chance to learn parenting ways.* [PP, HBD05]

Another shared facilitator was the influence of implementers, driven by social relationships. Some caregivers in the health care setting reported that their agreement to participate was influenced by their trust and social pressures from program implementers, such as face-saving norms, social obligations, or a sense of personal favor. Similarly, in the educational setting, the motivation to participate also stemmed from the influence of teachers.

> *The village doctor is our family doctor. He has helped us a lot and has a good relationship with us. He wants us to join the program, so we are willing to support him.* [PP, HBD11]

> *At first, the teacher encourages us to participate in this parenting program. I think if other children are participating, we shouldn't seem uncooperative with the teacher's efforts.* [PP, SBD11]

Parents in the health care setting also considered the background of the program developers. Knowing that the program was developed by a research team from a prestigious university in China enhanced its credibility and increased parents' perceived benefits. Similarly, parents in the educational setting shared the same view, trusting the program's credibility due to its association with a reputable institution, which further reinforced their belief in the program's potential benefits.

> *There is too much parenting information online, and it is often hard to tell what is true or false. But this online course is developed by a professional team, so we feel the content is reliable and will be helpful to me.* [PP, HBD10]

The convenience of learning was also an essential factor for program reach. Parents in both educational and health care settings appreciated that the chatbot-based delivery allowed them to access the content anytime and anywhere. The use of diverse formats, such as videos and text, accommodated different learning environments and individual learning preferences.

> *The timing is fine because it is flexible. You can choose when to learn, so it is convenient when you have free time.* [PP, SBD15]

> *The course offers both video and text options, which is suitable for different scenarios. When I have free time, I choose to read the text. When I am busy, I play the video and listen to the content.* [PP, HBD11]

Shared Barriers to Reach

In both settings, shared factors hindering parents' participation include parenting conservatism, a lack of understanding of the program, and limited time for learning.

A shared barrier in both settings was 'parenting conservatism,' where parents preferred to stick to traditional parenting methods. During the program promotion process, some parents in the educational setting with low engagement exhibited a form of 'parenting conservatism'. They preferred to maintain their existing parenting practices and felt it was unnecessary to learn about other approaches, believing that new practices might not be suitable for their own situations. Similarly, in the health care setting, some caregivers also displayed resistance to adopting new parenting knowledge, preferring to rely on their established practices.

> *I feel that every family has its own parenting style. My other children are raised according to my own parenting methods, and there is no need to change it.* [PP, SBD13]

Furthermore, a limited understanding of the program served as a barrier in both contexts. Some caregivers in the educational setting indicated that they did not fully understand the program, such as its content, learning format, and flexibility. Some caregivers claimed they had no spare time to engage with the digital program and chose not to participate, unaware that the learning sessions were brief and could be easily completed anywhere in just a few minutes.

> *I think the course will take up a lot of time. Since I have to work and take care of my family, I don't have much spare time for studying.* [PP, SBD13]

While some parents in the health care setting remained unaware of what they could gain from the program, this ultimately reduced their enthusiasm for participating.

> *At first, they don't tell me the specific details of the program. I don't know its benefits, so I initially see it as just a favor to village doctors.* [PP, HBD13]

Distinct Facilitators and Barriers to Reach

The urban educational setting presented several unique facilitators. These included urban parents' recognition of the parenting values conveyed by the program and their acknowledgment of the implementers' credibility and rationale in delivering parenting knowledge. These factors played a significant role in enhancing parental engagement in the educational setting. However, such facilitators were not observed in the health center-based program.

Some parents in the urban areas reported that the parenting concepts and attitudes conveyed through the program resonated with their own parenting beliefs. In contrast, parents in rural areas rarely expressed this kind of value-level recognition.

> *I agree with the parenting concepts in the course, and I am willing to learn it.* [PP, SBD08]

The perceived professional authority of the program implementers influenced caregivers' decisions to participate. Parents viewed preschools as appropriate platforms for parenting support, and headteachers were seen as credible and persuasive figures in promoting parenting knowledge.

> *This preschool and its teachers are the best in the area, and I trust the quality of both the preschool and the teachers. I believe their actions will be beneficial to me.* [PP, SBD18]

In contrast, the rural setting faced a unique barrier related to the implementers' professional role. In rural areas where village doctors delivered the parenting program for the first time, some doctors noted that because their routine work is not typically associated with parenting, parents were skeptical about their true intentions behind offering such services.

> *The parents doubt why I invite them to join the parenting program. They ask if I have received any benefits from the program organizers.* [VD, HBD25]

The summary of barriers and facilitators to reach can be seen in Multimedia Appendix 4.

Adoption—Facilitators and Barriers

Overview

At the setting level, since the program was conducted as a pilot, 1 urban preschool and 2 rural health centers agreed to participate upon invitation. At the staff level, in the preschool-based program, the primary implementers included headteachers and recruited social workers, all of whom joined the program in response to directives from their supervisors. In the health center-based program, the main implementers were 2 women's and children's health workers and 30 village doctors. Eventually, both maternal and child health workers participated, while 23 village doctors (76.7%) remained engaged, and 7 withdrew from the program. Overall, the adoption level of the program was relatively high.

Shared Facilitators for Adoption

At the setting level, relevant information was gathered through interviews with local leadership. The main shared factors that promoted adoption included trust in the program developer, alignment with organizational functions, and empowerment of the organization and staff.

A primary factor in facilitating successful cooperation and adoption in both settings was trust in the program developers. Leadership in the educational setting acknowledged that the developers' affiliation with a prestigious university in China enhanced their perception of the program's credibility and value. In the health care setting, management also demonstrated trust in the collaborating research team.

> *You are a research team from a top university in China, and the quality of what you developed is guaranteed. We also have confidence that parents will accept the program, and we believe it will have a positive impact.* [PM, SBD33]

Another shared facilitator was the importance of the alignment between the program and the implementing organization's core functions. In the educational setting, leaders reported that before adopting the program, they would assess whether their organization possessed the capacity and resources to support implementing the program and whether the initiative aligned with their institutional mandate. For instance, preschools regarded parenting services as a fundamental aspect of their work, viewing it as consistent with their educational responsibilities.

> *This is something I want to do. In 2010, our preschool established an 'Early Education Center,' and parenting is a part of our work.* [PM, SBD32]

Likewise, in the rural setting, health centers considered parenting support closely related to child health care and broader public health objectives.

> *This online-based parenting program focuses on promoting health education, especially concerning children's growth and development. This is also connected to our daily work in public health.* [GO, HBD32]

Local leadership in both settings also highlighted its potential to empower staff and foster organizational growth. In the educational setting, managers noted that the program could enhance headteachers' professional skills in parenting, positioning it as a valuable resource for supporting parents.

> *Our teachers gain many benefits during the implementation of the program, such as learning about family education and strengthening their connection with parents.* [PM, SBD30]

In the health care setting, leaderships emphasized that the program could strengthen the capabilities of village doctors as well as maternal and women's and children's health workers in delivering comprehensive children's healthcare services.

> *Our county pays great attention to the implementation of early childhood development work in rural areas. Involving village doctors and other staff in this parenting program allows them to gain experience in carrying out such work.* [GO, HBD27]

At the staff level, both task-driven (motivation that arises from external obligations to complete tasks assigned by others, such as supervisors or program coordinators) and intrinsic motivation (motivation from personal interest or intrinsic desire) were key shared factors promoting adoption. For example, in the health care settings, implementers reported that the program was perceived as a mandated task from higher-level leadership, who required them to carry out the program and follow the specified timeline and procedures.

> *Our leaders attach great importance to this program and repeatedly emphasize the need to cooperate with the program developers to complete it. We feel that this is a very important task for us.* [VD, HBD24]

Intrinsic motivation also played an important role. Some implementers in the health care setting expressed that they recognized the significance of this pilot and the potential benefits it could bring to caregivers. This sense of mission motivated them to actively adopt and support the program. In the educational setting, teachers also felt that the program could support the development of both parents and children, contributing to better educational outcomes.

> *Another reason I participate in this program is that I feel what we are doing is meaningful. In our rural area, such resources are very precious, and many parents also have a demand for parenting knowledge. By completing this program, we can provide help to children and their families.* [VD, HBD31]

Shared Barriers to Adoption

A major shared factor hindering adoption in both settings was the perceived difficulty of implementation due to limited time. Both implementers and local leadership expressed concerns that implementers were already occupied with their regular

responsibilities, which consumed most of their time. The entire program's especially tight schedule further compounded the issue, as they were expected to complete tasks within a short timeframe. This increased the pressure on implementers, making them feel even more stressed.

> *Our village doctors have a lot of work and are very busy. We have to both prescribe medical treatment and complete public health tasks such as chronic disease management and vaccination. The program requires us to complete the tasks within a short time, and it feels very stressful.* [VD, HBD25]

> *We also have a lot of teaching tasks at school to complete, and the time is not very sufficient.* [PT, SBD34]

Distinct Facilitators and Barriers to Adoption

At the staff and setting level, prior successful collaboration experiences served as a unique facilitator for the health centers' adoption of the program. However, health center-based implementers often lacked familiarity with parenting knowledge, and some faced difficulties in recruiting appropriate participants. The perceived difficulty in recruitment hindered program adoption among village doctors. Moreover, remuneration emerged as a significant motivating factor for implementers in the health care setting. In the educational setting, the teachers' professional roles in parenting acted as a key facilitator.

At the institution level, factors promoting adoption differed between the 2 contexts. In the health center-based setting, health care leaders and program officers highlighted that prior successful collaboration experience played a key role. The local government, supported by the donor, had previously implemented similar ECD parenting programs in other townships within the county, which helped establish mutual trust and efficient working mechanisms.

> *They agree because we have previously implemented an early childhood development program here. We are familiar with the local leaders and institutions, and have built a strong trust relationship.* [PD, HBD35]

At the staff level, the relevance of the task to the implementers' professional roles directly influenced their motivation to adopt the program. In the urban preschool setting, headteachers reported that parenting support was closely tied to their core duties, contributing to child development and the enhancement of educational quality. This strong connection fostered greater intrinsic motivation among them.

> *We also provide some parenting education in daily work. I review this program and feel it is quite good. If parents attend, it will benefit them.* [PT, SBD34]

In contrast, some village doctors and maternal and child health workers in the health care setting felt their routine work was less directly related to parenting. Consequently, they viewed the program more as a task assigned by higher-level leadership, with task-driven motivation playing a prominent role.

> *We have not done similar work before. I believe it is not our duty, as we are mainly responsible for public health. The main reason for implementing this program is that it is assigned by our leadership.* [VD, HBD24]

Some village doctors also reported difficulty in identifying parents who met the program's participation criteria and were able to join. This challenge led to frustration and, over time, caused some of them to gradually withdraw from participating in the program altogether.

> *The main challenge for me is that I really cannot find suitable parents, because many children in the village are migrant or left-behind children.* [VD, HBD30]

Additionally, village doctors noted that the remuneration provided by the program officers was an important incentive for them to complete their responsibilities.

> *We carry out the task as required and receive some compensation. If it is voluntary, I will not be willing to complete the task.* [VD, HBD24]

The summary of barriers and facilitators to adoption can be seen in Multimedia Appendix 5.

Implementation—Facilitators and Barriers

Overview

The investigation of implementation primarily focused on the program's fidelity, which is the extent to which the program is delivered as intended, and examined how this fidelity was achieved throughout the delivery process [40].

The program was delivered with high fidelity in both settings, as demonstrated by fidelity checklists. In the preschool setting, headteachers recruited parents and reminded them to complete the online modules, while 10 social workers facilitated group discussions and completed all assigned tasks. In the health care setting, village doctors conducted home visits, supported by maternal and child health workers. Follow-up phone calls with 74 parents confirmed the content of the visits. The village doctors achieved an average fidelity score of 7.81 out of 8, indicating strong adherence to the program protocol.

Shared Facilitators for Implementation

Several key shared factors were identified as promoting the fidelity of program implementation: adequate onboarding training, a supportive management system, timely external support, and clear work guidelines.

Adequate onboarding training was a shared facilitator in both settings. Implementers in the health care setting believed that the training helped them understand the parenting principles, tasks, potential challenges, and proposed solutions. They also noted that the time allocated for discussion created opportunities to express concerns, ask questions, and receive prompt responses. Similarly, in the educational setting, teachers and social workers affirmed that the training enabled them to understand their respective tasks and effectively contribute to the program's implementation.

> *The training before the program starts is essential. It helps us understand what we need to do, and the*

> *subsequent discussion sessions also address some issues.* [VD, HBD24]

A supportive management system involved a balanced combination of appropriate incentives and supervision to facilitate the successful implementation of the intervention. In both health care and educational settings, local leadership perceived that, to enhance fidelity, implementers required suitable incentives that align with their expectations, including both material and intrinsic (spiritual) rewards.

> *After all, the main work of village doctors is not parenting. They have limited time and energy, so they need to be compensated.* [GO, HBD27]

> *Our teachers need to have a sense of achievement when doing this program. Even giving them a certificate is an effective encouragement for them.* [PM, SBD32]

Meanwhile, while supervision was crucial in both contexts, its focus differed. Local program managers in the health care setting emphasized that supervision was essential to achieve a balance between quality control and task implementation efficiency. They believed that supervision should cause necessary work pressure while allowing sufficient flexibility in how tasks are carried out. In the educational setting, the focus of supervision was more on ensuring timely task completion, with managers highlighting the importance of regularly reminding teachers to meet deadlines.

> *Village doctors work hard. Sometimes, tasks cannot be completed due to external reasons. When supervising their work, we have to both consider the quality and avoid discouraging their motivation.* [WACNHW, HBD26]

Providing timely external support to implementers was perceived to be a critical shared factor for successful implementation, which involves access to expert advice, consultations, and problem-solving assistance from external consultants or organizations when issues arise during program implementation. Implementers in the health care setting reported that timely and adequate support—whether material, psychological, or resource-based—from organizations and program developers helped alleviate their stress, overcome challenges, and enabled them to successfully complete their tasks. Likewise, in the educational setting, implementers affirmed that support from program developers and managers was crucial for the smooth execution of their work.

> *I feel that the support is quite sufficient. You are always there whether we or the village doctors have any questions. I feel touched.* [WACNHW, HBD26]

Finally, having clear work guidelines was a key shared facilitating factor. Implementers in both educational and preschool settings noted that well-defined procedures contributed to smoother implementation by clearly outlining what needed to be done, when, and how. This clarity made it easier for them to carry out their tasks efficiently.

> *The clear work guidelines let me know what I need to do, making it easier to carry out my work.* [VD, HBD31]

> *This program provides clear instructions, and the guidance in all aspects is very detailed. So, we can implement it well according to the guidance.* [SW, SBD27]

Shared Barriers to Implementation

A lack of sense of purpose and psychological pressure was perceived as key shared challenges faced by some implementers in both settings. Psychological pressures refer to stressors such as heavy workloads, tight deadlines, and the emotional burden of ensuring the success of the program. These pressures can negatively impact the quality of program delivery and the well-being of implementers. While leadership demonstrated a clear understanding of the program's goals, some implementers lacked this clarity. During the implementation process, it was observed that certain implementers were unsure about the program's objectives and the value it could provide to caregivers. This uncertainty at times led to self-doubt, which had a negative impact on their motivation. Further communication with implementers confirmed this observation—several social workers from the educational setting and village doctors from the health care setting expressed confusion about the purpose of their roles and the potential benefits their efforts could bring to families.

> *When conducting home visits, we do not know our purpose. What exactly are we trying to do?* [VD, HBD24]

> *You do not know your role in this process, but you must do it. Moreover, at this point, you can feel quite confused.* [SW, SBD28]

Implementers in both settings shared the challenge of generating demand and encouraging active participation in the program, which caused psychological pressure among implementers.

> *Because not everyone is enthusiastic about participating, I think the appeal of the content to parents is crucial. Is the content we are providing useful to parents? Is it something they want?* [SW, SBD27]

Distinct Facilitators and Barriers to Implementation

A unique facilitator in the health care setting was the timing of implementation, which aligned well with the villagers' work schedules. However, in China, village doctors typically only conduct home visits for specific health care tasks. Also, in the health care setting, parenting home visits are irregular, and the long distances they needed to travel posed a challenge during program delivery. Furthermore, while clarity in work procedures was a shared facilitating factor across both settings, there was a notable difference in the need for implementation flexibility across the 2 settings.

First, in the rural setting, village doctors shared that the program was implemented during the off-season for farming, just before the Chinese New Year, a period when there was less agricultural work and many parents who normally worked away from home had returned. This created free time for caregivers to participate in the program.

> *Parents are generally at home in winter. As the weather is cold, there is no farming to do. Besides, they do not go out for labor during this season, so most of them stay home.* [VD, SBD24]

Second, village doctors also reported that the physical distance between households and their base locations created challenges in conducting home visits on time.

> *It is still too far, the road is inconvenient, and it is not easy to return.* [VD, D30]

Third, standardized workflow served as a double-edged sword, with its impact varying across settings. In the educational setting, especially among headteachers, implementers preferred greater flexibility. They expressed a desire to customize token economy systems to encourage daily participation in their own class and requested more adaptable web-based group interaction structures to better address the diverse needs of caregivers.

> *I feel that our online group discussions are a bit stiff. The content shared is fixed and does not capture parents' interest. If we integrate additional parenting support with our daily activities, it will be better.* [PT, SBD35]

In contrast, implementers in the rural health care setting, particularly village doctors who were typically older and had limited experience with parenting support, preferred a highly standardized process. They valued having clear guidance on what tasks to perform, when to perform them, and how to carry them out.

> *The workflow you provided is very clear. It outlines each step, and we just need to follow it to complete the task.* [WACNHW, HBD26]

The summary of barriers and facilitators to implementation can be seen in Multimedia Appendix 6.

Maintenance at the Setting Level—Facilitators and Barriers

Overview

This article primarily explores the factors that may facilitate or hinder the integration of the program into the established service system. In both settings, the leadership actively worked towards promoting the program's integration into the existing service infrastructure.

Shared Facilitators to Maintenance at a Setting Level

The shared factors were the integration of the program into an organization's daily operations, alignment between the program content and the organization's core functions, the availability of sufficient and appropriate internal human resources, and the low cost associated with digital delivery.

First, alignment with the organization's core mission was a key shared facilitator. Local leadership in the health care setting emphasized that the program's alignment with their existing responsibilities was essential for successful institutionalization beyond initial adoption. By supporting the organization's core mission, the program minimized additional costs and streamlined integration into routine work. Likewise, in the educational setting, managers emphasized that the parenting program was a natural fit for their institution's existing work and goals.

> *Normalizing it means integrating it with our public health services, which does not create any work pressure for us or add any burden. It should also benefit our daily work.* [GO, HBD27]

Second, leadership in both settings believed they had access to a well-suited workforce for program delivery. Village doctors in the rural setting and headteachers in the urban setting were described as stable, professionally trained in child development, and capable of ongoing learning. Their regular contact with families and their established trust and authority within the community made them particularly suitable for engaging caregivers and carrying out the program.

> *The village doctor team can handle this program. On one hand, they have good relationships with the villagers. On the other hand, they possess a lot of medical knowledge and have the ability to learn.* [GO, HBD32]

> *Our teachers are well-suited to take on this program. They already handle educational work and can easily use it as a tool in their daily teaching.* [PM, SBD33]

Third, local leadership in the educational setting emphasized that the low cost of digital delivery was a key factor facilitating program integration. By delivering core content via web through a WeChat-based chatbot, the program minimized the need for intensive offline operations. This digital approach not only helped maintain content quality but also significantly reduced the workload and operational costs for implementing organizations, making the program more sustainable and scalable within existing structures. Similarly, in the health care setting, managers highlighted that controllable costs were crucial for sustaining the program in rural areas.

> *I think the advantage of the online format is that, firstly, it can push information in real-time and is more flexible. At the same time, since we are in the information technology era, parents also use their phones often.* [PM, SBD27]

Shared Barriers to Maintenance at the Setting Level

Shared barriers to integrating the program into the organization's daily operations included institutional dependence on higher government authorization, challenges in sustaining staff motivation, and difficulties in generating parental demand for parenting support.

A primary barrier in both settings was the institution's reliance on higher-level government approval. In the rural context, health care leadership noted that integration into routine services would require authorization from senior government officials overseeing health affairs.

> *To integrate the program into our daily work, we need approval from the senior leaders in charge of this work at the higher level.* [GO, HBD33]

Similarly, in the urban context, preschool managers indicated that continued implementation in preschools would depend on approval and support from the education department.

> *To integrate the program into the preschool's daily work, we need support from the local education bureau leaders. It would be best to also gain official support from your university.* [PM, SBD32]

In addition, leaders in both settings expressed concerns about sustaining staff motivation over the long term. While staff had fulfilled their responsibilities during the pilot phase, there was uncertainty about how to provide sufficient and appropriate incentives to support ongoing, routine implementation once the program became part of daily work. This concern was echoed in the educational setting, where managers also stressed the need for incentives to maintain teachers' continued engagement.

> *If the work is unpaid and voluntary labor, as mentioned by the village doctor, it is a challenge for the village doctor.* [GO, HBD27]

Another significant barrier was the lack of perceived demand from parents. Government officers and organizational managers from both settings expressed concern that many parents did not recognize the value or necessity of parenting support. Without sufficient parental buy-in, they feared that efforts to integrate the program into routine services would result in low participation rates and limited impact.

> *After all, we are in the countryside. Some parents have a higher level of awareness and think that interacting with their children is meaningful. However, some parents feel it is unnecessary; if the children can play alone and do not cause trouble, they have done their job.* [WACNHW, HBD26]

> *Many parents, when it comes to parenting, understand but not to a great extent, which causes a disconnect. They feel they somewhat understand but not fully, and accepting some new concepts is difficult.* [PM, SBD30]

Distinct Facilitators and Barriers to Maintenance at the Setting Level

A unique facilitating factor in the health center-based delivery was the close relationship between village doctors and local families, which enhanced trust and communication. However, implementation in this setting also faced a unique challenge in securing resources for sustainable material incentives. Both the health care and educational settings shared the need for further localized contextual adaptation of the program. Nonetheless, the focus of these recommended adaptations differed between the 2 settings.

In the rural health care setting, leaderships perceived that parenting programs facilitated by village doctors were feasible for sustained implementation in rural health care settings. They believed that village doctors, who often had strong, long-standing relationships with families—sometimes dating back to prenatal care—were uniquely positioned to gain family acceptance of the program and successfully conduct home visits. In contrast, the preschool program relied on teachers leading group-based remote support and did not require the same depth of ongoing personal relationships with students' families as village doctors had.

> *In our rural areas, village doctors are like family doctors, closely connected to the families. People know each other well, and home visits are easy. In the city, living in apartment buildings makes it less convenient, and people are more guarded.* [GO, HBD32]

In addition, the approach to sustaining staff motivation differed between the 2 settings. In the educational setting, preschool managers noted that parenting work is closely aligned with headteachers' core educational duties. As a result, integrating the program into daily operations was more natural and did not significantly increase their workload. Therefore, spiritual incentives, such as recognition and a sense of professional fulfillment, were seen as important for promoting long-term motivation.

> *Parenting is already part of our teachers' work, so it does not add extra burden. However, some motivation is still needed, such as certificates or awards.* [PM, SBD33]

In contrast, in the health care setting, leadership emphasized that village doctors primarily focused on public health responsibilities. Parenting-related tasks were viewed as additional duties, which increased their overall workload. In this context, material incentives were considered more effective, as they better compensated for the extra effort required for sustained engagement. By comparison, for preschool teachers, parenting was closely integrated with their daily work. The program did not add to their workload but rather complemented it, serving as an educational tool to support their parenting-related tasks.

> *Our village doctors' main work is in public health. This task adds extra duties for them, so compensation is needed.* [GO, HBD28]

> *I don't think this is a burden for the teachers, as they are already engaged in education. Parenting is also familiar to them. They can adapt the program content into teaching tools based on their needs.* [PM, SBD30]

Furthermore, adaptations to each specific implementation context were perceived as important. In the preschool, leaderships suggested that for the program to be effectively integrated into daily work, the digital learning format, duration, and additional parenting support needed to be further adapted to better align with teachers' schedules and classroom activities. This type of adaptation primarily involved organizational alignment, ensuring the program fit seamlessly within existing school routines.

> *To become part of our daily work, the program needs to align with the kindergarten's teaching needs and integrate with our activities. Teachers have to be the leaders.* [PM, SBD30]

In the health care setting, health care managers believed that for long-term implementation, the program needed to be adjusted to include special groups, such as left-behind children and children cared for by grandparents, who make up the majority in the local area, and also need parenting support. However,

this time, the adaptation focused more on tailoring the program to parents who stayed at home to care for their children, as a result of careful consideration of available implementation resources and the exploratory nature of the pilot as an initial test of digital interventions in rural areas.

> *Like in our area, most young parents go out to work, leaving grandparents behind. Therefore, these families need more services.* [GO, HBD33]

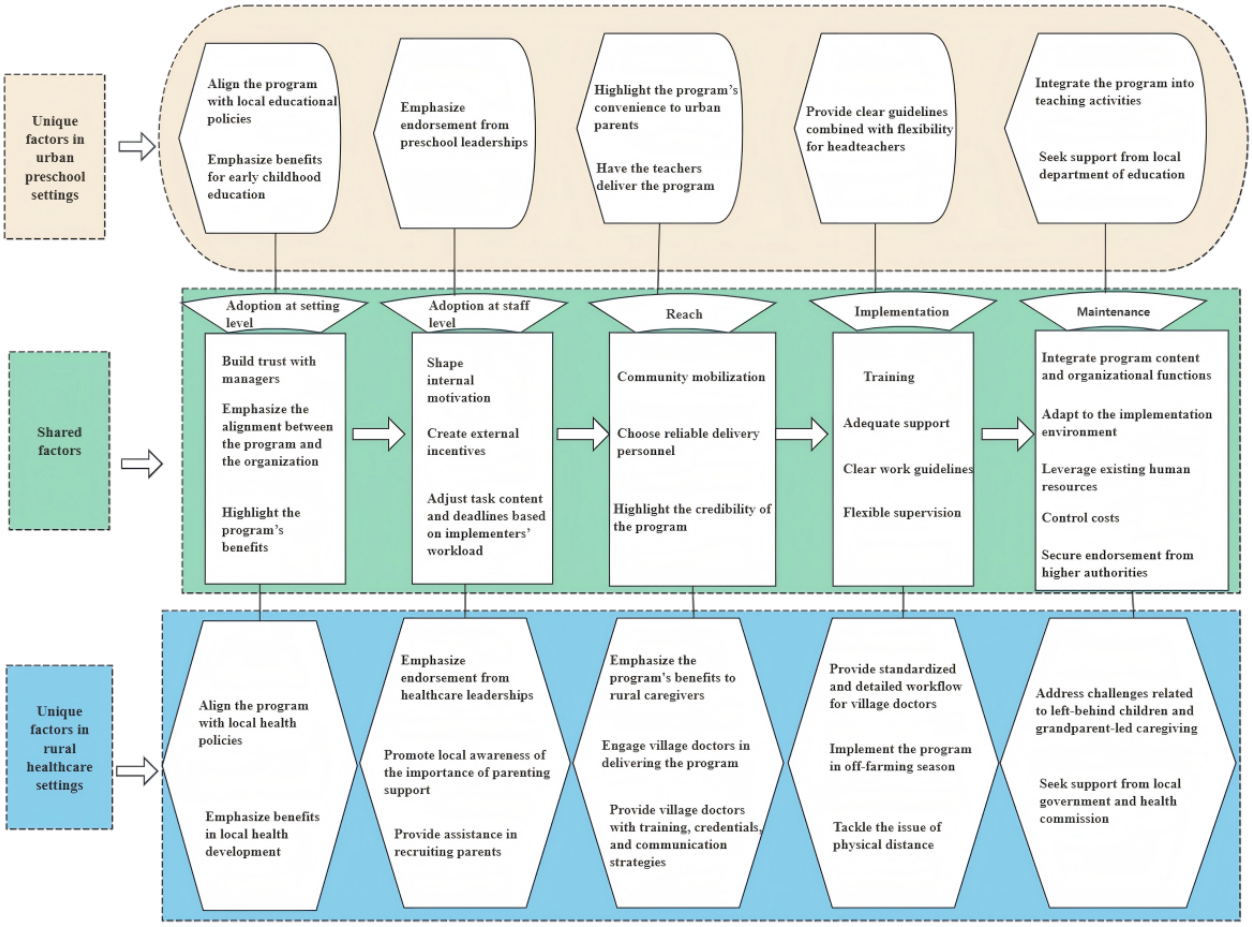
The summary of barriers and facilitators to maintenance at the setting level can be seen in Multimedia Appendix 7.

Differentiated Models of Digital Parenting Program Implementation in Two Sectors

Based on the results, we summarize two models for implementing and institutionalizing the digital parenting program in rural health care and urban educational settings (Figure 3). The basic sequence starts with promoting organizational adoption of the program, followed by encouraging staff adoption, then expanding reach. After that, the focus shifts to implementation and finally to maintenance. In impoverished rural areas, digital interventions need to be complemented by individualized human-led offline support to enhance the impact. Accordingly, we propose a model that involves collaboration with the health center and leverages village doctors to deliver the digital program alongside home visits. For urban areas, we suggest a model where digital components are combined with online parent groups led by teachers.

During the organizational adoption stage, building trust with managers, emphasizing the alignment between the program and the organization, and highlighting the program's benefits are crucial. Trust can be fostered by demonstrating the evidence base and credibility of the program, which helps managers recognize the program's potential. Emphasizing how the program aligns with the organization's goals encourages adoption of the program and fosters positive expectations regarding its completion.

Figure 3. Differentiated models of delivery in urban preschool and rural health care settings.



In rural health care settings, aligning the program with local health policies can strengthen its acceptance, particularly by emphasizing benefits such as improving early childhood development and addressing population health challenges. In contrast, urban educational settings can benefit from closer ties to educational policies, where the program's role in enhancing teaching quality, promoting parent-teacher collaboration, and reducing behavioral problems in preschool environments is more prominent. Thus, the focus in rural areas is more health-centered, while urban settings prioritize educational outcomes.

At the staff-level adoption stage, it is essential to shape internal motivation, create external incentives, and adjust task content and deadlines based on implementers' workload. First,

effectively communicating the program's significance helps foster internal motivation and enables implementers to recognize its benefits. Preschool teachers typically have stronger internal motivation because their daily work is directly related to parenting, allowing them to see immediate benefits. In contrast, village doctors in health centers, whose routine duties are less connected to parenting, require communication and training to understand how parenting relates to their role and to enhance their perception of the program's importance.

Second, when internal motivation alone is insufficient, forming external incentives becomes essential. Depending on the program's context, it is necessary to strike a balance between material and intrinsic incentives to fully motivate implementers. For example, in the rural pilot, providing village doctors with reasonable compensation effectively promoted their active participation in program implementation.

Regarding recruitment, urban preschools generally experience less difficulty, as parents tend to cooperate more readily with teachers. However, in rural areas, recruiting parents is more challenging due to complex family structures and village doctors' limited experience with parenting work. This necessitates additional support from implementers and institutional leaders.

In the reach stage, community mobilization, choosing reliable delivery personnel, and highlighting the credibility of the program content are essential. Through community mobilization, parents can understand the program's goals, content, and requirements, and most importantly, recognize the benefits of the program and that the learning process is convenient and low in time cost. In addition, it is worthwhile to highlight the program's convenience to urban parents and emphasize its benefits to rural parents. During the promotion, it is also essential to highlight the program's being systematic, distinguishing it from fragmented parenting information online. In urban preschools, teachers can serve as program implementers due to their close relationships with parents. In rural health care settings, village doctors can take on this role, as they are generally trusted by families. However, since parenting is not a routine part of village doctors' responsibilities, providing them with adequate training, relevant credentials, and communication strategies is necessary to reduce parental skepticism about the program.

In the implementation stage, training, adequate support, clear work guidelines, and flexible supervision are essential for ensuring fidelity. However, the specificity of work guidelines should be tailored to the implementers' roles. In rural health care settings, village doctors, who are generally unfamiliar with parenting work, require standardized and highly detailed workflows to guide their delivery. Conversely, urban preschool teachers, already experienced with parenting-related tasks, benefit from clear guidelines combined with flexibility to facilitate group discussions during parent meetings or school activities, supported by suggested discussion topics. Additionally, in rural areas, particular consideration must be given to the timing and logistics of home visits, as busy farming seasons often limit the availability of both village doctors and families for such visits.

In the maintenance stage, several factors are critical to ensuring the program's sustainability: integrating program content with organizational functions, adapting to the implementation environment, leveraging existing human resources, controlling costs, and securing endorsement from higher authorities. Controlling costs is paramount, as high expenses threaten the long-term sustainability of the program.

Various strategies can be used to reduce implementation costs. Similar to adoption, alignment between organizational functions and program content is important, but in the maintenance stage, this alignment emphasizes better integration of the program with the organization's daily work content and clarifying the position of the program task in the organization.

Using existing human resources by providing adequate onboarding and ongoing training can make the best use of the organization's current staff rather than hiring new personnel. Furthermore, it is necessary to obtain endorsement from higher authorities, with preschools needing support from the education department and health centers from public health authorities.

Adaptations must reflect the distinct realities of urban educational and rural health care settings. In urban preschools, the program needs to be integrated into teaching activities, becoming a practical tool within educators' daily routines. Conversely, rural areas must also address challenges related to left-behind children and grandparent-led caregiving to ensure these families are included in the services.

Discussion

Principal Findings

This study aimed to identify multilevel factors influencing the implementation of a digital parenting program across 2 distinct settings. The findings addressed this aim by revealing both shared and setting-specific facilitators and barriers across the RE-AIM dimensions, providing a comprehensive understanding of how digital parenting programs may be effectively implemented and sustained in different institutional contexts.

While well-known digital parenting programs such as Triple P Online and Incredible Years Online have shown positive outcomes in several countries [48-50], this evidence is predominantly from high-income countries, with limited exploration of their adaptability and sustainability across diverse implementation contexts. Our study directly addresses this gap by examining the implementation of a digital parenting program in 2 distinct settings in China—an urban educational setting and a rural health care setting—thereby contributing crucial evidence from a large low- and middle-income country.

Parents in both urban and rural areas expressed a desire for parenting knowledge, which was motivated by their wish to support their children in growing up healthy. Although the internet provided access to information, much of it was fragmented and lacked a systematic approach. As a result, parents often struggled to build a coherent knowledge system or apply these concepts in practice. This finding is consistent with previous research [51]. In contrast, the digital parenting

program offers culturally adapted, evidence-based content that is systematic, practical, and easy to access.

Trust is indispensable to a program's success, as previous study shows [52]. It must be built among organization managers, implementers, and the beneficiaries. First, building trust with managers and implementers to get their support is important [53]. It can be fostered by showcasing the program's evidence base, emphasizing its benefits, and selecting those with prior cooperation experience. Second, building trust with beneficiaries requires the credibility of the delivery channel and the implementer. A trusted implementer can boost parents' confidence in the program and provide extra motivations, such as social consideration (eg, face-saving or relationship building). In rural areas, village doctors, trusted as family doctors, are well-suited for this role [54], while in urban areas, preschool teachers hold similar credibility and respect.

Similar to previous research [55], we found that community mobilization for both parents and implementers before implementation is important for generating demand, thereby increasing the adoption and program reach. Parents should be introduced to the importance of evidence-based parenting, the benefits of the program, and how it works. At the same time, implementers need to understand the connection between the program and their routine work, its significance for them, and the necessity of the human-led components. Additionally, fostering a shared vision with all stakeholders is essential.

Providing support for implementers is also crucial, which aligns with previous research [56]. It is important to provide adequate training to equip them with implementation skills and clearly define their responsibilities. Establishing communication channels related to parenting support within the organization, such as regular meetings to discuss issues and digital systems to monitor progress. This will facilitate efficient vertical communication, supervision, and problem-solving mechanisms between implementers and organization managers.

Appropriate incentives for implementers are essential. Previous research emphasizes their importance, but it often lacks guidance on how to provide them [57]. We found that material and psychological incentives should be based on the workload and the fit between the implementer's tasks and capabilities. When human-led responsibilities exceed usual duties, greater incentives may be required to ensure motivation and sustained engagement.

Building on these findings, several practical and theoretical implications emerge for strengthening digital parenting interventions across diverse contexts. Program adaptation is necessary for maintenance, which aligns with previous research [53]. Adaptation occurs at 2 levels: content and context [58]. Content adaptation involves adding information relevant to the organization's functions and the local population's needs, such as child nutrition and disease prevention in rural health care, and early education in urban preschools. Context adaptation involves adjusting delivery methods to fit the organization's characteristics, ensuring that the program becomes integrated into regular work [56]. In rural areas, additional focus on left-behind children and grandparent caregivers is necessary because of their population structure [59]. While urban settings should incorporate the program into daily school activities, such as parent meetings and lectures.

Implications for Policy, Practice, and Research

To better support families in both urban and rural areas, governments should invest in providing trustworthy and accessible parenting resources. Trusted institutions, such as preschools and health centers, can serve as effective channels for delivering this information. With government support and institutional credibility, families may be more likely to engage in the programs.

When implementing digital parenting programs, it is essential to tailor strategies to local contexts, considering organizational mandates, local culture, demographic profiles, and economic conditions. Integrating the program into existing institutional workflows can reduce costs and promote sustainability. Establishing trust with organizational leaders, frontline implementers, and the beneficiaries is also key and should be supported by early and continuous community mobilization and engagement. Importantly, implementation must strike a balance between fidelity to core content and flexibility in delivery. Aligning program delivery with the institutional capabilities and work patterns, while providing clear and structured workflows, can help maintain quality and adapt to implementers' needs on the ground.

Future research should explore a broader range of settings and more diverse implementation strategies. Additionally, this study primarily used the RE-AIM framework to evaluate implementation at the mezzo- and macro-levels. However, parents, as direct beneficiaries, also play a crucial role. Their acceptance and participation significantly influence program success. Therefore, future research should adopt a micro-perspective focusing on parents' perceptions, attitudes, acceptance, and engagement. Such insights would inform future implementation of digital parenting programs.

Conclusions

This study's findings go beyond demonstrating the feasibility of digital parenting programs in low-resource settings to highlight a key lesson for their institutionalization: successful scaling is not about a single "one-size-fits-all" digital solution. Effective implementation requires hybrid models that strategically combine low-cost technology with trusted local human infrastructure, such as teachers in urban schools or village doctors in rural clinics.

Our comparison of urban and rural settings shows that the human-led component must be carefully tailored. Urban environments can benefit from flexible online group support, whereas rural contexts often require the structure and accountability of in-person visits. These insights provide a roadmap for policymakers and practitioners to move beyond standardized rollouts and develop a flexible "implementation playbook." By prioritizing adaptation to local social and organizational contexts, evidence-based digital parenting interventions can bridge the gap from efficacy to sustainable, equitable, and real-world impact.

Limitations and Strengths

First, this study did not report on the program's effectiveness. This may raise concerns about its impact. We plan to address this in a forthcoming publication specifically focusing on impact evaluation. Second, this study did not delve into micro-level aspects, especially parents' adoption of and attitudes toward the program. While this is an important area, it could not be adequately covered due to space limitations and will be examined in future research. Third, this study was limited to 2 pilot sites. Including more case studies in future research will help enrich the findings and enhance external validity.

The strength of this study lies in its focus on the implementation process of digital parenting programs, providing valuable insights for future program implementation. We also explored different implementation models across urban and rural education and health care sectors. This can support potential scale-up in diverse contexts. Additionally, we discussed the use of human-led models in different practical settings. This can provide guidance for choosing appropriate approaches in future hybrid (digital and human-led) parenting programs.

Acknowledgments

We extend our sincere gratitude to Xuechen Zhang, Ruinan Zhou, Taoran Li, Xinran Liu, Qingyang Zhang, Laurie Markle, Chiara Facciolà, Wenhao Ma, Zhen Liu, Yicong Guo, Edmud Moss, Ian Stride, Lily Clements, Dongping Qiao, and Xiying Wang for their valuable contributions to the program adaptation. We are especially grateful to Yicong Guo for her assistance with data collection. We wish to thank Xinnan Zhao, Bing Shen, and Jiawen Zhu for providing implementation assistance. We are deeply grateful to the county and township governments, local program staff, maternal and child health workers, village doctors, Jiangxi Xinyu Chengbei Preschool, headteachers, social workers, and participating families. Their engagement and support were vital to the success of this research. Language in this manuscript was improved using generative artificial intelligence tools. No content was generated by artificial intelligence.

Funding

China Postdoctoral Science Foundation (2022M720467), LEGO Foundation, CICC, and the CICC Charity Foundation. The funders were not involved in the design and conduct of the study, the collection, management, analysis, and interpretation of the data.

Data Availability

Deidentified participant data will be made available from the corresponding author upon reasonable request, following publication of the article.

Authors' Contributions

ZF and XS conceptualized the study. YQ and NZ supported the local implementation. RR and XS curated and analyzed the data. XS, ZF, RR, and NZ interpreted the results. XS drafted the manuscript with support from ZF. All authors, including XS, RR, YQ, JML, NZ, and ZF, reviewed and revised the manuscript.

Conflicts of Interest

YQ is an employee of the China Development Research Foundation. JML is the CEO of Parenting for Lifelong Health (PLH), a charitable organization based in the United Kingdom that developed the adapted program. PLH programs are open access and licensed under a Creative Commons 4.0 Attribution Share-Alike license. ZF has worked as a consultant for PLH in the past. JML has (and is participating) in a number of research studies involving the program, as an investigator, and the University of Oxford and University of Cape Town receive research funding for these.

Abstract

Background: Evaluating implementation of digital health interventions (DHIs) in practice settings is complex, involving diverse users and multistep processes. Proactive planning can ensure implementation determinants and outcomes are captured for hybrid studies, but operational guidance for designing or planning hybrid DHI studies is limited.

Objective: This study aimed to proactively define, prioritize, and operationalize measurement of implementation outcomes and determinants for a DHI hybrid effectiveness-implementation trial. We describe unique advantages and limitations of planning the trial implementation evaluation among a large-scale cohort study population and share results of a pretrial organizational readiness assessment.

Methods: We planned a cluster-randomized, type II hybrid effectiveness-implementation trial testing *PositiveLinks*, a smartphone app for HIV care, compared to usual care (n=6 sites per arm), among HIV outpatient sites in the DC Cohort Longitudinal HIV Study in Washington, DC. We (1) defined components of the DHI and associated implementation strategy; (2) selected implementation science frameworks to accomplish evaluation aims; (3) mapped framework dimensions, domains, and constructs to implementation strategy steps; (4) modified or created instruments to collect data for implementation outcome measures and determinants; and (5) developed a compatible implementation science data collection and management plan. Provider baseline surveys administered at intervention sites probed usage of digital tools and assessed provider readiness for implementation with the Organizational Readiness to Implement Change tool.

Results: We specified DHI and implementation strategy toward planning measurement of DHI and broader program reach and adoption. Mapping of implementation strategy steps to the Reach Effectiveness Adoption Implementation Maintenance framework prompted considerations for how to capture understudied aspects of each dimension: denominators and demographic representativeness within reach or adoption, and provider or organization-level adaptations, dose, and fidelity within the implementation dimension. Our process also prompted the creation of tools to obtain detailed determinants across domains and constructs of the Consolidated Framework for Implementation Research within a large sample at multiple time points. Some aspects of real-world *PositiveLinks* implementation were not reflected within the planned hybrid trial (eg, research assistants selected as de facto site implementation leads) or were modified to preserve internal validity of effectiveness measurement (eg, “Community of Practice”). Providers and research assistants (n=17) at intervention sites self-reported high baseline use of digital tools to communicate with patients. Readiness assessment revealed high median (48, IQR 45 - 54) total Organizational Readiness to Implement Change scores, with research assistants scoring higher than physicians (52.5, IQR 44-55 vs 48.0, IQR 46-49).

Conclusions: Key takeaways, challenges, and opportunities arose in planning the implementation evaluation within a hybrid DHI trial among a cohort population. Prospective trial planning must balance generalizability of implementation processes to

"real world" conditions with rigorous procedures to measure intervention effectiveness. Rapid, scalable tools require further study to enable evaluations within large multisite hybrid studies.

Introduction

Digital health interventions (DHIs) including web-based and mobile health (mHealth) interventions can improve clinical outcomes for chronic health conditions. DHIs apply behavior change theories with variable mechanisms of action, such as enhanced motivation, self-management, and peer support. Munoz et al [1] and Hermes et al [2] describe the spectrum of behavioral intervention technologies ranging from adjunctive tools embedded within clinic-based care to support provider tasks, to fully-automated direct-to-consumer technologies for patient self-management. Implementation outcomes or the 'who,' 'how,' 'how much,' and 'how well' needed to implement DHIs [3] can vary widely as a result. Clinic-embedded DHIs may require significant engagement by multiple providers and staff. Additionally, DHIs with multiple features can generate large amounts of backend paradata related to usage that are important for quantifying implementation reach and adoption. Capturing DHI implementation outcomes and determinants can thus be complicated. Curran et al [4] describe 3 designs of hybrid effectiveness-implementation studies. However, the literature provides little operational guidance or shared procedural knowledge on planning hybrid studies to capture implementation outcomes and identify salient implementation determinants for complex multifeature multiuser DHIs.

We reviewed several comprehensive efforts to recharacterize or adapt broader health service implementation science frameworks for the study of DHIs. Recent examples related to evaluation frameworks, which evaluate implementation outcomes, include (1) a workshop conducted by the Dissemination and Implementation Core of the Center for Technology and Behavioral Health at Dartmouth College [5], (2) Hermes et al's [2] recharacterization of Proctor's outcomes for implementation research for technology-based behavioral interventions, and (3) De la Vega et al's [6] post hoc app of this recategorized framework against Glasgow's Reach Effectiveness Adoption Implementation Maintenance (RE-AIM) framework [7,8]. Determinant frameworks answer the question: 'Why was the intervention/practice/innovation implemented or not implemented?' Several frameworks applied to DHI implementation research include the Consolidated Framework for Implementation Research (CFIR) [9-12], the Theoretical Domains Framework [13], Promoting Action on Research Implementation in Health Services [14], and others. Application of these frameworks for DHI trials is often done post hoc rather than proactively, and practical guidance on incorporating frameworks into DHI hybrid trial planning is limited, despite their importance in revealing why implementation of DHIs tested within real-world settings did or did not meet expectations.

The *PositiveLinks* platform is a clinic-embedded multifeature smartphone app with patient and provider-facing components. It was developed and refined following a rigorous, iterative process of user-centered design to support people with HIV receiving outpatient care [15]. Program implementation among a cohort in Central Virginia where the intervention was developed and refined has demonstrated long-term usage and significant improvement in clinical outcomes at 1 [16], 2 [17], and 3 years [18]. The platform has been adapted for other chronic conditions, end users, and contexts [19-24]. To date, *PositiveLinks* has been implemented as part of routine clinical care at 9 clinics in Virginia, and 8 sites in other states, and is considered an evidence-based intervention for HIV care by several national consensus guidelines [25-28]. Clinical effectiveness of PositiveLinks is currently being tested against usual care in a hybrid effectiveness-implementation trial, the *PositiveLinks* in DC Cohort Study, using a cluster randomized controlled trial design (ClinicalTrials.gov NCT04998019) [29]. The trial is being conducted among sites in the DC Cohort Longitudinal HIV Study (DC Cohort Study) following over 12,800 people with HIV at 14 outpatient HIV practice settings, including Federally Qualified Health Centers and academic medical centers [30]. The DC Cohort context for this trial, including cohort site characteristics, as well as study design, site selection, randomization, recruitment, data collection, and statistical analysis procedures, is outlined in the study protocol paper [29].

For complex DHIs like *PositiveLinks* engaging multiple end users collectively within an 'implementation climate,' it is important to establish readiness for the coordinated actions needed to implement the intervention across the organization. The theory-based measure, Organizational Readiness for Change (ORIC), was designed and validated by Weiner et al [31] to measure collective readiness for implementation of health care innovations. We opted to measure organizational readiness at each intervention site, including the survey items within provider baseline surveys, in order to understand (1) which relatively lower-scoring sites may require additional support or attention during implementation and (2) to understand at the back end postimplementation if baseline readiness was an influencing factor in provider adoption of *PositiveLinks*. To this end, we also assessed baseline provider usage of mHealth or digital health tools to understand how this experience might shape

provider adoption of a new tool within each 'implementation climate.'

We share our process to proactively define, prioritize, and operationalize evaluation of relevant implementation outcomes and determinants for this type II hybrid effectiveness-implementation trial [4] testing a complex DHI among six DC Cohort sites randomized to the intervention over a 12-month study period. We highlight the unique opportunities and challenges that emerged for planning of a hybrid DHI trial among a large-scale epidemiologic cohort study population. This manuscript shares a practical set of takeaways and considerations that stood out to us as novel or distinct from the available literature we reviewed as we prepared for our DHI trial, that is, what we 'wish we knew' before embarking on our extensive planning stage. Several lessons are considerations for teams that would ideally be incorporated as early as the study conception and design stage. Finally, we share the results of an assessment of provider baseline technology usage and pretrial readiness to implement the intervention across participating sites and discuss how results may inform posttrial analyses of implementation outcomes and determinants.

Methods

Study Team and Process Refinement

The hybrid trial planning phase spanned an 18-month period preceding onboarding of the first site in December 2022, conducted by an interdisciplinary research team. Research team members hold an established record of clinical research experience, including conducting formative evaluations and observational studies testing clinical efficacy of *PositiveLinks*. Investigators' primary expertise includes clinical psychology, program evaluation, qualitative methods, instructional design, software development, and implementation research. Program managers contributed empirical observation of *PositiveLinks* implementation processes over a decade that assisted with conceptualization of the intervention, implementation contexts, and components of the implementation strategy. The trial planning team also included DC Cohort Study investigators with expertise in epidemiologic and intervention studies at the cohort sites. The methodological approach to proactively integrate implementation evaluation activities within the hybrid trial required iterative steps conducted through multiple cycles of team feedback, consensus, and refinement (Checklist 1).

Specify Components of the DHI and Associated Implementation Strategy

Given the multifeature, multiuser nature of the intervention, we created a specified list of components of the DHI implementation process and discrete steps of the implementation strategy. This process was informed by team experience with implementation of *PositiveLinks* in other contexts as part of usual care, including a prior rigorous qualitative study summarizing key in-clinic processes necessary for *PositiveLinks* implementation [32], and a formative preimplementation study engaging stakeholders within the DC Cohort Study context to tailor the app and implementation strategy [33]. Implementation strategy steps were further specified in terms of actors, corresponding actions, and action targets mapped specifically to the DC Cohort Study context [34,35].

Select Appropriate Implementation Science Frameworks to Accomplish Evaluation Aims

We identified aims for the implementation evaluation arm of the hybrid trial: (1) define and measure implementation outcomes of interest and (2) elucidate determinants of implementation in a rapid, scaled fashion across participating sites. We first used narrative reviews of theories, models, frameworks, and strategy categorization to assess the most widely used determinant and evaluation frameworks [36,37]. We then reviewed technology-specific compendia and original research studies reconceptualizing broader health service frameworks toward DHIs, including hybrid study designs [2,5,6,8,10]. We subsequently selected the RE-AIM evaluation framework and CFIR determinant framework for our first and second implementation evaluation aims, respectively.

Map Framework Dimensions, Domains, and Constructs to Steps of the Implementation Strategy

We mapped each dimension of the evaluation framework, RE-AIM, to specified components of the intervention and implementation strategy steps, informed by prior efforts in the literature [2,6]. We prioritized measurement of specific steps based on impact of findings for informing future *PositiveLinks* implementations in this context and others, and the feasibility of measurement within the hybrid trial study. For implementation determinants, we selected salient domains/constructs identified from our prior detailed qualitative CFIR-guided assessment of several sites implementing *PositiveLinks* [32]. We also identified salient CFIR interview guide questions for conversion into survey items, which could be rapidly deployed among a larger sample of up to 50 or more cohort providers employed across trial intervention sites at multiple predefined time points (baseline, 6 months, and 12 months).

Modify or Create Instruments to Support Data Collection for Implementation Outcome Measures and Determinants

Existing data collection instruments developed for the DC Cohort Study or for prior *PositiveLinks* real-world implementation were modified with additional items or created *de novo* within Research Electronic Data Capture to completely assess each RE-AIM implementation outcome measure and salient implementation determinants. Provider survey items were generated using close-ended questions (eg, dichotomous or Likert scale responses), as well as optional free-text responses, and planned for distribution at 6- and 12-months into implementation. Semistructured interviews and focus groups were planned to elicit more detailed feedback post-implementation among a smaller subset of both provider and patient participants, respectively, with guides designed using CFIR.

Develop a Compatible Data Collection and Management Plan for Implementation Evaluation

Finally, we generated an overall plan for participant data collection and management that ensured compatibility between the clinical effectiveness arm of the trial and the implementation evaluation. Plans for implementation outcome or determinant data collection and abstraction were incorporated into patient approaches for follow-up, study monitoring, and data abstraction already planned for the trial's effectiveness arm. Provider-related activities specific to the implementation evaluation were incorporated into study onboarding processes.

Measurement of Baseline Provider Technology Usage and Implementation Readiness

Providers completed an electronic baseline assessment upon enrollment in the study with items related to familiarity, knowledge, and usage of available patient and provider-facing mHealth tools, apps, and portals in routine HIV care, probing specific experience with mHealth tools sharing functionality with components of the *PositiveLinks* intervention. The ORIC 12-item tool [31,38,39] assesses organizational members' shared resolve to implement a change (change commitment) and shared belief in their collective capability to do so (change efficacy). The ORIC was distributed as part of the provider baseline survey to provider participants at intervention sites.

Analysis

Descriptive statistics were used to analyze responses to provider survey items related to baseline technology usage and implementation readiness (close-ended response options or free-text responses). Each ORIC item is rated on a 5-point ordinal scale (1="disagree" to 5="agree"). Responses were analyzed for frequency, median value, or free-text content as appropriate. ORIC scores were characterized using medians and IQR for total scores (sum of all items) and individual subscores related to change commitment (n=5 items) and change efficacy (n=7) [38]. Statistical analysis was conducted using R version 4.1.2 (R Foundation for Statistical Computing).

Ethical Considerations

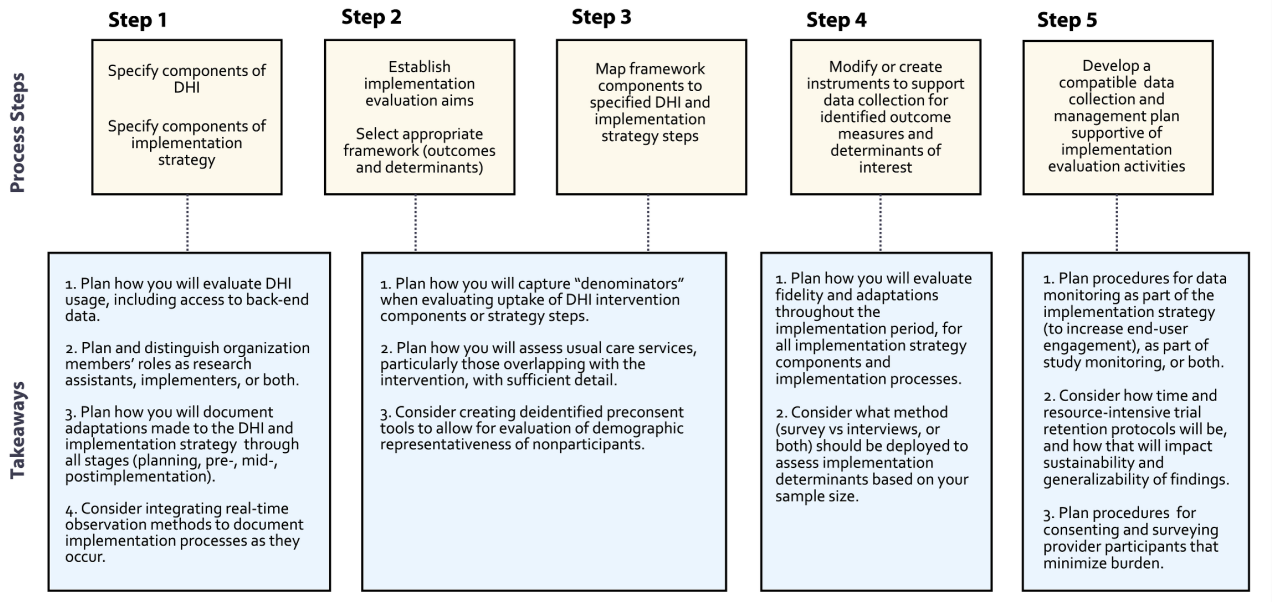
Ethical approval was obtained upon human subject research ethics review by the George Washington University Institutional Review Board (IRB) (Protocol NCR202829; ClinicalTrials.gov NCT04998019) and site-specific IRBs as required. Written study-specific informed consent for all procedures of this trial was collected in addition to the consent obtained for inclusion of clinical data among patient participants upon enrollment in the DC Cohort Study. Written informed consent was obtained for all trial provider participants using procedures outlined in the IRB-approved study protocol. Data collection, storage, and management followed all outlined procedures (eg, deidentification of baseline survey data and use of an assigned study ID with a separate link long). No monetary compensation was provided to participants for study activities described in this paper.

Results

Key Process Steps and Takeaways

Our hybrid DHI trial planning process is summarized in Figure 1, including key process steps and takeaways for research teams aiming to perform similar prospective hybrid trials in real-world settings, where complex DHI implementation and associated study procedures can be planned in advance. We highlight takeaways that emerged from our experience and lacked more applied experience or specific guidance within the literature.

Figure 1. This figure summarizes the 5-step process to plan an implementation evaluation within a hybrid trial for prospective testing of a digital health intervention (DHI). Process steps are outlined, along with respective generalizable takeaways for research teams planning comprehensive implementation evaluations for trials testing DHIs.

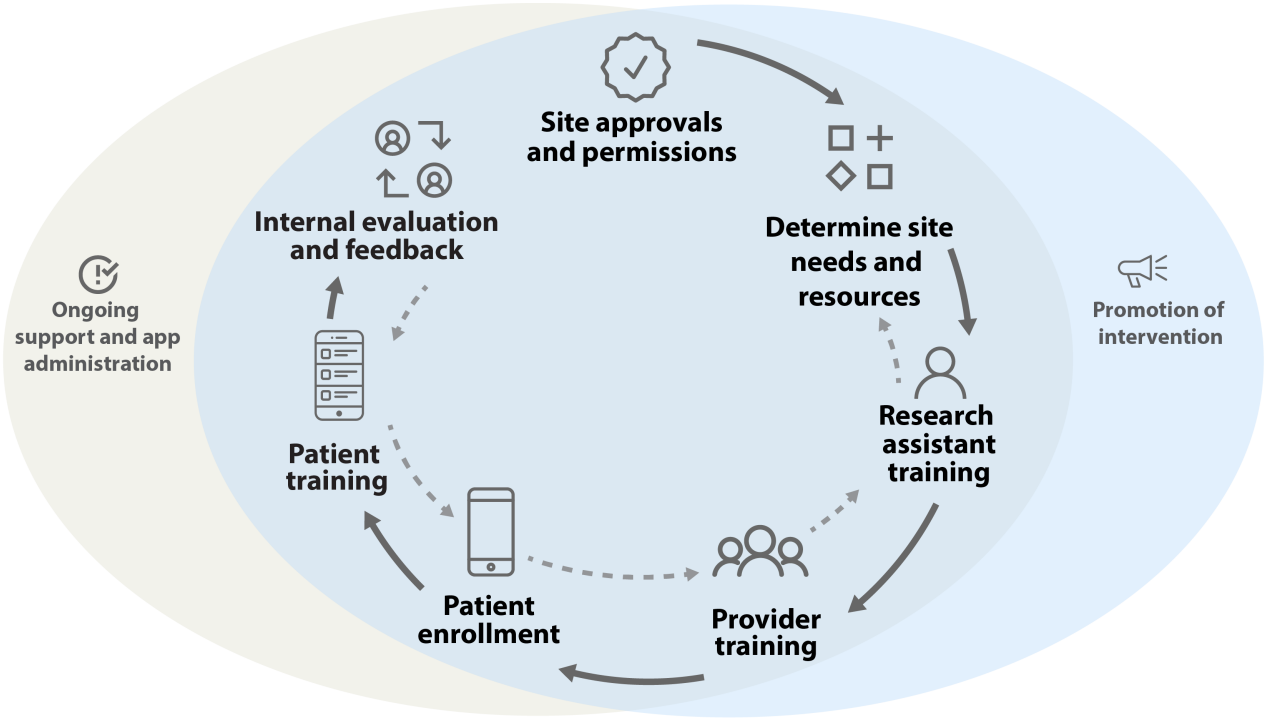


Define Components of Intervention and Implementation Strategy

Step 1 of the planning phase included specification of *PositiveLinks* intervention components (both patient and provider-facing elements) as well as the respective paradata generated by usage of each feature. The *PositiveLinks* platform contains a large amount of backend data (often described as metadata or paradata) that can be analyzed individually for every participant by feature and is accessible to the study team for analysis. Specific paradata were defined by end user group and data format (individual activity reports over selected time intervals with frequency of use, or free-text post content) in order to plan metrics of uptake for related implementation outcomes defined in steps 2 and 3. Takeaway 1: Research teams should consider during the planning stage what backend data is directly accessible for tools they are studying early in the planning process. Other pragmatic DHI trials may test commercially available tools developed by external companies or vendors, necessitating data-sharing agreements with vendors or suppliers of these tools, proactive design of trial assessments that allow participants to self-report usage at regular (eg, weekly) intervals, or integration of other commercially available tools to track DHI usage into study budgeting, design, consenting, and data collection processes.

Steps of the planned implementation strategy specified for the DC Cohort context are shown in Figure 2. “Actors” include the *PositiveLinks* core team’s program managers who assist remotely with implementation activities and troubleshooting at partner sites. The study team includes researchers involved with coordinating the specific intervention study being conducted to test *PositiveLinks* in the DC Cohort. Study team members were planned to have a larger role in site onboarding processes (determine site needs and resources, conduct research assistant and provider training) within the hybrid trial when compared to real-world implementation. Research assistants employed at DC Cohort Study sites are familiar with recruiting and consenting patients, uploading relevant patient data, and conducting assessments throughout the study period. Site research assistants were thus selected as actors to conduct several steps of the implementation strategy in this context, whereas in real-world implementation, the program is administered by individuals with a range of roles, typically identified by leadership or self-identified as the site lead for implementation. This was a decision made across sites given the extensive role and protected time research assistants have to assist with studies. Takeaway 2: Research teams designing or planning hybrid trials must consider “actors” both in terms of their research roles and implementation roles. If implementation activities in a trial are primarily assigned to a research team member, organization members already responsible for existing usual care activities overlapping with the intervention (eg, for *PositiveLinks*, retention-in-care activities) should also be engaged as early as possible. Shifting more implementation responsibilities to a research team member reduces the pragmatic nature of the trial and challenges intervention sustainability, as teams must decide who will execute those responsibilities when the trial is over.

Figure 2. Discrete implementation strategy steps expected for program deployment at DC Cohort sites are demonstrated in the figure and described, specified by step, actions, and actor in the table below it. The arrows show the sequential nature of the activities, but also note the gray dotted arrows indicate the iterative nature of using evaluation and feedback to inform various process steps as implementation proceeds. HIPAA: Health Insurance Portability and Accountability Act; PL: PositiveLinks



Step in implementation strategy	Actions	Actors	Action target
Site approvals and permissions	• Promote intervention to clinic and higher level leadership (study team) • Secure organizational approval of site use of intervention (study team, site principal investigator) • Identify and obtain required permissions related to patient IT security or privacy or HIPAA (study team, site principal investigator)	• Study team • Site principal investigator	• Organizational leadership
Determine site needs and resources	• Clarify roles of providers in implementation, establish staffing needs • Establish how providers will communicate with each other about program • Identify clinic values or clinical goals and how they may or may not align with PL • Determine how clinic providers would like to use portal (content shown, functionality) • Identify patient subgroups likely to benefit, needs that can be addressed with PL and issues that may arise for them related to using PL	• Study team • Site research assistant • Site Providers	• Site providers
Promotion of intervention	• Disseminate information about PL or site-specific benefits of PL to rest of site and larger organization	• Study team • Site principal investigator • Site research assistant	• Site providers • Patients • Organizational leadership
Research assistant training	• Inform site research assistant of app features so they understand how to use the app themselves and can explain benefits to providers and clinic processes, and benefits to their patients	• PL core team • Study team	• Site research assistant
Provider training	• Inform providers of app features so they understand how to use the app themselves • 'Sell' providers on the app's potential benefits to their patients, efficacy • 'Sell' app functionalities (mechanics of program) to site providers and how it will benefit them or their ability to provide care • Ensure newer providers are aware of procedures if there is turnover or new hiring	• Site research assistant	• Site providers
Patient enrollment	• Offer enrollment in the app as part of the research study and obtain informed consent • Provide preview of benefits or ease of use to patient • Sign patient up on the spot (requires WiFi access, time during appointment) • Provide smartphone or dataplan if needed	• Site research assistant	• Patients
Patient training	• Inform patient of how to navigate app interface or features and explain each in real time • Demonstrate app security or anonymity to patient • Demonstrate the customizable way patient can use the app	• Site research assistant	• Patients
Ongoing Support and app administration	• Communicate with PL core team about logistical or technical issues (site research assistant) • Troubleshoot patients' technical issues in real time or in-house when core team not available (site research assistant) • Assist research assistant with software or advanced technical issues nonurgently (PL core team)	• Site research assistant • PL core team	• PL core team • Site research assistant
Internal evaluation and feedback	• Perform surveillance or tracking of program progress, present to rest of site providers (study team and site research assistant) • Develop and carry out action plans based on interim site-specific progress or feedback (study team, site research assistant and site providers) • Ongoing champion activity to support maintenance of intervention (site providers and site research assistant)	• Study team • Site research assistant • Site providers	• Site providers • Patients

Distinctions between real-world implementation processes and those expected for the trial emerged at this planning stage. The learning management system (LMS) is a series of interactive online training modules developed for providers and staff, aimed

primarily at increasing knowledge and familiarity with the use of platform features (followed by a posttraining feedback survey). Prior to site onboarding for the study, several cohort site principal investigators expressed they would expect significantly lower enrollment of providers if LMS completion was mandatory, primarily due to significant provider clinical burden or competing demands. As a result, participating providers could opt out of LMS completion but were expected to undergo group onboarding or one-on-one training with the site research assistant prior to study participation. Takeaway 3: Research teams should consider incorporating a process to regularly document throughout the pre-, mid-, and postimplementation period, how their specific instance of DHI implementation for the trial diverges from other implementations, adaptations, or real-world practice, representing fidelity of implementation through every stage (not just during the intervention implementation period).

Real-world *PositiveLinks* implementation offers collaboration between sites in a "Community of Practice," to share implementation challenges, solutions, and unique adaptations to improve patient experiences and engagement. In contrast, we sought to maintain internal validity and avoid cross-site contamination for the trial, so intervention sites were not included in the "Community of Practice." Additionally, steps like administration of as-needed technical app support/troubleshooting and promotion of the intervention are usually more informally evaluated through site discussions and internal meetings during real-world implementation. During planning, we determined they would be challenging to evaluate with structured tools and opted to evaluate them through qualitative interviews at completion of the study. Takeaway 4: Clinic-embedded DHIs implemented in real-world practice can involve complex interactions between actors both across sites and within sites, and over time. Reserving evaluation of these processes to the late stages of implementation can result in missed opportunities to capture important real-world factors influencing implementation. Within the constraints of budget and time, research teams should consider inclusion of study methods to obtain real-time observations of these implementation processes as they occur. These could include direct observations (with field logs or notes) by implementers (providers, RAs), and small "check-ins" or "debriefs" conducted by a study team member throughout the study period.

Select Appropriate Frameworks and Map Components to Implementation Strategy Steps

Output for steps 2 and 3 are summarized in Table 1. Specifically, RE-AIM evaluation framework dimensions were mapped to each prioritized step within the implementation strategy. During this step, we identified discrete datapoints that required collection to assess each RE-AIM dimension. Other DHI hybrid trials with detailed reporting of framework app describe similar approaches, aligning DHI usage and other aspects of program uptake by patients and providers with reach and adoption dimensions, respectively [6,32]. Several unique takeaways emerged in our effort.

Table . RE-AIM[a] framework mapped to intervention/implementation strategy, corresponding outcome measures, data collection methods[b].

RE-AIM dimension	Outcome measures	Data source or data collection instrument
Reach: *How do I reach the targeted population with the intervention?*	Number of patients offered enrollment/number seen at site	DC Cohort Database, DC Cohort Study Patient Consent Logs
	Number of patients completing enrollment/number offered	PL[c] Platform Paradata, DC Cohort Study Patient Consent Logs
	Number of patients accessing PL app/number enrolled	PL Platform Paradata
	Sociodemographics of patients enrolled (representativeness)	DC Cohort Database
	Sociodemographics of patients declining enrollment (representativeness)	DC Cohort Study Patient Consent Logs
Effectiveness: *How do I know my intervention is effective?*	HIV viral load suppression (<200 copies/mL)	DC Cohort Database

[a]RE-AIM: Reach Effectiveness Adoption Implementation Maintenance.

[b]Data collection methods include abstraction from one or more items from existing data sources, modification or addition of items to existing data collection instruments, or creation of new instruments. Visit constancy is the proportion of 4-month intervals a visit is completed in 12 months. Retention in care per HRSA-1 definition: 2 appointments attended at least 90 days apart within 12 months.

[c]PL: PositiveLinks.

[d]LMS: learning management system.

As we reviewed the reach and adoption dimensions, we conceptualized how we could measure not only absolute numbers as measures of uptake (eg, number of patients/providers who download and use the app), but also estimate proportions: how many people could have taken up the DHI when it was offered at each site? The DC Cohort Site Assessment Survey is periodically deployed to cohort sites for updated assessment of available service delivery. We added several items to this Site Assessment Survey to capture the denominator of people employed for each type of provider role (eg, attending physician, clinic nurse, case manager, social worker, etc) as well as site-level baseline mHealth or technology use (Multimedia Appendix 1) to more adequately assess the adoption dimension for *PositiveLinks* implementation. Takeaway 1: Research teams should consider in advance how they will capture 'denominators' for both patients (reach) and providers/staff

serving as implementers (adoption), including a need for pretrial site-level data collection that can provide denominators, and with what frequency they need to be deployed surrounding implementation.

Several existing Site Assessment items were identified for abstraction for evaluation of the adoption dimension of RE-AIM (eg, on-site clinical services and support services, updated staffing of clinical and nonclinical providers, specialty training). Takeaway 2: Research teams testing DHIs across multiple care settings must consider how they will sufficiently characterize existing "usual care" services available, which can vary widely across care settings and change over time. This step is particularly important for DHIs that do not study direct-to-consumer tools, but instead require DHIs to become integrated into, or penetrate, an implementation climate and existing practices. Understanding to what extent the tool is serving as an adjunct or supplementary tool layered on top of an already robust organizational usual practice, versus creating a service where none existed, is crucial for interpreting and contextualizing effectiveness findings from a hybrid trial, in addition to other implementation outcomes.

A distinct opportunity also arose from conducting the hybrid trial among the DC Cohort Study. DC Cohort patients who choose not to participate in the *PositiveLinks* program at intervention sites have already consented to inclusion of their data in the cohort database, so these nonparticipants could be examined to understand sociodemographic representativeness, a component of patient "reach" within RE-AIM that appears infrequently in published applications of this framework. Patient consent logs standardized for the DC Cohort Study include patients' reasons for declining participation, with up to 3 approaches. These logs were modified to query a selected number of demographics for cohort participants declining to participate in the study (age, sex, race, ethnicity, insurance status, last CD4 count, and last HIV viral load). Takeaway 3: Teams designing DHI trials outside of existing cohorts with available data should consider use of preconsent tools that collect deidentified demographics of interest among clinic patients who decline the intervention, in order to evaluate this understudied component of patient reach.

Modify or Create Instruments to Support Data Collection for Implementation Outcome Measures and Determinants

Our process yielded several strategies to support data collection of all identified implementation outcomes: (1) *creation* of new instruments for prospective data collection specific to the implementation evaluation, (2) *modification* of standardized tools used for DC Cohort intervention studies or *PositiveLinks* evaluations or (3) *abstraction* from existing *PositiveLinks* or DC Cohort sources (eg, DC Cohort Database storing patient encounter, laboratory, and sociodemographic data). Modification and abstraction planned based on steps 2 and 3 from existing data sources are described previously.

Instruments created specifically for the implementation arm of the hybrid trial included surveys directed at providers not usually targeted by data collection for intervention studies at cohort sites. The provider baseline survey (Multimedia Appendix 2) and follow-up survey (Multimedia Appendix 3), annotated with respective framework components, were designed to capture otherwise unincorporated data points for measurement for the implementation dimension of RE-AIM (eg, fidelity, dose, and any adaptations made to steps of the implementation strategy by site providers or research assistants). Many DHIs require a complex set of steps to ensure both patient and provider engagement. For *PositiveLinks*, this included providers themselves understanding the app features, how they work and their impact, then remembering and being motivated to bring up the app and promote it during a routine clinical encounter, be able to describe its features and benefits, and refer the patient to a staff member (eg, research assistant). The research assistant must then effectively assist the patient to download the app, register for the account, and train them on its usage (Figure 2). The provider follow-up surveys were thus designed to capture the extent to which providers performed each of these tasks over multiple time points (Multimedia Appendix 3), in addition to questions probing self-rated fidelity and adaptations made to the use of the tool and its features over multiple time points. Takeaway 1: Comprehensive evaluations of DHIs should consider fidelity and adaptations of aspects of implementation beyond direct end user engagement with the digital tool, and data collection instruments may consequently need to be created to assess implementation outcomes related to these specific steps over multiple time points.

Salient implementation determinants adapted for inclusion from our prior CFIR-guided rapid evaluation study of *PositiveLinks* real-world implementation were: inner setting (compatibility), outer setting (patient needs and resources, external policy, and incentives), characteristics of individuals (knowledge and beliefs), innovation characteristics (adaptability and complexity), and implementation process (planning and engagement of key stakeholders). Postimplementation patient focus group and provider in-depth interview guides were also adapted from prior *PositiveLinks* implementations using salient CFIR 1.0 domains or constructs. Takeaway 2: Surveys designed using CFIR or other determinant frameworks offer an opportunity to more rapidly probe a wide array of domains and constructs among a larger sample, but should be planned in conjunction with richer data collection methods (qualitative). The surveys we designed were limited to previously identified salient constructs during our rapid evaluation study in other contexts (cite), and if used alone would miss important contextual factors for this trial.

Develop a Compatible Data Collection and Management Plan for Implementation Evaluation

Finally, we developed a plan to specify timing and frequency of data abstraction (eg, from the DC Cohort Database) and collection in relation to planned activities for the effectiveness arm of the trial (eg, patient consent or enrollment, administration of baseline, 6 mo, and 12 mo assessments). For patient data, plans were designed to minimize separate approaches as well as 'data pulls' from existing sources anticipated to support evaluation of clinical effectiveness outcomes. Further, monitoring of feature usage from platform paradata for patients and providers is a routine part of real-world *PositiveLinks* implementation, to guide efforts to engage and re-engage staff

and enrolled patients, troubleshoot concerns in real-time, and ensure sustainability. Frequency of paradata abstraction for monitoring was thus predetermined for specific features at timepoints throughout implementation. Takeaway 1: Research teams should consider data monitoring both as a study activity and as a part of the implementation strategy. If regular data monitoring is expected to increase engagement or generate actionable data for implementers, this activity itself becomes a component of the implementation strategy and should both be integrated into program planning and measured for fidelity to plans along with other strategy components. Takeaway 2: Similarly, trial retention protocols whereby participants showing low engagement are contacted by study team members through a series of time and resource-intensive activities ultimately impact intervention uptake (reach and adoption). The design of these protocols should be considered in the interpretation of generalizability/sustainability of observed implementation outcomes.

We required informed consent for all provider activities in the evaluation, including collection of provider survey responses and participation in postimplementation in-depth interviews. Selection of the timing and frequency of provider survey administration required consideration of provider turnover, particularly in participating intervention sites with higher expected turnover (eg, trainees like infectious disease fellows rotating within academic centers). Takeaway 3: Implementation evaluations engage providers as participants, which is distinct from most intervention efficacy trials, and onboarding processes should consider integrating consent procedures and baseline survey administration to reduce the burden and frequency of study procedures on participating providers.

Baseline mHealth/technology Use and PositiveLinks Implementation Readiness

A total of 17 providers and RAs have completed provider baseline surveys to date. Self-reported mHealth/technology use for various aspects of patient care at baseline is summarized in Table 2. Among the 17 respondents, 9 reported access to a patient messaging feature via their electronic medical record system (EMR). Usage of additional non-EMR messaging tools was reported by 6 providers. Overall satisfaction with non-EMR methods of messaging was high for those reporting usage (n=6), and reported frequency of use was higher for non-EMR tools compared to EMR-based messaging. Fewer respondents completed optional survey items related to non-EMR tools for sharing lab results or exchanging documents with patients, with variable frequency and satisfaction with described tools.

We incorporated the ORIC tool into the provider baseline survey to assess collective baseline readiness at each site [31]. The median total ORIC score for all providers was 48 (IQR 45 - 54, possible score range 12 - 60), with RAs scoring slightly higher than physicians (52.5 (44-55) vs 48.0 (46-49)). Median total scores for change commitment and change efficacy were 20 (IQR: 19 - 22, possible score range 5 - 25) and 28 (27 - 30, possible score range 7 - 35). Total change efficacy scores were slightly higher for RAs compared to providers (30.5 vs 28.0).

Table . Provider and research assistant baseline usage of mobile health (mHealth) tools by functionality.

Baseline survey questions	Response rate, n (%)
Messaging	
Does your EMR[a] system have a patient portal that allows you to directly message with your patients? (n=17)	
Yes	9 (53)
No	6 (35)
Not sure	2 (12)
If yes, how frequently do you use it to message with your patients? (n=9)	
Never	2 (22)
Rarely	2 (22)

Satisfied	1 (50)
Very satisfied	0 (0)

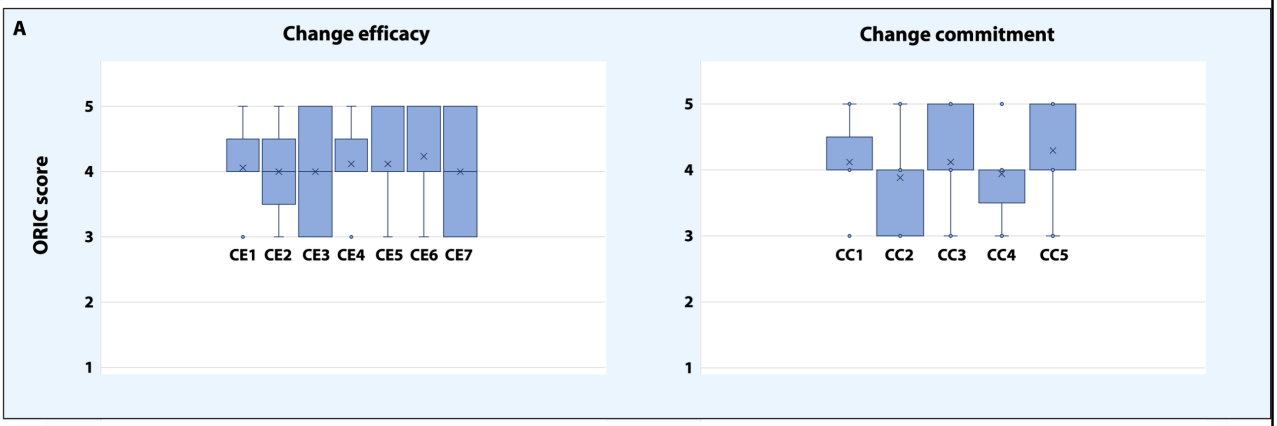
[a]EMR: electronic medical record.

Individual items corresponding to change efficacy (CE1-CE7) were scored on average between 4 and 4.2, with median scores of 4 (IQR 3-4) for all items (“Somewhat agree”), and no items scoring lower than 3 (“Neither agree nor disagree”; Figure 3). All change efficacy scores ranged from 3 to 5 except for CE7 (‘People who work here feel confident that they can manage the politics of implementing this change’), which along with CE3 (”People who work here feel confident that the organization can support people as they adjust to this change”) had a distribution with greater spread due to relatively higher frequency of neutral or “3” scores.

ORIC items corresponding to change commitment (CC1-CC5) similarly scored with a median of 4 (IQR 3-5) for all items (Figure 4), means ranging from 3.88 to 4.2, and scores also ranged from 3 to 5 for all items. Change commitment score distributions were slightly more negatively skewed for items CC2 (“People who work here will do whatever it takes to implement this change”) and CC4 (“People who work here are determined to implement this change”). When analyzed by provider type, mean scores were higher across all individual ORIC items for RAs compared to physicians. Median scores within subgroups were 4 (with IQR values ranging from 3.5 to 5, Figure 4) for a majority of items except for two change commitment items with higher median scores for RAs: CC3 (“People who work here want to implement this change”) and CC5 (“People who work here are motivated to implement this change”).

Figure 3. Baseline ORIC scores summarized for all respondents (n=17) at 6 sites randomized to implement the intervention (A) as well as by respondent type such as research assistants and attending physicians (B). One social worker completed the survey but ultimately withdrew from the program. ORIC: Organizational Readiness to Implement Change.

A



B

ORIC Item		All (n=17)	Research assistants (n=9)	Attending physicians (n=7)
Change efficacy				
CE1: People who work here feel confident that the organization can get people invested in implementing this change.	Median (IQR)	4.0 (4,4)	4.0 (4,5)	4.0 (3.5,4)
	Mean (SD, Range)	4.1 (0.7, 3-5)	4.3 (0.5, 4-5)	3.9 (0.7, 3-5)
CE2: People who work here feel confident that they can keep track of progress in implementing this change.		4.0 (4,4)	4.0 (4,5)	4.0 (4,4)
		4.0 (0.7, 3-5)	4.2 (0.8, 3-5)	3.9 (0.4, 3-4)
CE3: People who work here feel confident that the organization can support people as they adjust to this change.		4.0 (3,5)	4.0 (4,5)	4.0 (3,4)
		4.0 (0.8, 3-5)	4.2 (0.8, 3-5)	3.6 (0.5, 3-4)
CE4: People who work here feel confident that they can keep the momentum going in implementing this change.		4.0 (4,4)	4.0 (4,5)	4.0 (3,4)
		4.1 (0.6, 3-5)	4.3 (0.7, 3-5)	4.0 (0.0, 4-4)
CE5: People who work here feel confident that they can handle the challenges that might arise in implementing this change.		4.0 (4,5)	4.0 (4,5)	4.0 (4,4)
		4.1 (0.7, 3-5)	4.1 (0.8, 3-5)	4.0 (0.6, 3-5)
CE6: People who work here feel confident that they can coordinate tasks so that implementation goes smoothly.		4.0 (4,5)	4.0 (4,5)	4.0 (4,4)
		4.2 (0.7, 3-5)	4.2 (0.8, 3-5)	4.1 (0.4, 4-5)
CE7: People who work here feel confident that they can manage the politics of implementing this change.		4.0 (3,4)	4.0 (4,5)	4.0 (3.5,4)
		4.0 (0.8, 3-4)	4.2 (0.8, 3-5)	3.9 (0.7, 3-5)
Change commitment				
CC1: People who work here are committed to implementing this change.	Median (IQR)	4.0 (4,4)	4.0 (4,5)	4.0 (4,4)
	Mean (SD, Range)	4.1 (0.6, 3-5)	4.4 (0.5, 4-5)	3.9 (0.4, 3-4)
CC2: People who work here will do whatever it takes to implement this change.		4.0 (3,4)	4.0 (4,5)	4.0 (3.5,4)
		3.9 (0.7, 3-5)	4.1(0.8, 3-5)	3.7 (0.5, 3-4)
CC3: People who work here want to implement this change.		4.0 (4,5)	5.0 (4,5)	4.0 (4,4)
		4.1 (0.7, 3-5)	4.3 (0.9, 3-5)	4.0 (0.0, 4-4)
CC4: People who work here are determined to implement this change.		4.0 (4,4)	4.0 (4,5)	4.0 (4,4)
		3.9 (0.7, 3-5)	4.1 (0.8, 3-5)	3.9 (0.4, 3-4)
CC5: People who work here are motivated to implement this change.		4.0 (4,5)	5.0 (4,5)	4.0 (4,4.5)
		4.3 (0.7, 3-5)	4.4 (0.7, 3-5)	4.3 (0.5, 4-5)

Discussion

Principal Results

We describe a study team's experience planning and proactively integrating implementation science methodology into a hybrid DHI study conducted within an existing cohort study. This experience included a process to proactively define, prioritize, and operationalize measurement of implementation outcomes salient to a prospective DHI hybrid trial, as well as development of data collection instruments compatible with rapid assessment of implementation determinants and outcomes at scale for a large cohort and over multiple time points throughout the trial. Our experience highlights the limitations of prospective "pragmatic" trial designs to reflect real-world DHI implementation, and the unique opportunities and challenges of DHI trial planning within a large-scale cohort study population. We assessed baseline provider mHealth or technology usage and organizational readiness at baseline, which will be applied as a site-level characteristic or covariate during exploratory analysis of differential site and provider-level adoption of the intervention, including specific features, throughout the implementation period. We predict findings may align with site-specific implementation determinants revealed by CFIR application (eg, innovation relative advantage) during qualitative analysis, as well as account for variation in implementation outcome measures (eg, adoption by platform feature) across sites where providers and research assistants, for example, were already frequently using existing digital tools overlapping with *PositiveLinks* functionality that were fully integrated into their clinic's EMR with a high degree of satisfaction and had high ORIC scores. Readiness assessment results varied across sites but were not sufficiently different to prompt differential approaches to implementation support across sites. Results suggest that among the providers and RAs queried at the 6 intervention sites preimplementation, belief in their sites' collective capability to implement the program was high overall, particularly in relation to internal abilities to coordinate tasks and handle challenges arising within the sites. However,

respondents' confidence was lower in external actors' influence on implementation, or the organizational politics and support necessary to execute program components. To increase collective change efficacy of providers and research assistants, concerted preimplementation evaluation efforts may be needed in future *PositiveLinks* implementations to build site members' confidence that higher organizational levels of support for the program are present.

Comparison With Prior Work

To apply relevant implementation science frameworks to DHI implementation evaluation, we reviewed how investigators compared Proctor's Outcomes for Implementation Research recategorized for DHIs against RE-AIM [2,6]. These and other original research studies had limitations including a lack of measurable eligible "denominators" available for certain outcomes (eg, provider adoption dimension of RE-AIM). Prior studies also focused on conceptualizing outcomes for a primarily patient-facing intervention itself (eg, different ways of leveraging back-end usage capture data and tracking referrals of patients by clinic to the study), rather than including additional strategy steps to implement a dual-facing (patient and provider) intervention (mapped in Figure 2), which require dedicated measurement of both patient and provider inputs.

While RE-AIM offered adequate operational guidance to evaluate this DHI and implementation strategy as with some prior studies [2,6], several takeaways, opportunities, and challenges arose throughout our planning process as detailed throughout this article and summarized in Figure 1. Since the completion of our planning process and preparation of this manuscript, a framework for designing DHI hybrid trials has been published [32], which shares similarities with our identified planning process steps (specify components of the digital intervention as well as support services and implementation strategy, delineate domains being studied, ie, actors and action targets). Our takeaways delve deeper into considerations researchers should make based on specific experience with: (1) designing a randomized trial where the digital intervention is tested against a usual care condition, contains multiple features and engages both patients and providers or organization members; (2) integrating understudied components of RE-AIM and related evaluation frameworks into DHI trial design (eg, representativeness, fidelity, dose, and adaptation); and (3) conducting a trial among an epidemiologic cohort.

There is a well-recognized tension between maintaining the rigor and validity of randomized trial designs and establishing pragmatic conditions more relevant to real-world implementation [40]. By performing a preimplementation planning phase for a prospective DHI trial that incorporated frameworks proactively, we ensured collection of a robust set of quantitative and qualitative data. In contrast, post hoc evaluations conducted in other studies available in the literature are frequently reported among "real world" conditions or 'usual care' expected of implementation research as most strictly defined. When not planned in advance for inclusion, there are significant limits on the extent to which additional implementation outcomes like fidelity, dose, program adaptations, and uptake of specific components or steps of implementation have been evaluated with sufficient granularity and coverage of participants over the course of implementation [41,42] in these studies. Simultaneously, however, tighter control of prospective hybrid trial conditions and administration of the program through protocolized research activities inherently limits how well 'real-world' or pragmatic conditions are reflected within a hybrid trial.

Limitations

Several limitations emerged within our process. This more comprehensive planning process for the implementation evaluation was undertaken following receipt of funding for the award, which is common for hybrid trials. We found that ideally, this process should be undertaken as early as possible. Several takeaways from our planning process require attention this early, impacting study design and planned procedures, and consequently even impacting study budgeting and scope of work for research staff.

We noted several key limitations regarding the intended pragmatic nature of our prospective hybrid DHI trial. Real-world *PositiveLinks* implementation often relies on outreach by partner sites, by individuals who serve as champions of the intervention with an active role in obtaining site approvals (related to data security and patient privacy), and who continue to promote the intervention. Research assistants were assigned as de facto program managers at sites participating in the hybrid trial; however, this is a major distinction from real-world implementation. This decision, while needed to rapidly plan and conduct a multisite trial within budgetary and time-related constraints, represents a tradeoff in terms of generalizability of this planned prospective *PositiveLinks* implementation research when the intervention requires a distinct, multilayered 'implementation climate' and 'champions' within that climate. These 'climates' typically require gradual building of multiple, interacting implementers' self-efficacy, motivation, and longitudinal intervention promotion efforts to ensure site readiness and penetration.

Additional considerations for hybrid trials implementing DHIs may represent challenges to generalizability in terms of real-world maintenance and sustainability, including providing technology to patients (eg, smartphones, data plans), incentives for usage of the intervention or specific features, and participant retention protocols common for clinical efficacy trials. Real-world PositiveLinks implementation variably includes provision of phones and data plans, depending on specific partner site funding availability and patient need, and re-engagement protocols are also a routine part of implementation at several sites. For this trial, we planned to rely on existing site-specific or federal subsidy programs available to participants in the context (eg, Federal Communications Commission Lifeline program) before providing smartphones and data plans, and a retention protocol was used by site RAs to periodically re-engage patients. No additional incentives were planned for higher levels of app usage, however, and patients who do receive smartphones can keep them for the duration of the study regardless of app usage.

Examining implementation in parallel with a cluster randomized effectiveness trial among an epidemiological cohort presented

another set of unique challenges and opportunities. This hybrid approach allows for a scaled implementation evaluation to occur across multiple sites simultaneously, leveraging existing research infrastructure, including site staffing with research assistants and existing data collection instruments. The scaled, simultaneous multisite approach, however, engages a larger number of patients and providers within time and funding constraints of a single hybrid trial and necessitates consideration of more rapid, cost-effective approaches to implementation evaluation (acknowledged by de la Vega et al [6]). Provider surveys, for example, were designed to capture implementation outcome measures and determinants for the larger expected sample of respondents at 6 intervention sites than are typically engaged with more in-depth qualitative processes applying these frameworks, in particular CFIR. There is no consensus in the implementation science field about how these frameworks reflecting complex psychosocial/behavioral constructs should be applied, including whether to attempt to dichotomize or categorize items for broader, rapid distribution. Surveys could, for example, introduce study team bias during creation and selection of specific items to probe and limit more systematic application of the framework [37]. Combining surveys and qualitative approaches can offer opportunities to validate the latter methods, but more extensive psychometric validation of survey tools is needed to ensure generalizability and validity. Finally, readiness assessment findings are based on self-reported survey items, subject to scoring biased by the individuals' level of involvement with pretrial planning and other procedures (eg, research assistants vs physicians).

Conclusions

Implementation research for complex DHIs can expand understanding of how these interventions will behave in "real world" conditions. Prospective hybrid effectiveness-implementation trials can facilitate more in-depth implementation evaluations at scale if appropriately planned. Our experience highlights the ways in which evaluations must attempt to balance rigor, proximity to "real world" implementation climates, and incorporate multiple key implementation outcomes and determinants within the time and resource constraints of a prospective DHI hybrid trial. Based on our experience, planning processes for hybrid DHI trials should include:

- Specification of discrete DHI and associated implementation strategy components, considering how end users will engage with each, and what study procedures should be planned and budgeted to adequately measure that engagement (eg, backend paradata).
- Strategies to observe and document adaptations and real-time implementation processes throughout the planning, pre-, mid-, and postimplementation periods.
- Plans ahead of time to capture denominators of uptake outcomes (reach for patients and adoption for providers), demographic representativeness within those reached by the DHI versus not, and a method to capture usual care services that overlap with DHI functionalities across trial sites.
- Plans to evaluate fidelity and adaptations to the DHI and implementation strategy steps carried out among the implementing organization site that go beyond the use of the tool itself.
- Considerations for how to obtain detailed descriptive data related to implementation determinants in a larger sample size of participants (eg, design survey tools, interviews, or both using determinant frameworks).
- Plans for study procedures that minimize provider or implementer burden but enable consenting, data monitoring, and surveying of those providers, and consider in protocol design how retention protocols and use of research staff over "usual care" staff challenges generalizability or sustainability.

Acknowledgments

The authors would like to acknowledge all the collaborators of the participating DC Cohort clinics as well as input from members of the PositiveLinks team. No generative artificial intelligence tools were used for manuscript preparation.

Data in this manuscript were collected by the DC Cohort Study Group with investigators and research staff located at: Children's National Hospital Pediatric clinic (Natella Rakhmanina); the Senior Deputy Director of the DC Department of Health HAHSTA (Clover Barnes); Family and Medical Counseling Service (Rita Aidoo); Georgetown University (Princy Kumar); The George Washington University Biostatistics Center (Tsedenia Bezabeh, Vinay Bhandaru, Asare Buahin, Nisha Grover, Lisa Mele, Susan Reamer, Alla Sapozhnikova, Greg Strylewicz, and Marinella Temprosa); The George Washington University Department of Epidemiology (Shannon Barth, Morgan Byrne, Amanda Castel, Alan Greenberg, Shannon Hammerlund, Paige Kulie, Anne Monroe, Lauren O'Connor, James Peterson, and Mark Storey) and Department of Biostatistics and Bioinformatics; The George Washington University Medical Faculty Associates (Jose Lucar); Howard University Adult Infectious Disease Clinic (Jhansi L. Gajjala) and Pediatric Clinic (Sohail Rana); Kaiser Permanente Mid-Atlantic States (Michael Horberg); La Clinica Del Pueblo (Ricardo Fernandez); MetroHealth (Duane Taylor); Washington Health Institute, formerly Providence Hospital (Jose Bordon); Unity Health Care (Gebeyehu Teferi); Veterans Affairs Medical Center (Debra Benator and Rachel Denyer); Washington Hospital Center (Adam Klein); and Whitman-Walker Institute (Stephen Abbott).

Funding

AC and KI are multiple principal investigators on this project which is funded by the National Institute of Mental Health (R01MH122375). The DC Cohort Longitudinal HIV Study is funded by the National Institute of Allergy and Infectious Diseases

(UM1AI069503 and 1R24AI152598-01). JH received additional support from the National Institutes of Health (T32AI007046 and 5P30AI064518-20). The funders had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Data Availability

The datasets used and analyzed during the current study are available from the DC Cohort Longitudinal HIV Study following approval of request(s) from the study team and DC Cohort Executive Committee. Access is restricted in this way to protect the privacy of cohort participants, who have consented to inclusion of their data according to this restricted access policy. Requests for access can be submitted to the study authors and will be followed by a screening process first by the study team, then by the DC Cohort Executive Committee.

The datasets used and analyzed during the current study are available from the DC Cohort Longitudinal HIV Study following approval of request(s) from the study team and DC Cohort Executive Committee.

Conflicts of Interest

ALW and KI have active consulting agreements with Warm Health Technology, Inc., a wholly owned subsidiary of the University of Virginia Licensing & Ventures Group, which distributes the *Positive Links* program as *PL Cares*. JH is the founder and CEO of emPath technologies, LLC.

Abstract

Background: Meditation apps are increasingly popular, yet there is limited understanding of how much users actually engage with them. While meditation apps show promise for supporting mental health, engagement in real-world settings appears to be notably low. The patterns of app use and the factors that influence usage remain relatively unclear.

Objective: This study aims to examine the extent of meditation app use and the factors associated with user engagement.

Methods: We conducted a cross-sectional survey of 536 recent meditation app users across 5 English-speaking countries. Engagement data were collected via self-report and app-verified screenshots. Assessed factors included user characteristics (age, education, income, sex, country, personality, self-efficacy, readiness and expectations for change, self-compassion, and quality of life), mental health (distress, well-being, life satisfaction, anxiety, depression, support, and stress), and app-related elements (therapeutic alliance, appeal, functionality, aesthetics, information, quality, and perceived impact). The 4 outcome variables representing engagement were app-verified minutes, self-reported minutes, app-verified minutes per year (adjusted for app download date), and self-reported minutes per year (adjusted for app download date). Associations between app use and variables of interest were examined using correlations. Factors with significant associations were then included in multivariable regression models to identify those most strongly associated with engagement.

Results: Age (ρ=0.13-0.15, PP^{FDR}, where FDR is false discovery rate), expectations for sleep (ρ=0.12-0.33, P^{FDR}<.05), and expectations for thriving (ρ=0.12-0.18, P^{FDR}<.05) were associated with all outcome measures except adjusted objective minutes. Readiness to change was associated with all outcome measures (ρ=0.24-0.33, P^{FDR}<.05). Among app factors, appeal (ρ=0.18-0.23, P^{FDR}<.05) and perceived impact (ρ=0.23-0.32, P^{FDR}<.05) were associated with all outcome measures except adjusted self-report minutes, while perceived quality (r=0.28-0.51, P^{FDR}<.05) was associated with all outcome measures. Robust linear regressions showed that greater readiness to change (β=0.005-0.026, *P*=.006-.02), higher education level (β=0.029-0.540, *P*<.001), and higher openness (β=0.004-0.010, *P*=.008-.03) were associated with increased engagement. Additionally, greater expectations for sleep (β=0.004-0.009, *P*=.02-.04), greater expectation match (β=0.023, *P*=.03), and higher perceived app quality (β=0.008-0.042, *P*=.001-.01) were uniquely associated with increased engagement.

Conclusions: Most individuals who download meditation apps engage minimally. Our findings suggest that users who are more educated, open to new experiences, and hold strong beliefs in the effectiveness of meditation apps are more likely to use them regularly. Longitudinal studies are needed to examine patterns of use and strengthen causal inferences.

KEYWORDS

meditation; mindfulness; engagement; app; meditation apps; digital mental health intervention; behavior change

Introduction

Background

Around 1 billion people globally live with a mental health disorder [1], creating a demand that exceeds available resources. As the rise of technology has coincided with increasing strain on mental health systems, digital mental health interventions have gained popularity due to their accessibility [2,3]. Fully automated versions of these interventions may reduce reliance on limited human resources. However, engagement remains a challenge, with fewer than 20% of users continuing beyond 7 days [4].

Meditation apps are among the most common digital mental health tools [4,5]. Meditation encompasses a wide range of techniques across different traditions and religions and typically involves emotional and attentional regulation [6]. Mindfulness meditation, for example, emphasizes nonjudgmental awareness of the present moment [7]. Among regular meditators, most have used a meditation app [8]. While global rates of meditation remain unknown, 70 million people had downloaded Headspace by 2022 [9]. Thus, it is likely that a very large proportion of the population has tried meditation through an app. Given the high accessibility of meditation apps among those facing barriers to mental and physical health care, it is important to examine the practical limitations of such programs, with engagement being a key shortfall in app-based behavior change [10,11].

Most current information on meditation app use comes from clinical trials, which are not representative of real-world use. While randomized controlled trials of meditation apps show small- to medium-sized effects [12], real-world estimates suggest exceedingly high discontinuation rates [4]. As behavioral interventions are only effective if used, this presents a major challenge for apps [4]. For digital offerings to be truly useful, a better understanding of the factors associated with sustained use is essential. This study examines engagement rates and identifies who is most likely to engage with meditation apps.

Mindfulness-Based Programs and Meditation Apps

While a limited number of meditation apps have shown some efficacy for mental health outcomes [12], they should be considered separately from the established evidence base for mindfulness-based programs (MBPs) [13]. MBPs are arguably the most popular form of meditation training in clinical and academic settings, likely due to their strong evidence base [14,15]. By contrast, most popular meditation apps depart from the guided, intensive structure of MBPs [16]. Only 4% of popular apps provide evidence of their benefits [17]. Even where apps show potential efficacy, recent reviews highlight engagement as a major limitation to intervention effectiveness [12,18-20].

The Digital Transition

Digital health interventions generally face engagement issues, which likely reduce their benefits [4]. In nonpharmacological interventions, adherence is linked to outcomes [21], yet it tends to be worse in digital formats than in face-to-face interventions [22]. For behavior change apps (and apps more broadly), discontinuation occurs in 40%-60% of users [11]. In naturalistic settings, 21%-88% of users engage with an app at least once, but only 0.5%-28% sustain engagement (eg, completing all assigned modules or continuing use beyond 6 weeks [23]). Engagement decreases when digital interventions lack interactive human or human-like support [24], posing challenges for fully automated meditation apps. Clarifying who engages meaningfully with meditation apps is therefore important, given the link between adherence and outcomes.

Attrition, Adherence, and Engagement

Engagement refers to the extent of intervention use, including the amount, frequency, duration, and depth of use [25]. Attrition and adherence are related terms that describe levels of (dis)engagement in research studies. Attrition refers to discontinuation or dropout from the intervention program or from research data provision during a study [11]. For MBPs, attrition is around 19% [26], whereas app-based interventions show an average attrition of 42% in studies lasting 10 days to 12 weeks [12]. Real-world estimates for meditation apps indicate disengagement rates as high as 94% within the first 2 weeks [4].

Adherence refers to the extent to which an individual follows a prescribed treatment or intervention [21]. As no clear guideline exists for the amount of practice required to achieve an effect in mindfulness or meditation [16,27], adherence can only be considered in relation to recommended practice amounts (see example in [28]). In meditation training, prescribed engagement time ranges from as little as 35 minutes [28] to 3 hours per week in the widely used Mindfulness-Based Stress Reduction program [7]. By contrast, many apps recommend as little as 5 minutes per day or provide no clear guidance regarding minimum practice length, session duration, or overall time commitment needed to establish a practice [29]. Given the limited knowledge about dose-response relationships in meditation [16,29] and the tendency for most people to discontinue practice relatively early [4], engagement serves as a useful proxy for understanding who practices, what type of practice they follow, and why.

Why Do People (Dis)Engage With Meditation and Apps?

Overview

Understanding engagement in meditation apps requires consideration of various behavior change and persuasive systems design frameworks. Behavior change frameworks—including habit formation theory, social cognitive theory, the theory of planned behavior, and the transtheoretical model of change—suggest that user characteristics such as expectations, motivation, readiness to change, consistency of use, and self-efficacy influence engagement with behavioral interventions [30-33]. The persuasive systems design framework highlights

app design features that shape engagement and therapeutic alliance [34].

Habit formation theory emphasizes reward and associative cues as central to establishing habits, with positive outcomes reinforcing continued engagement [33]. Context can shape how rewards are perceived, influencing whether a habit is formed [35]. The theory of planned behavior further posits that perspective and context guide behavior [30,36]. Broad factors such as sociodemographics, mental health, and personality also influence engagement [30]. Expectations are shaped by attitudes and norms, with positive expectations and attitudes predicting greater meditation app engagement [36]. The transtheoretical model outlines stages of change, with later stages—more closely aligned with commitment to action—linked to more sustained behavior change [32]. Readiness to change reflects an individual's stage of change and is associated with successful maintenance of behavior change [37]. The Sussex Meditation Model identifies preintention, preparation, action, and maintenance stages as relevant to establishing a meditation practice [38,39]. Persuasive systems design, which examines how digital interventions can be structured to influence user behavior, highlights app features that enhance engagement, such as reminders and personalization [34]. Drawing on these frameworks, factors relevant to engagement in behavior change, meditation, or app use were categorized into user-related factors (sociodemographics, personal/user characteristics, and mental health factors) and app-related factors.

Sociodemographic Factors

Sociodemographic factors associated with disengagement from meditation include lower levels of education [40]; however, men, people with less education, and those with poorer health are less likely to begin meditating [41]. Meditators are also more likely to be wealthier than nonmeditators [41]. In online and app-based meditation, older age, positive expectations, and intrinsic motivation are associated with greater engagement [42,43].

Personal/User Factors

Personality factors have also been shown to influence engagement with meditation apps. Conscientiousness has been associated with meditation in general [44]. Openness predicts meditation practice outside formal program training, reflecting the "in-the-wild" context of app use [45].

Behavior change factors may also influence engagement with meditation apps. Self-efficacy and readiness to change have been linked to successful habit formation [46]. A higher intention to practice is associated with greater engagement [46]. Intrinsic motivation moderates behavior change success across demographic groups [47] and is crucial for making initial behavior change choices. Self-compassion and self-efficacy have also been found to be positively associated with engagement in behavior change [47,48].

Expectations for program efficacy can also influence behavior change. Positive experiences that meet expectations can facilitate ongoing engagement. Conversely, engagement may decline when a program or behavior does not deliver the anticipated positive outcomes [49]. Experiences of progress enhance engagement in both behavior change apps and meditation apps [50,51]. Positive expectations also predict higher engagement with digital meditation resources [42].

Mental Health Factors

Health characteristics are also important for engagement. People may be motivated by physical or mental health issues, but these same issues can also act as barriers [43]. This paradox can be explained by the desire to address a problem that simultaneously hinders the ability to engage in practice. Additionally, limited perceived gains may lead to early discontinuation. Barriers to mental or physical health care, which can impact quality of life, may further motivate meditation app use to address unmet health needs [11,41]. Although meditation use among individuals with mental health problems is common, depression is associated with low adherence to behavior modification recommendations in clinical populations [52,53]. The very symptoms people seek to address—such as amotivation, distressing thoughts, and irritability—can also complicate their efforts. Meditation apps may be moderately effective for depression, anxiety, and stress [12,19,50], potentially fostering an experience of progress. However, a minimal level of engagement is necessary to achieve efficacy [4,27]. Consequently, failure to achieve expected outcomes may lead to decreased engagement.

App Factors

The user's relationship with the app is also relevant. Therapeutic alliance—the collaborative relationship between the user and the app—predicts engagement with mental health apps [53]. Ease of use, the ability to personalize settings, reminders, progress tracking, and positive perceptions of the app also predict higher engagement with mental health apps, though these factors have not been extensively examined in meditation apps [42,53,54]. Usability (ie, the app's functionality) was identified as a key factor related to engagement in a systematic review of mental health apps [55].

This Study

Previous literature highlights factors that may be associated with meditation app use. In a cross-sectional survey capturing demographics, retrospective reports of app use, mental health factors, and perspectives on apps, we aimed to examine engagement rates and identify factors significantly associated with engagement.

This study focused on several preregistered questions:

1. To what extent are *user-related factors*—including sociodemographic characteristics, spirituality, personality, self-efficacy, self-regulation, motivation, expectations, self-compassion, mental health care status, and psychological distress—associated with mindfulness *app engagement*?
2. To what extent are *user-app relationship factors*—including therapeutic alliance, agreement on tasks and goals, and perceived app empathy and expertise—associated with mindfulness app *engagement*?
3. To what extent are *app-related factors*—including appeal, functionality, aesthetics, information quality, quantity, and

credibility, customization, accessibility, and usability—associated with mindfulness app *engagement*?

Additional questions included in the preregistration are not addressed in this paper.

Methods

Deviations From Preregistration

For clarification, we have changed the term "mindfulness apps" to "meditation apps" to capture a broader range of relevant practices. Mindfulness can, but does not necessarily, entail meditation and is variably represented as a capacity, skill, or technique. Meditation, by contrast, encompasses a broad array of spiritual and secular practices that use techniques such as focusing on an object, experience, image, or idea [56].

Deviations from the preregistration included the following: (1) focusing on 4 definitions of minutes as the primary outcome and omitting the second preregistered outcome variable—regular practice hours—for simplicity. Regular practice hours were not included because their calculation combined multiple variables and, therefore, could be subject to estimation error. The 4 variations of the outcome variable were included to capture the complexity of user behavior. (2) We did not report 95% odds ratios, as continuous outcomes were used. (3) The final sample size was substantially reduced to 536 from the target of 1000 due to a smaller-than-anticipated eligible pool. This reduction decreased statistical power, although it still allowed adequate power to detect small effects. The reduced pool also led to a fourth deviation. (4) Recruitment was extended to Australia, Canada, the United Kingdom, and New Zealand. An additional deviation involved (5) not analyzing motivation for use, as this information was captured in open-text responses and could not be used in this quantitative analysis.

Ethical Considerations

This study was conducted in accordance with ethical guidelines and was approved by the Office of Research Ethics and Integrity at the University of Melbourne (approval number 2025-23969-62994-8).

Participants provided informed consent to participate in the study via the Qualtrics survey (Qualtrics International Inc). Consent was obtained within the survey, which also included a downloadable copy of the plain language statement. The plain language statement is available in Section S1 in Multimedia Appendix 1. Provision of informed consent included acknowledgment of the right to withdraw at any time without providing an explanation. Participants also consented to secondary analyses. Survey questions were coded so that participants could not proceed without providing consent. All included responses were double-checked to ensure consent had been given.

Participants were compensated Aus $0.30-0.50 (US $0.20-0.33) for completing the screening survey (mean duration 1 minute 49 seconds) and Aus $6-8 (US $3.96-5.29) for completing the follow-up survey (mean duration 22 minutes 57 seconds), averaging Aus $20.59 (US $13.60) per hour. Survey compensation varied slightly based on median completion time; compensation was occasionally increased to better approximate the proposed hourly rate if the median completion time indicated the study took longer than expected.

Privacy and Confidentiality

Where possible, identifying information was removed from the dataset. Any copies of datasets containing identifying information were stored securely in accordance with relevant privacy guidelines and encrypted using Transport Layer Security (also known as HTTPS).

Study Design

Overview

This was a cross-sectional analysis of data collected from participants.

Procedure

Participants were recruited via Prolific (Prolific Academic Ltd) to complete a survey hosted on Qualtrics. The survey was accessible to potential participants in the United States, the United Kingdom, Canada, Australia, and New Zealand between August 1 and October 6, 2023. Participants were invited to complete a prescreening survey, and eligible individuals were sent the full survey within 1-2 days. Surveys were completed online using a laptop or mobile device. Participants were asked to upload a screenshot of their app use statistics, which provided information such as minutes, days, sessions, streaks, and the original date of download, depending on the app.

App Selection

We collected engagement information for popular meditation apps listed on the iOS (Apple Inc) and Android (Google LLC/Alphabet Inc) app stores (see Section S2 in Multimedia Appendix 1). Participants using apps in which meditation—including mindfulness meditation—was the primary intended function were included, based on app descriptions, marketing, and in-app features.

Participants using any app could complete the prescreening survey. Two (JA and JD) researchers assessed whether the app (1) prominently promoted itself as a mindfulness meditation tool and (2) provided techniques to practice mindfulness or another form of meditation. Meditation or mindfulness could not be a secondary component. We did not evaluate app content in relation to any specific definition. We adopted this approach because meditation apps do not offer a single type of meditation, nor do mindfulness apps (eg, Headspace) necessarily adhere to the MBP definition of meditation. Apps were excluded if they focused exclusively on fitness/exercise, employee well-being, cognitive behavioral therapy, or other mental health interventions. All included apps were fully automated (ie, without human support).

Participants

Inclusion criteria required participants to have used an eligible meditation app within the past 180 days; be fluent in English; and reside in Australia, Canada, New Zealand, the United Kingdom, or the United States. Exclusion criteria included failure to provide evidence of app use or use of an app in which meditation was not the primary focus.

A total of 6137 prescreening surveys were completed. We excluded 5307 responses: 4343 (70.77%) were unable to demonstrate access to an app, 316 (5.15%) had not used the app in the past 180 days, 319 (5.20%) had downloaded an ineligible app, and 329 (5.36%) self-reported zero use. Of the remaining surveys, 800 (13.04%) met the inclusion criteria.

Of the 800 participants invited to the survey, 677 (84.6%) completed it. Among the 675 survey responses received, 18 (2.3%) were identified as likely bots or fraudulent responses based on fraudulent screenshots or failed reCAPTCHA (reverse Completely Automated Public Turing Test to Tell Computers and Humans Apart), and 13 (1.6%) exhibited suspiciously high average session lengths (>3× the IQR, 70.35 minutes). An additional 22 participants (2.8%) timed out before completing the survey, 25 (3.1%) failed attention checks, 59 (7.4%) failed screenshot checks, 86 (10.75%) responded twice, and 21 (2.6%) declined to complete the survey. These categories were not mutually exclusive. The resulting sample consisted of 563 (70.4%) participants who consented and completed the full survey. Finally, 27 (4.8%) multivariate outliers were excluded according to the preregistration, yielding a final sample of 536 participants.

Measures

Engagement

To verify the reliability of self-reported information, we collected both subjective self-reports and objective, app-verified data (screenshots provided by participants), which included minutes, days, streaks (consecutive days of use), number of sessions, average session length, and duration of app ownership (Table 1). These metrics were collected using recent app duration, defined as the number of days between first and last app use. App-verified duration was recorded if a participant validated the download period via screenshot.

The primary engagement variable was minutes of app use. Four variations were analyzed: (1) objective unadjusted minutes, representing total app-verified minutes; (2) self-reported or "subjective" unadjusted minutes, representing total unverified self-reported minutes; (3) objective adjusted minutes, calculated as app-verified minutes adjusted for app-verified duration of use, expressed as minutes per year; and (4) self-reported or "subjective" adjusted minutes, calculated as self-reported minutes adjusted for self-reported duration of use, expressed as minutes per year. Adjusted variables accounted for the duration of access to the app (from the download date to the last use). As only a limited number of apps reported objective start dates, and app-verified duration correlated highly with self-reported duration, the adjusted variables were calculated using the time between the first and last reported use.

Table 1. Descriptive statistics for engagement outcomes among meditation app users.

Statistics	n	Mean (SD)	5th percentile	25th percentile	50th percentile (median)	75th percentile	95th percentile
Subjective							
Total minutes	483	3562.78 (8616.39)	4.10	76.00	420.00	2474.00	21735.10
Total sessions	452	108.43 (197.00)	0.58	9.40	37.33	130.30	407.25
Duration (days)	477	894.16 (854.20)	16.80	158.00	621.00	1342.00	2689.80
Minutes per session	454	16.60 (29.74)	3.00	5.81	10.51	18.09	35.41
Estimated minutes per month[a]	477	148.77 (304.56)	0.48	8.41	40.25	137.20	789.44
Estimated sessions per month[a]	437	9.35 (16.61)	0.13	0.93	3.29	11.05	34.79
Objective							
Total minutes	483	3358.69 (8607.36)	12.00	96.50	465.00	2410.00	21735.10
Total sessions	151	61.89 (194.90)	0.61	3.36	12.22	39.95	167.23
Minutes per session	151	49.21 (89.20)	1.98	7.26	25.92	55.90	154.08
Estimated minutes per month[a]	151	73.58 (223.73)	0.61	2.39	10.61	35.09	313.31
Estimated sessions per month[a]	148	9.44 (47.63)	0.02	0.10	0.66	2.32	17.29

[a]Estimated minutes per month and sessions per month were calculated by total engagement in minutes divided by duration of app use in years divided by 12.

Self-Reported Measures

Sociodemographic Information and Meditation History

Sociodemographic information included household income, education level, religion, app name, and approximate start and stop dates of use. Most data were self-reported via the survey. Prolific provided additional information, including age, sex, language, student and employment status, country of birth, and current residence. Regular practice information included minutes per session, sessions per day, and days per week. Meditation

history was assessed by asking participants to report their previous meditation experience in hours, ranging from 0-100 hours to 1000+ hours. See Table 1 for regular practice information, and Sections S3-S5 in Multimedia Appendix 1 for sociodemographic statistics, meditation app frequencies, and a detailed survey flow.

Attention Checks

Three attention checks were included in the survey to assess participant engagement. Participants failing 2 or more attention checks were excluded. The attention checks were designed to mimic the scale items within which they appeared; for example, "In general, select dissatisfied to show that you are paying attention."

The EuroQoL Health and Wellbeing Assessment—Short Form

The 9-item EuroQoL Health and Wellbeing (EQ-HWB-9) is a newly developed quality-of-life measure by Brazier and colleagues [57]. It assesses quality of life with a focus on health and well-being. The scale consists of 9 items, each rated from 1 (no difficulty, none of the time, and no physical pain) to 5 (unable, most or all of the time, and very severe physical pain). In this study, the 9 items of the EQ-HWB-9 demonstrated very good internal consistency (Cronbach α=0.873), and McDonald hierarchical omega was relatively high (ω=0.732). The EQ-HWB-9 was used with permission from the EuroQol Group.

The Kessler Psychological Distress Scale

The Kessler Psychological Distress Scale (K10) assesses psychological distress over the past 30 days [58]. This 10-item questionnaire, measuring anxiety and depressive symptoms, uses a 5-point scale ranging from 1 (none of the time) to 5 (all of the time). In this study, the scale demonstrated excellent internal consistency (Cronbach α=0.930; McDonald ω=0.799).

The Warwick-Edinburgh Mental Wellbeing Scale

The Short Warwick-Edinburgh Mental Wellbeing Scale (WEMWBS) was used to assess positive aspects of mental health [59]. This 7-item scale uses a 5-point response format, ranging from 1 (none of the time) to 5 (all of the time). In this study, the scale demonstrated high internal consistency (Cronbach α=0.879; McDonald ω=0.790).

The Satisfaction with Life Survey (Single Item)

The Satisfaction with Life Survey Single Item is an abbreviated version of the established Satisfaction with Life Survey (SWLS) [60]. The scale demonstrates reasonable criterion validity with the full SWLS (zero-order r=0.62-0.64). This single-item measure asks participants to rate their life satisfaction on a scale from 1 (extremely dissatisfied) to 7 (extremely satisfied).

7-Item Generalized Anxiety Disorder Scale

The 7-Item Generalized Anxiety Disorder Scale is used to screen for general anxiety symptoms [61]. Each item is rated from 0 (not at all) to 3 (nearly every day). In this study, the scale demonstrated high internal consistency (Cronbach α=0.899; McDonald ω=0.863).

Depression (8-Item Patient Health Questionnaire)

The 8-item Patient Health Questionnaire is used to assess depressive symptoms [62]. Each item is rated from 0 (not at all) to 3 (nearly every day). In this study, the scale demonstrated high internal consistency (Cronbach α=0.881; McDonald ω=0.781).

Self-Compassion Scale

The Self-Compassion Scale consists of 12 items assessing participants' ability to be compassionate toward themselves [63]. Each item is rated from 1 (almost never) to 5 (almost always). In this study, the scale demonstrated high internal consistency (Cronbach α=0.881; McDonald ω=0.656).

Self-Efficacy (6-Item Generalized Self-Efficacy)

The 6-item Generalized Self-Efficacy assesses self-efficacy, or an individual's perceived ability to achieve goals [64]. Each item is rated from 1 (not at all true) to 3 (exactly true). The scale demonstrated high internal consistency (Cronbach α=0.821; McDonald ω=0.788).

Readiness to Change 1-Item

The Readiness to Change 1-item assessment is a 10-point scale that measures an individual's preparedness to enact a behavioral change [37]. The scale ranges from 0 (not prepared to change) to 10 (already changing). It has been validated to reflect actual readiness in clinical contexts [37,65,66].

6-Item Digital Working Alliance Inventory

The 6-item Digital Working Alliance Inventory (DWAI-6) [5] is a rating scale that assesses the therapeutic alliance between an individual and their health care provider, adapted for smartphone interventions (ie, referring to "the app" rather than "the therapist"). Items are rated on a 7-point scale from 1 (strongly disagree) to 7 (strongly agree), with subscales evaluating goal alliance (agreement on goals), task alliance (agreement on tasks), and bond (connection between app and user). The overall scale demonstrated good internal consistency (Cronbach α=0.850; McDonald ω=0.830). The Goal subscale showed high consistency (Cronbach α=0.766), the Bond subscale demonstrated acceptable consistency (Cronbach α=0.676), and the Task subscale showed poor consistency (Cronbach α=0.402).

Common Factors Domains (Modum Process Outcome Questionnaire)

We used a subset of items from the Common Therapeutic Relationship Factors Questionnaire (Modum Process Outcome Questionnaire) to assess the therapeutic relationship beyond the DWAI-6 [67]. The original questionnaire, which focuses on the clinician-patient relationship, was adapted to refer to the app-user relationship (eg, "I am able to be open and honest when interacting with the app"). Three items from the 12-item scale were included, each rated from 1 (strongly disagree) to 7 (strongly agree), with a "not applicable" option. The items demonstrated low internal consistency (Cronbach α=0.612; McDonald ω<0.001), likely due to being an unintended subset. Consequently, results will be reported for each item individually rather than as a total score.

The Big Five Inventory Short Form 2 (BFI-S-2)

The Big Five Inventory Short Form 2 (BFI-S-2) is a 30-item questionnaire assessing 5 personality domains: Extraversion, Agreeableness, Conscientiousness, Negative Emotionality/Neuroticism, and Open-Mindedness [68]. Each subscale consists of 6 items. Internal consistency, assessed using Cronbach α and McDonald ω, ranged from acceptable (Extraversion, α=0.766; ω=0.636/Agreeableness, α=0.744; ω=0.549/Openness, α=0.785; ω=0.664) to high (Conscientiousness, α=0.812; ω=0.738/Negative Emotionality, α=0.884; ω=0.841).

User Mobile Application Rating Scale

The user Mobile Application Rating Scale (uMARS) is a 27-item instrument for assessing the quality of mobile apps [69]. The scale includes subscales evaluating engagement (referred to as "appeal" in this study for clarity: "Is the app fun/entertaining to use?"), functionality ("How accurately and quickly do the app features and components work?"), aesthetics ("How good does the app look?"), information ("Is the app content correct, well written, and relevant to the goal/topic of the app?"), perceived/subjective quality ("Would you pay for this app?"), and perceived impact ("This app has increased my knowledge/understanding of meditating"). The scale asks participants to rate app elements on a 5-point scale ranging from 1 (poor) to 5 (excellent), with specific descriptions for each item. The overall scale demonstrated high internal consistency (Cronbach α=0.866) but only moderate reliability (McDonald ω=0.606). The additional subscale for perceived impact was also highly consistent (Cronbach α=0.863; McDonald ω=0.761). The Functionality subscale demonstrated high internal consistency and reliability (Cronbach α=0.803; McDonald ω=0.739), whereas the Engagement (Cronbach α=0.734; McDonald ω=0.628), Aesthetics (Cronbach α=0.761; McDonald ω=0.658), and Information (Cronbach α=0.762; McDonald ω=0.688) subscales showed acceptable consistency and reliability. The Subjective Quality subscale was consistent (Cronbach α=0.629; McDonald ω=0.667). The Aesthetics subscale showed variable internal consistency (Cronbach α=0.762; McDonald ω=0.065), indicating unequal item contributions.

Analysis Plan

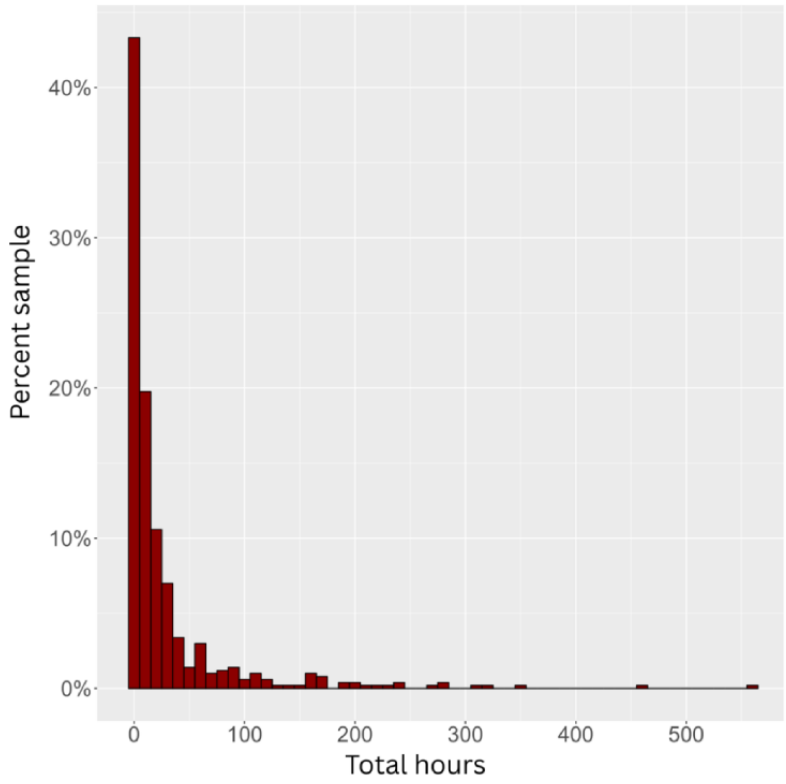
Sample Size Determination

Given an unknown effect size due to the absence of robust data, and guided by prior estimates of effect sizes for meditation apps [12], we aimed to calculate statistical power based on the smallest effect size we could reasonably detect. The target sample size was 1000 participants, providing 90% power to detect an effect of r=0.102, corresponding to a small effect. Because of recruitment challenges, the final sample size before analyzing the main engagement variable was 536, representing nearly 54% of our target population (n=1000). Although this reduction decreased statistical power (80% power to detect r=0.122), given that the a priori effect size was unknown, the study remained adequately powered to detect relatively small effects, albeit slightly larger than initially anticipated.

Planned Statistics

As outlined in the preregistration, we explored associations between user-related factors (Q1, H1), user-app relationship factors (Q2, H2), app-related factors (Q3, H3), mental health factors (Q5, H5), and predefined engagement variables. All engagement variables were heavily skewed and nonnormal (see Figure 1 and Sections S11-S14 in Multimedia Appendix 1); therefore, Spearman rho correlations were estimated. Variables that were significantly associated with any outcome variable were subsequently used to build regression models for each of the 4 outcomes. As transformations did not normalize the variables, untransformed variables were analyzed using robust regression with the "robustbase" package in R (R Foundation), employing an MM-type regression estimator with a bisquare redescending score function [70,71]. This method applies case weighting to account for nonnormality. All analyses were conducted in RStudio (R Foundation).

Figure 1. Histogram of self-reported practice hours (x axis) shown as the percentage of the sample (y axis), with values converted from minutes for visualization purposes.



Regression Models

Robust linear regression was used to investigate which factors accounted for significant variance in engagement. For each of the 4 outcome variables—adjusted objective minutes, adjusted self-report minutes, objective minutes, and self-report minutes—a separate regression model was created using the respective measure as the outcome variable. No stepwise regression was implemented. Instead, independent variables were selected from user, mental health, and app factors that were significantly associated with at least one outcome measure in the correlation analyses, following correction for multiple comparisons.

Multiple Comparisons Correction

We explored correlations between the 4 engagement outcomes and related factors, applying a false discovery rate (FDR) correction to account for multiple comparisons [72].

Data Cleaning

Duplicate and invalid responses were removed. The data demonstrated weak correlations, positive skew, and extreme values, indicating potentially high variability or inconsistency (see Sections S6-S10 in Multimedia Appendix 1). After adjusting for app duration, we implemented several data-cleaning procedures. Intraindividual response validity calculation, LongString Identification [73], and inconsistency of responses on the BFI-S-2 [68] were each used to identify and exclude extreme cases; however, none of these approaches resulted in major changes to the results (see Sections S10-S12 in Multimedia Appendix 1). As specified in the preregistration, multivariate outliers were removed, identified as cases with a Mahalanobis distance greater than the 95th percentile on the BFI-S-2 (see Section 13 in Multimedia Appendix 1).

Results

Overall Engagement

Overall, most users completed only a few minutes across limited sessions. Despite generally low engagement, 134 out of 536 (25%) users reported more than 11 sessions per month (approximately 1 session every 3 days), while the top 5% (27/536) reported around 35 sessions per month (more than 1 session per day). These patterns align with prior findings, including a median of 90% of users dropping off within the first week of real-world use and an average 42% drop in participation in meditation app randomized controlled trials spanning 1-2 months [4,12]. Notably, 402 (75%) participants reported more than 9 sessions, which contrasts with prior findings suggesting that most users disengage completely within a week of download. However, only the top 5% (25/536, 4.7%) engaged at levels consistent with clinically meaningful change [16], while the top 25% (134/536) engaged at levels comparable to the dose of mindfulness-based interventions [27].

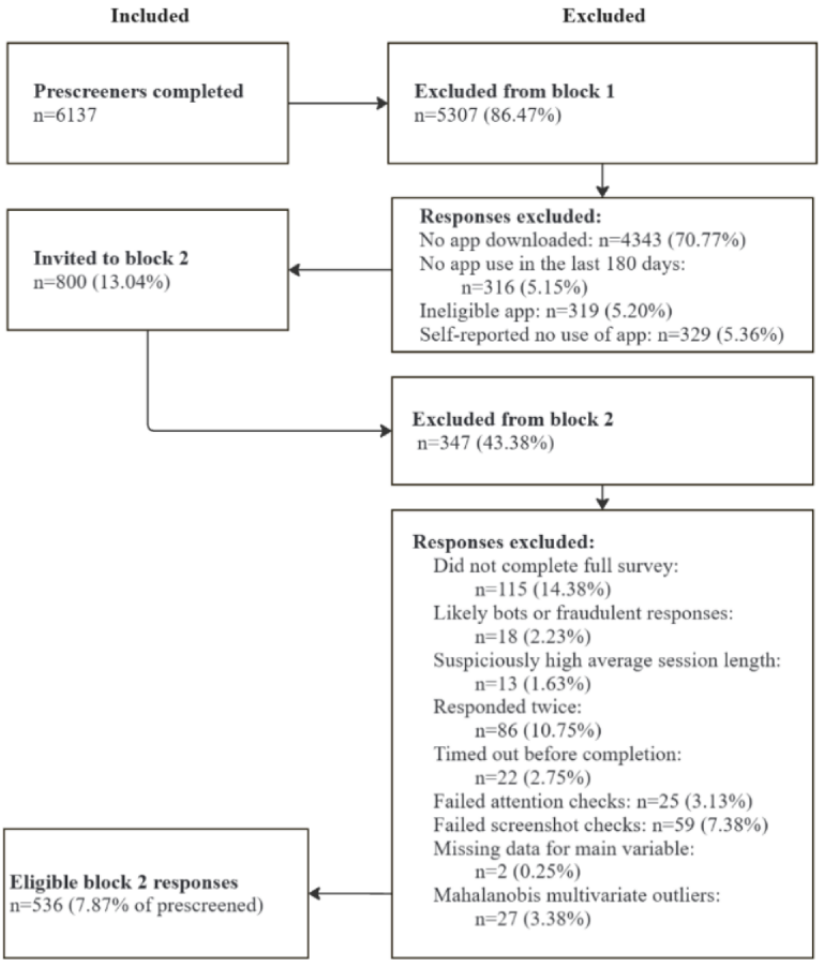
Participant Characteristics: Descriptives

Sociodemographic Features

Participants (N=536) ranged from 18 to 70 years of age (mean 36.56 years, SD 10.68 years) and were predominantly female (n=366, 68.3%). See Figure 2 for participant flow. Most resided in the United States 253 (47.20%) or the United Kingdom

(n=226, 42.2%), with smaller proportions from Australia (n=27, 5%), Canada (n=21, 3.9%), and New Zealand (n=6, 1.1%). The majority identified as White (n=422, 78.73%) and were highly educated, with 387 (72.20%) holding at least a bachelor's degree. Participants were also relatively wealthy, with nearly one-third reporting a combined income of $100,000 or more (n=145, 27.05%). Note that income brackets were not adjusted across countries. Nearly half of the participants reported no religious affiliation (n=264, 49.25%). The most frequently used apps were Headspace (n=191, 35.6%) and Calm (n=123, 22.9%), which together accounted for 58.6% of the sample (n=314). Full details are provided in Sections S3 and S4 in Multimedia Appendix 1.

Figure 2. Participant flow.



Meditation Experience

Most users (n=330, 61.6%) reported between 0 and 100 hours of overall meditation experience. Meditation experience varied across meditation apps (χ^2_4=34.18, P<.001); users with 0-100 hours were most likely to use Headspace (124/377, 32.9%), followed by Calm (75/377, 19.9%) and Insight Timer (25/377, 6.6%; see Table 2).

Table 2. Frequency and relative percentage of Calm, Headspace, and Insight Timer users by self-reported meditation experience level (n=377).

Duration (hours)	Calm, n (%)	Headspace, n (%)	Insight Timer, n (%)	Total, n (%)
0-100	75 (19.9)	124 (32.9)	25 (6.6)	224 (59.4)
101-1000	35 (9.3)	46 (12.2)	46 (12.2)	127 (33.7)
1001+	6 (1.6)	11 (2.9)	9 (2.4)	26 (6.9)
Total	116 (30.8)	181 (48.0)	80 (21.2)	377 (100)

Engagement

After excluding invalid responses and duplicates, engagement levels remained low, with a positive skew for both hours and sessions (see Figures 2 and 3). Adjusting for app duration showed low engagement regardless of how long the app had been available to users (see Figures 4 and 5). Estimated minutes per month and sessions per month were adjusted within each user to provide clearer engagement metrics. The median number

of sessions per month was 3.29. With a median of 40.2 minutes per month, this equated to roughly three 12-minute sessions.

Figure 3. Histogram showing the total number of self-reported sessions (x axis) by the percentage of participants (y axis).

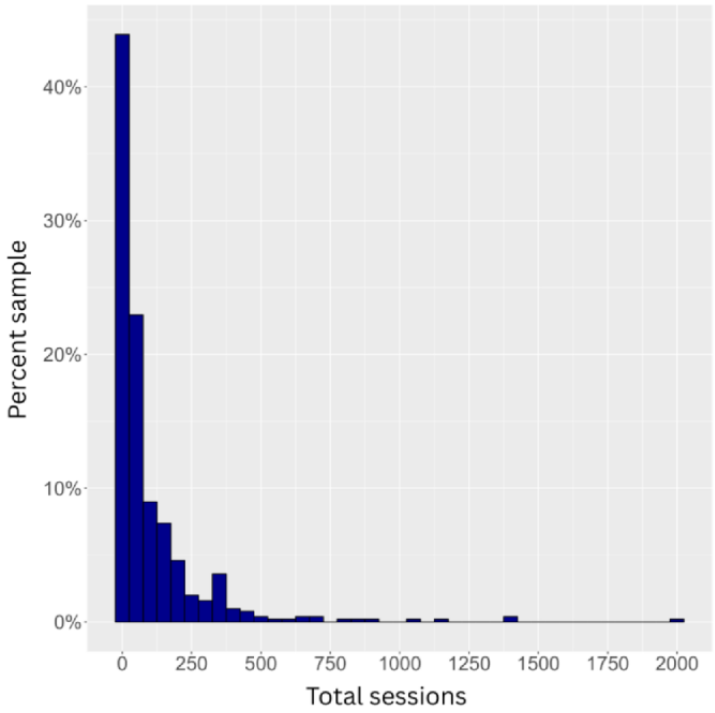


Figure 4. Total hours of practice by categorical groups based on time since app download. The y axis is truncated at 50 for visualization purposes, capturing 75% of the data. Horizontal bars indicate the median value for each category.

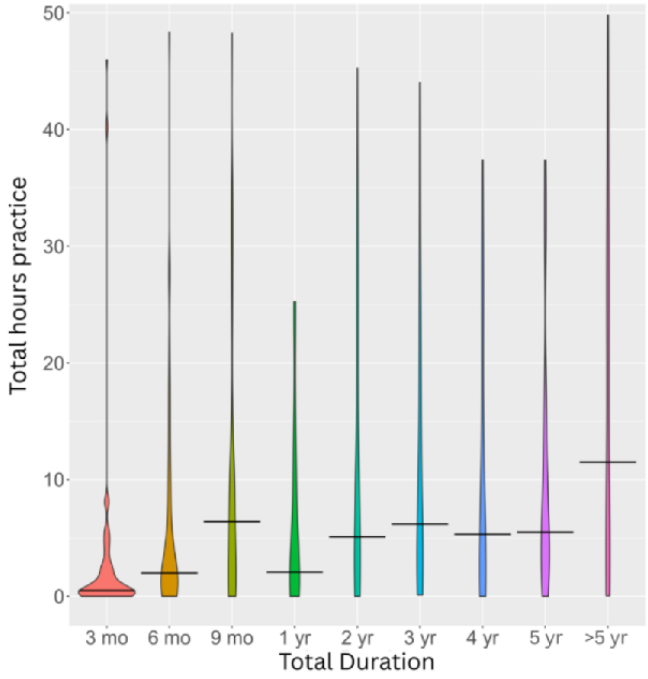

Figure 5. Total sessions by categorical groups based on time since app download. The y axis has been truncated for visualization purposes, capturing 75% of the data. Horizontal bars indicate median values for each category.

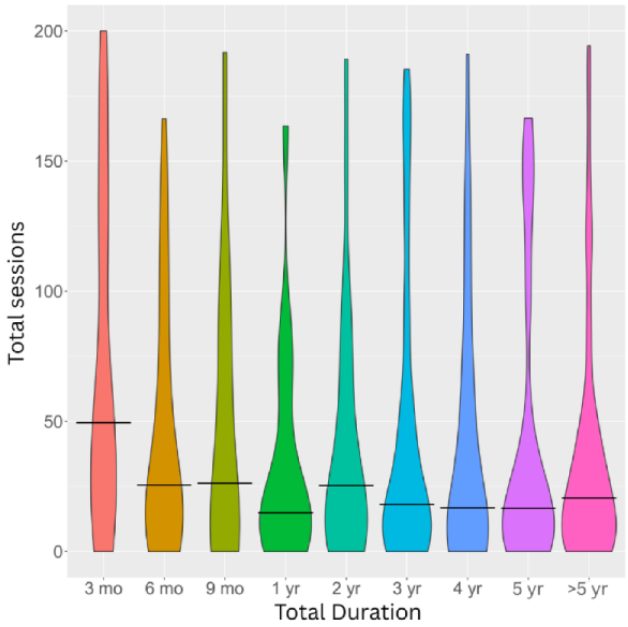


Engagement Statistics

Engagement variables were highly intercorrelated (r=0.495-0.999; see Section S14 in Multimedia Appendix 1). Objective adjusted minutes were the most reliable variable, but the sample was small and limited to 2 apps (n=156; Headspace and Waking Up). By contrast, subjective minutes with a subjective start date had a sample size 3 times larger (n=536). Given the strong association between objective and subjective start dates (r=0.783, P<.001), adjusted subjective minutes were calculated using subjective duration as the denominator to maximize sample size.

Categorical Demographic Factors and Engagement

Categorical demographic associations with engagement are reported in Table 3. Being female was associated with lower engagement on 1 outcome, while residing in the United Kingdom was associated with higher engagement across 3 of the 4 outcome variables.

Table 3. Point-biserial correlations for the association between noncontinuous variables and engagement.

Variables	Objective minutes	Subjective minutes	Adjusted objective	Adjusted subjective
Sex[b]	–0.019	0.080	–0.296[a]	–0.016
Residence				
Australia	–0.027	–0.016	–0.004	–0.040
United States	–0.071	–0.069	–0.065	–0.068
United Kingdom	0.102[a]	0.110[a]	0.075	0.106[b]
Canada	–0.032	–0.062	–0.029	–0.068
New Zealand	–0.021	–0.031	–0.007	0.038

[a]P<.05 without multiple comparisons correction.

[b]P<.05 with multiple comparisons correction. For the biserial sex correlation, 1=female, 0=male.

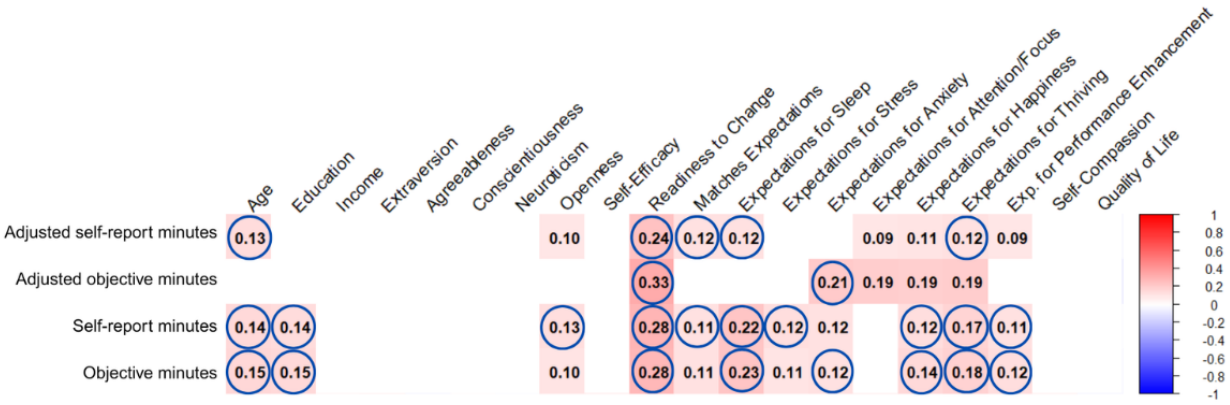
Engagement by App

Three 1-way analyses of variance indicated a significant effect of app type on engagement for subjective minutes ($F_{2,362}$=9.03, P=.002, η^2=.05) and adjusted subjective minutes ($F_{2,358}$=7.63, P=.001; see Sections S15 and S16 in Multimedia Appendix 1). No significant differences were found for objective minutes ($F_{2,362}$=0.972, P=.38).

User Factors

We defined robust associations as those present across 3 or more of the 4 engagement outcomes. Among user factors, only 9 of 20 variables met this criterion (see Figure 6): age, openness (BFI-S-2), readiness to change, expectation match, expectations for sleep, expectations for anxiety, expectations for happiness, expectations for thriving, and expectations for performance enhancement. After FDR correction, only 4 of 20 remained: age, readiness to change, expectations for sleep, and expectations for thriving (see Section 17 in Multimedia Appendix 1 for CIs).

Figure 6. Heatmap of correlation results for user factors and adjusted self-report, adjusted objective, total self-report, and total objective minutes of meditation app use. The heatmap illustrates the direction and magnitude of Spearman correlations, as shown in the legend. Numbers indicate correlation coefficients. Asterisks denote correlations significant at $P<.05$ after correction for multiple comparisons. Nonsignificant correlations are omitted. Outcomes include self-reported total minutes of meditation app use, self-reported minutes adjusted for app duration, objectively verified total minutes of use (via app screenshot), and objective minutes adjusted for app duration.



Mental Health Factors

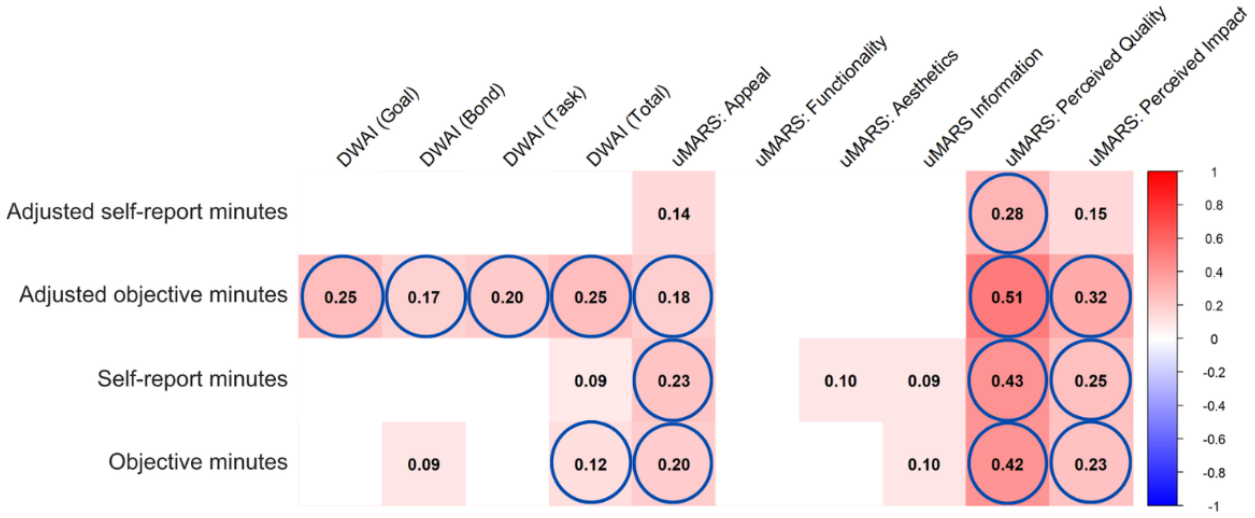
Self-reported stress, depression, and psychological distress were negatively associated with app use. Specifically, distress was negatively associated with adjusted self-reported minutes, depression with unadjusted self-reported minutes, and current stress with both unadjusted self-reported minutes and objective minutes. However, no mental health factors remained significantly associated with any engagement outcome after correction for multiple comparisons (see Figure 7).

Figure 7. Heatmap of correlations between mental health factors and adjusted self-report, adjusted objective, total self-report, and total objective minutes of meditation app use. The heatmap shows the direction and magnitude of Spearman correlations, as indicated by the legend. Numbers represent correlation coefficients. Circles denote significant correlations at $P<.05$ after correction for multiple comparisons. Nonsignificant correlations are omitted. Outcomes include self-reported total minutes of meditation app use, self-reported minutes adjusted for app duration, objectively verified total minutes of use (via app screenshot), and objective minutes adjusted for app duration.

App Factors

DWAI-6 Total, uMARS Appeal, uMARS Perceived Quality, and Perceived Impact were associated with 3 of the 4 outcome variables. Of the app factors investigated, 7 were associated with at least one engagement outcome after FDR correction (see Figure 8): DWAI-6 Total, as well as Goal, Bond, and Task subscales, and uMARS Appeal, Perceived Quality, and Perceived Impact.

Figure 8. Heatmap of correlations between app factors and meditation app use outcomes. Displayed are Spearman correlation coefficients (numbers) showing the direction and magnitude of associations as indicated in the legend. Circles denote correlations significant at $P<.05$ after multiple comparison correction, and nonsignificant correlations are omitted. Outcomes include self-reported total minutes of app use, self-reported minutes adjusted for app duration, objective total minutes of use (verified via app screenshot), and objective minutes adjusted for app duration. DWAI: Digital Working Alliance Inventory; uMARS: user Mobile Application Rating Scale.



Outcome Regression Models

All models demonstrated a reasonable fit, explaining 12%-16% of the variance (see Table 4 and Section 18 in Multimedia Appendix 1). Significant ($P<.05$) predictors in 1 or more regression models included education, readiness to change, expectations for sleep, expectation match, the Perceived Quality subscale of the uMARS, and the Openness subscale of the BFI-S-2.

Table 4. Regression model coefficients for adjusted objective minutes, total objective minutes, adjusted self-report minutes, and total self-report minutes.

Standardized β coefficients for predictors in models 1–4	Adjusted objective minutes[a], standardized β coefficients	Objective minutes[b], standardized β coefficients	Adjusted self-report minutes[c], standardized β coefficients	Subjective minutes[d], standardized β coefficients

Discussion

Principal Findings

We examined factors associated with engagement in popular meditation apps among 536 participants. Consistent with prior findings, most participants engaged minimally. Although apps were available for an average of 894 days (about 2.5 years), participants reported an average of 108 sessions, while app-verified data from about one-third of participants indicated 62 sessions on average. Half of the sample engaged in 3 or fewer sessions per month. Notably, engagement did not increase with longer app availability, suggesting a pattern of persistently low overall engagement.

Few significant correlations between individual user factors and engagement were observed, most of which were small in magnitude (r=0.09-0.30), with a few reaching the moderate range (r=0.30-0.50). After correction for multiple comparisons, positive associations with engagement remained for male sex, older age, higher education level, readiness to change, and expectations of the app for stress reduction, sleep improvement,

anxiety reduction, happiness, thriving, and performance enhancement. These results suggest that older, more educated users with greater readiness to change and higher expectations of the app are more likely to engage regularly. App factors—including perceived appeal, quality, and impact—were consistently associated with higher engagement, as were the 3 digital working alliance subscales (Goal, Task, and Bond). This indicates that both perceptions of the app and the perceived relationship with it may be important determinants of engagement.

User Factors Related to Use

Sociodemographics

Education was the variable most consistently associated with higher engagement. Meditation is more common among individuals who are White, middle-aged, wealthier, and better educated [41]. Lower levels of education have been linked to earlier disengagement or a failure to engage in meditation at all [41]. Higher education is also associated with greater engagement in mindfulness practices in US nationally representative surveys [11]. Lower levels of education have also been linked to poorer health outcomes [74,75] and are related to health literacy, which partially mediates health-promoting behaviors [76,77]. While lower education may contribute to poorer health outcomes and lower health literacy, other social factors may also reduce engagement. For example, individuals with lower education often have more fragmented leisure time, leaving less opportunity for regular, recurrent activities [78]. Male sex was associated with 1 engagement measure, which contrasts with prior research showing that females are generally more likely to engage in meditation practice, even after controlling for other demographic factors [12,42,79]. Previous studies have also found that males may demonstrate greater persistence in meditation [80]. As this correlation was observed only for adjusted objective use (available for Headspace and Waking Up), it may reflect patterns specific to users of these apps rather than meditation app use more broadly [40]. Notably, sex did not emerge as a significant predictor in the regression models.

Personality

Of the personality factors, only openness was related to engagement. Openness reflects general curiosity and a willingness to explore novel perspectives of one's subjective experience [81]. Individuals higher in openness are more likely to try meditation initially and persist despite encountering difficulties. Openness has also been associated with meditation practice outside of group meditation class settings [45]. In contrast to prior research, we found no associations between engagement and conscientiousness, extraversion, agreeableness, or neuroticism [55,82,83]. While conscientiousness was not related to engagement in this study, it has previously been linked to positive attitudes toward practice [43]. Similarly, neuroticism showed no association with engagement here, although prior work has linked it to perceiving more barriers to practice [84,85].

Mental Health

None of the 8 mental health factors were significantly associated with engagement. Previous research has found meditation apps to be modestly effective for depression and anxiety [12,19], potentially serving as a form of self-managed treatment for individuals facing barriers to mental health care [41]. However, no such associations with mental health factors were observed in this study. In a previous study, motivation for mental health was negatively associated with app use [40]. Meditation can negatively impact mental health [86]. While these meditation-related adverse events do not always result in impairment, about half of meditators report experiencing an adverse effect, and 9.1% report functional impairment as a result [86]. Individuals who do not experience benefits or who encounter adverse effects may disengage shortly after download. Furthermore, meditating for mental health reasons has been negatively associated with the total amount of meditation practice completed over the long term [27,87]. Individuals with higher lifetime meditation practice often shift toward spiritual motivations as their practice progresses [29]. However, the retrospective design of our study limits causal inferences.

App Factors

uMARS

Five of the 6 uMARS subscales were associated with engagement. Previous research suggests that aesthetics and appeal relate to meditation app engagement [53], although in our study, aesthetics were not robustly associated after FDR correction. The Perceived Quality subscale showed the strongest association (r=0.51), indicating that user perceptions may drive both usage and beliefs in the app's effectiveness. Perceived impact was also robustly associated with engagement. Given the retrospective design, survivorship bias should be considered: users who continued using the apps likely enjoyed them, while those who did not may have stopped. It is also possible that users who experienced benefits from their chosen app developed increasingly positive app appraisals over time.

Digital Working Alliance

The DWAI-6 Goal, Bond, and Task subscales, as well as the overall score, were associated with engagement, consistent with prior findings [88]. All subscales correlated with adjusted objective minutes—the most reliable outcome measure, computed using app-verified minutes and download date—but this could only be calculated for apps that provide download dates (Headspace and Waking Up; n=151). Therapeutic alliance and engagement may promote each other [88]. While therapeutic alliance is considered important in digital mental health [89], current measures are adaptations of traditional, human-centered alliance scales. Incorporating human-computer interaction perspectives may provide greater nuance, particularly for anthropomorphic scale items [90]. Despite this limitation, therapeutic alliance with apps remains relevant to engagement, as alignment between a user's goals and perceived app support may encourage continued use.

One consideration for both the uMARS and DWAI-6 is that several subscales demonstrated relatively poor internal consistency. The reliability of the uMARS Engagement and

Subjective Quality subscales, as well as the DWAI-6 Bond and Task subscales, ranged from acceptable to poor, which reduces confidence in the constructs being measured.

Expectations for Efficacy

Higher expectations of efficacy across 6 of the 7 domains assessed (sleep, stress, anxiety, happiness, thriving, and performance enhancement) were generally associated with higher engagement, with the exception of expectations for attention/focus. Only expectations for sleep were significant in the regression model. These findings align with our predictions. Experimental and prospective studies have shown that failing to meet expectations is more predictive of behavior than matched expectations [91,92]. Unmet or low expectations negatively influence engagement and perceived usefulness, whereas met or exceeded expectations positively affect behavior and perceptions [92]. Expectations are closely linked to app ratings, as features such as goal setting and feedback enhance beliefs in an app's effectiveness [34]. These features can also foster positive experiences of progress, creating a feedback loop that promotes further engagement [33,48]. In the absence of human interaction, the relationship between a user and an app is shaped by the "user journey"—the path a user follows through the app's design. Persuasive design can help establish and meet user expectations.

A general rating of whether expectations were met was weakly associated with engagement. This result aligns with literature suggesting that matched expectations have a positive influence on behavior and mismatched expectations have a negative effect [93]. It is worth noting that we asked, "To what extent did your experience match your initial expectations?" without specifying which expectations participants should consider. Consequently, this approach may have captured only an overall impression of expectation match.

Readiness to Change

Readiness to change showed robust, moderate associations and accounted for a significant proportion of variance in the regression model. The readiness-to-change ruler used in this study is actively employed in behavior change interventions and is based on the Transtheoretical Model of Change, which conceptualizes behavior change in stages [32,94,95]. Readiness to change shows promise as one of the most predictive factors of actual behavior change, as it is conceptually closely linked to both motivation and behavior. These findings align with broader evidence connecting readiness ratings to actual behavior change, particularly in health-related contexts [63,95,96]. This relationship could inform app design, allowing offerings to be tailored to users' readiness levels. The same single-item measure used in our study could be implemented immediately after app download to tailor the length, complexity, and type of practice to users' readiness levels. For example, users with lower readiness could be offered shorter, simpler meditations or psychoeducational content about meditation to reduce perceived barriers and enhance understanding of the practice.

Self-Efficacy and App Ratings in Building Habits

Contrary to our expectations, self-efficacy was not related to engagement. Previous research on habit formation suggests that self-efficacy may support the maintenance of a target behavior before a habit is established. There is limited evidence that self-efficacy promotes habit-building [33,48,97] and increases with ongoing meditation practice [98]; however, results are mixed [99,100]. One likely reason self-efficacy did not predict engagement is that expectations, perceptions, and habit formation played larger roles. A person may believe they can achieve a goal, but if they are not committed or do not perceive long-term utility, they may lack motivation to engage. This may explain why readiness to change was associated with engagement, whereas self-efficacy was not.

Limitations

One key limitation of this study is that its retrospective design precludes causal inferences, although research on meditation app engagement is generally scarce. Additionally, we cannot confirm detailed usage patterns, such as extended gaps or cessation points; however, our estimates of sessions per month provide a rough indication of practice regularity. This study included cross-app comparisons, which few prior studies have conducted. Such comparisons are valuable, given that all therapeutic alliance subscales and half of the uMARS subscales were associated with engagement after correction for multiple comparisons. However, by not focusing on a specific app, the sample was disproportionately composed of users of the most popular apps.

Another limitation was that our most reliable outcome variable—objective minutes adjusted for verified app duration—was restricted to apps that displayed the month or year of joining. As a result, the sample for objective-adjusted minutes comprised only about one-third of the self-reported sample. Nevertheless, objective minutes were highly correlated with self-reported minutes, which may mitigate some concerns, although it is possible that individuals who can view their app-recorded minutes rely on these records when self-reporting.

Our data quality may have been influenced by self-selection, socioeconomic skew, and the compensation structure in our Prolific sample. Nevertheless, research indicates that among popular online survey platforms, Prolific consistently provides high-quality data across a wide range of measures [101]. Additionally, our data may have been skewed by the overrepresentation of the most popular meditation apps, limiting the generalizability of the findings to less popular apps or those with a narrower focus.

A final significant issue concerns what the outcome measures captured. While meditation was the central focus of the included apps, many also offer alternative exercises that contribute to the measured minutes, including—but not limited to—breathwork, sleep stories, and podcasts. This is an issue because sleep stories may continue running for hours after an individual falls asleep and be recorded as meditation. Future studies that can distinguish between different activities will provide more accurate statistics on meditation engagement.

Future Directions

A group-level comparison of engagers and disengagers could reveal cluster effects, where active users share similar characteristics. Baumel et al [4] observed a drop-off trend in a

large sample but noted that understanding precisely why people engage or disengage during this period would be of interest. While there is a high use rate among those who continue engaging beyond the first week, this represents only a small portion of users. By including all users over the past 180 days, we obtain a general picture of app use across the population; however, this approach results in a large sample of disengagers and only a small sample of active users, limiting our power to detect effect sizes within the subsample of engagers.

Longitudinal analysis could directly examine temporal and causal aspects of engagement, account for changes in contributing factors over time, and provide a clearer understanding of baseline predictors. For example, longitudinal data could track whether changes in mental health outcomes influence engagement. This study did not find any significant associations for mental health outcomes that survived multiple comparisons. However, we relied on participants' reports of mental health status following meditation app use. Apps have been shown to reduce outcomes such as stress, depression, and anxiety [12], and such changes could positively or negatively reinforce app use. Moods, circumstances, and lifestyles can fluctuate widely over extended periods. User ratings of apps using scales such as the uMARS may better explain engagement when app rating and user engagement occur close together. Longitudinal analysis also allows for baseline measurement of variables, such as expectations, which can then be compared with actual experiences at follow-up. The low proportion of variability accounted for suggests that factors outside the model have a significant impact on engagement.

Conclusions

This study aimed to explore factors influencing engagement with popular meditation apps, highlighting a substantial early drop-off. Although the models accounted for only a small proportion of overall variance, the findings emphasize the importance of user characteristics and app quality in sustaining engagement. This exploratory study aimed to examine a wide range of factors potentially relevant to meditation app engagement. The results indicated that older, more educated users, as well as those with higher expectations of apps and greater readiness to change, were more likely to engage with the apps regularly.

Acknowledgments

We acknowledge the coding contributions of Alex Burger and Karen Trapani, as well as the administrative support of Cathleen Benevento. This study would not have been possible without the support of the Contemplative Studies Centre and the Melbourne School of Psychological Sciences community at the University of Melbourne. Abstract

Background: Given the global demographic shifts and rapid digitalization, digital engagement has emerged as a critical determinant of healthy aging. While previous research has linked digital engagement to cognitive outcomes, the underlying mechanisms remain underexplored among Chinese older adults.

Objective: This study aimed to analyze the relationships between digital engagement and cognitive function among older adults in China through a moderated mediation model guided by the technological reserve hypothesis, with digital health literacy (DHL) and social support as mediators and living arrangements as a moderator.

Methods: We conducted a cross-sectional questionnaire survey using stratified multistage sampling from June to November 2024, including 8123 participants aged 55 years and older. Digital engagement, defined as older adults' use of contemporary digital technologies to support routine daily activities, autonomy, independence, and social inclusion, was assessed using a multidimensional questionnaire. The Chinese eHealth Literacy Scale, the 3-item short version of the Perceived Social Support Scale, and the Mini-Cog test were used to assess DHL, social support, and cognitive function. Guided by a directed acyclic graph based on the technological reserve hypothesis, mediation and moderated mediation analyses were performed using the PROCESS macro in SPSS (IBM Corp) with 5000 bootstrap resamples.

Results: Digital engagement was positively associated with cognitive function among older adults (β=0.241, 95% CI 0.216-0.265). This association was partially mediated by DHL (β=0.059, 95% CI 0.049-0.069) and social support (β=0.012, 95% CI 0.008-0.016), with the combined indirect effects accounting for 29.5% of the total effect (β=0.071, 95% CI 0.061-0.082). Additionally, living arrangements significantly moderated the associations between digital engagement and cognitive function (β=0.109, 95% CI 0.052-0.166), digital engagement and DHL (β=0.063, 95% CI 0.014-0.112), and digital engagement and social support (β=0.151, 95% CI 0.089-0.212). These effects were stronger among older adults living alone.

Conclusions: This study contributes to the understanding of cognitive aging in the digital environment from the perspective of the technological reserve hypothesis and digital engagement. Digital engagement influenced cognitive function via DHL and social support, and these associations of digital engagement with cognitive function, DHL, and social support were stronger among older adults living alone. Digital health interventions and public health policies should target both DHL and social support among older populations and prioritize older adults living alone.

Introduction

Background

Cognitive function is a critical determinant of dementia, functional independence, quality of life, and health care burden [1]. With an increasingly aged population, cognitive impairment and dementia have become major health and social issues worldwide [2]. Research has indicated that there are about 15.07 million patients with dementia in the population aged 60 and older in China, while the prevalence of mild cognitive impairment is 15.54%, and the number of patients is 38.77 million [3]. The disease burden of dementia and cognitive impairment is huge. The estimated total annual costs of dementia in China will reach 114.2 billion US dollars in 2030 [4]. Since there is currently no effective pharmaceutical treatment for dementia and mild cognitive impairment, it is important to identify modifiable intermediate risk factors that could prevent cognitive decline [5].

With rapid digitalization and the widespread integration of technology into daily life, digital technologies have emerged as a potential determinant of healthy aging. In China, as of 2025, the number of internet users aged 60 and older has reached 161 million, accounting for nearly 14.4% of all internet users [6]. Many studies have indicated that older people are competent and skilled users of digital technologies [7-9]. Consequently, the concept of digital engagement has been introduced to emphasize the breadth and extent of digital technology use among older people [10]. Every day, digital engagement provides new opportunities for older adults to address age-related cognitive decline. Engagement in cognitively challenging activities, such as learning new digital skills or knowledge, plays a protective role against age-related cognitive decline [11,12]. Meanwhile, access to communication technology and social media facilitates interpersonal interactions and enhances social support [13], which helps maintain cognitive health in older adulthood.

Against this background, exploring the association between digital technology use and cognitive health in later life has become an important research focus. However, the cognitive impact of digital technology use in China has not been sufficiently studied and understood [7,14]. First, research has focused on how access to the internet relates to cognitive function and the associations between use frequency in specific domains and cognitive outcomes [8,15-17]. Many studies in China have investigated the effect of internet or social media use on cognitive function [18,19]. But limited studies give attention to the concept of digital engagement [20] and comprehensively measure the dimensions and frequency of digital technology use. As digital technologies have become increasingly integrated into older adults' daily lives, it is important to shift research focus from use to meaningful digital engagement to better understand the cognitive effects of digital technology use [7].

Second, although evidence has established the efficacy of digital health interventions for cognitive decline and cognitive impairment, including dementia [21-23], little is known about how they lead to an improvement in symptoms or behavior. The identification of these mediating mechanisms would be useful for tailoring interventions that specifically target these pathways, improving intervention effectiveness. Some studies in China have estimated the mediating roles of physical activity [14] and social support [20,24]. However, few studies have simultaneously examined the roles of multiple mediators. Including multiple mediators can better reflect real-world mechanisms, help understand the relative importance of different intervention pathways, and reduce bias [25].

Third, while digital technologies become increasingly integrated into older adults' everyday life, growing urbanization and economic reforms in China have transformed intergenerational living arrangements patterns [26]. However, limited studies in China have examined how the association between digital technology use and cognitive function may vary by living arrangements. As the number of older adults living alone in China increases, examining the moderating role of living arrangements in this association is meaningful for developing targeted interventions.

The technological reserve hypothesis provides a theoretical framework for addressing these gaps. This hypothesis, developed by Benge and Scullin, focuses on how digital technology use can counteract cognitive decline and reduce disease burden [27-29]. Technological reserve is defined as "the development of a culture and environment of technology use in older adults that can buffer against the impact of cognitive decline on day-to-day activities" [27]. Further study developed the technological reserve concept and summarized 3 central pathways through which digital technology may prevent cognitive decline [28,30]. First, technology can generate cognitive complexity by engaging older adults in cognitively demanding activities that strengthen cognitive reserve [12,31,32]. By enabling access to diverse information sources (eg, online health information), promoting mentally stimulating activities, and requiring continual learning and adaptation, digital technologies help sustain and challenge cognitive capacities [33]. Second, technology fosters social connection and engagement, which are well-established protective factors against cognitive decline [34]. Through platforms such as social media, messaging apps, and video calls, older adults can maintain social ties, reduce loneliness, and access emotional and instrumental support. Finally, technologies can function as cognitive prosthetics by directly compensating for lapses in memory and executive function, particularly those involved in completing activities of daily living. For example, smartphone apps can deliver reminders for medication adherence [35].

Guided by the technological reserve hypothesis, this study aimed to examine the mediating effect of digital health literacy (DHL) and social support on the relationship between digital

engagement and cognitive function, as well as the moderating effect of living arrangements on the relationships among digital engagement, DHL, social support, and cognitive function.

Theoretical Framework

Digital Engagement and Cognitive Function

Within the technological reserve framework, digital technology use as a modifiable lifestyle behavior is a critical factor that can promote better cognitive outcomes than would be expected based on age, brain injury, or disease stage [30]. In this study, we adopted the term "digital engagement" to define digital technology use among older adults. Digital engagement among older adults refers to their use of contemporary digital technologies and devices to carry out routine and enjoyable everyday activities that support autonomy, independence, and social inclusion [8]. This concept emphasizes how older adults integrate information and communication technologies into daily activities and information-seeking behaviors rather than focusing on limitations [36]. Research has investigated the potential association between digital engagement and cognitive function among older adults. Although some studies suggest potential risks such as sleep disruption or social isolation [37-39], the prevailing evidence supports that digital engagement is positively linked to cognitive function [26,40,41]. Empirical findings generally suggest that regular use of digital technologies (such as social media and online social networking) is positively associated with better cognitive outcomes [42-44]. These benefits are often attributed to increased cognitive stimulation, enhanced social connectivity, and greater engagement in mentally active tasks afforded by digital technology [45,46]. Longitudinal studies further suggest that consistent internet use is associated with slower cognitive decline and a lower subsequent risk of dementia compared with nonuse [47,48]. Meta-analyses of randomized controlled trials also support the effectiveness of digital interventions in improving specific cognitive domains [49,50]. Despite growing evidence, the mechanisms through which digital engagement benefits cognition remain insufficiently understood.

The Mediating Role of DHL

DHL is the ability to seek, understand, evaluate, and apply health information from digital sources to support health-related decision-making [51]. Within the technological reserve framework, DHL can strengthen cognition by engaging older adults in cognitively demanding processes such as evaluating online resources, learning new digital skills, and applying health information in daily life. These processes involve active learning, adaptive reasoning, and problem-solving, which are consistent with mechanisms that sustain cognitive reserve [30]. Moreover, empirical studies support this pathway. Higher DHL is associated with greater adoption of preventive health behaviors, better management of chronic conditions, improved adherence to treatment, and more informed health decisions [52-55]. Such behaviors not only enhance health outcomes but also contribute to maintaining and preserving cognitive function in later life. Thus, DHL may mediate the association between digital engagement and cognitive function.

The Mediating Role of Social Support

Within the technological reserve framework, another plausible pathway operates through social connectivity. Social connectivity refers to the structural and functional aspects of individuals' social relationships, and in later life, is often reflected through social support received from their networks [56-58]. Socioemotional selectivity theory points out that social participation requires a certain cost investment, and members who engage in social participation are bound to consider cost-benefit issues [59]. For older adults, declining physical and cognitive abilities raise the cost of offline social participation, leading to a gradual reduction in face-to-face interactions [60]. Digital technologies offer alternative and more accessible avenues for maintaining social support [61]. Some empirical studies have shown that digital engagement is positively associated with increased social support in later life [61-63]. Social support, in turn, is a well-established protective factor for cognitive function: Older adults with stronger support networks tend to perform better cognitively and face a lower risk of cognitive decline or dementia [64-66]. Thus, social support may serve as a mediator linking digital engagement to cognitive outcomes.

The Moderating Role of Living Arrangements

Economic reforms and urbanization in China since the 1980s have profoundly reshaped family structures, particularly impacting older adults. This shift aligns with modernization theory, predicting smaller families and fewer older adults co-residing with children [67]. Consequently, more older adults live only with a spouse or alone [68]. Given the central role of family in Chinese culture, the study shifted to investigate the moderating role of living arrangements. Within the framework of the technological reserve hypothesis, the cognitive benefits of digital engagement are expected to vary across social contexts that shape baseline access to cognitive and social resources. Living arrangements represent a contextual factor in later life, as co-residence with others may provide routine cognitive stimulation and social interaction, whereas living alone is often associated with reduced offline engagement. Consequently, digital engagement may play a more pronounced compensatory role for older adults living alone by supplementing limited in-person cognitive and social resources. This theoretical perspective provides a rationale for examining living arrangements as a moderator in the association between digital engagement and cognitive function. Additionally, living arrangements may shape both the opportunities and the need for engaging with digital technology [69]. Older adults living alone often rely on digital technologies to maintain social ties, bridge social gaps, and manage independent living [70,71]. In contrast, those in multigenerational households may experience "proxy internet use" (eg, reliance on family members for online tasks), reducing direct engagement and the attendant cognitive stimulation [72]. Digital engagement may therefore be especially protective for those living alone.

Hypotheses

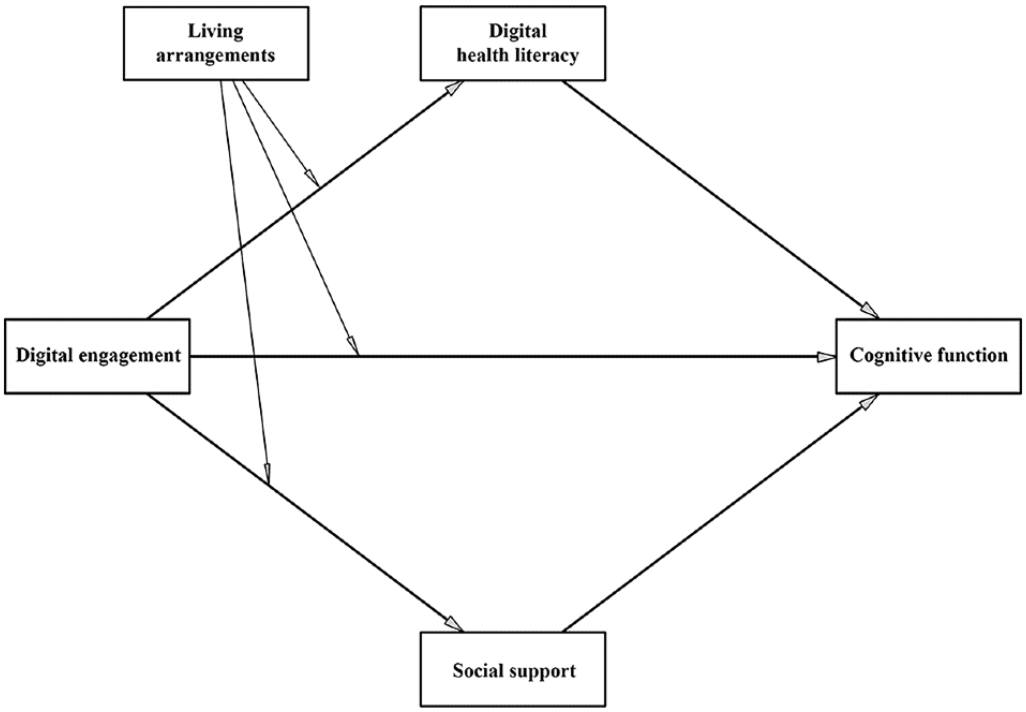
Guided by the technological reserve hypothesis, this study tested a moderated mediation model to examine whether digital engagement is associated with cognitive function through DHL

and social support, and whether these pathways are moderated by living arrangements. Based on the theoretical framework and prior empirical evidence, we propose the following hypotheses:

1. Hypothesis 1: higher digital engagement is correlated with greater cognitive function among older adults.
2. Hypothesis 2: higher digital engagement is associated with higher DHL among older adults.
3. Hypothesis 3: higher DHL is correlated with greater cognitive function among older adults.
4. Hypothesis 4: DHL is a mediator between digital engagement and cognitive function among older adults.
5. Hypothesis 5: higher digital engagement is associated with greater social support among older adults.
6. Hypothesis 6: greater social support is correlated with greater cognitive function among older adults.
7. Hypothesis 7: social support is a mediator between digital engagement and cognitive function among older adults in China.
8. Hypothesis 8: living arrangements moderate the associations of digital engagement with cognitive function, DHL, and social support.

To guide the analyses, we specified a directed acyclic graph (DAG) illustrating the hypothesized relationships among digital engagement, cognitive function, DHL, social support, and living arrangements (Figure 1).

Figure 1. The hypothesized moderated mediation model.



Methods

Study Design and Sampling Procedures

This study used data collected through a large-scale, cross-sectional survey conducted concurrently by 5 academic teams affiliated with 4 major universities in China. To ensure methodological uniformity, all participating sites adhered to a unified research protocol during the implementation phase.

A stratified, multistage sampling framework was used to enhance representativeness across regions with different levels of socioeconomic development. China was first stratified into eastern, central, and western regions, which reflect well-documented gradients in economic development, urbanization, and digital infrastructure. One to 2 provinces were randomly selected from each region. The final sample included Hubei (central China), Shandong and Jiangsu (eastern China), and Guangxi (western China), thereby capturing substantial regional heterogeneity in demographic structure and digital development. Within each selected province, 1 to 2 urban or county-level administrative units were further sampled based on local economic conditions, followed by cluster sampling of communities or villages.

Sample size estimation followed the standard formula for proportion-based calculations:  , where u_α represents the critical value for a 95% CI (u_α=1.96), p is the estimated proportion of older internet users based on the China Internet Network Information Center's 51st Statistical Report [73], *q* is the complementary proportion (*q*=1–p), and *d* denotes the allowable error (1.2%). Based on these parameters, the minimum required sample size was calculated as 6616. To account for possible nonresponses and invalid questionnaires, a 20% oversampling rate was applied, resulting in a target sample of approximately 7940 individuals.

Data Collection and Quality Control

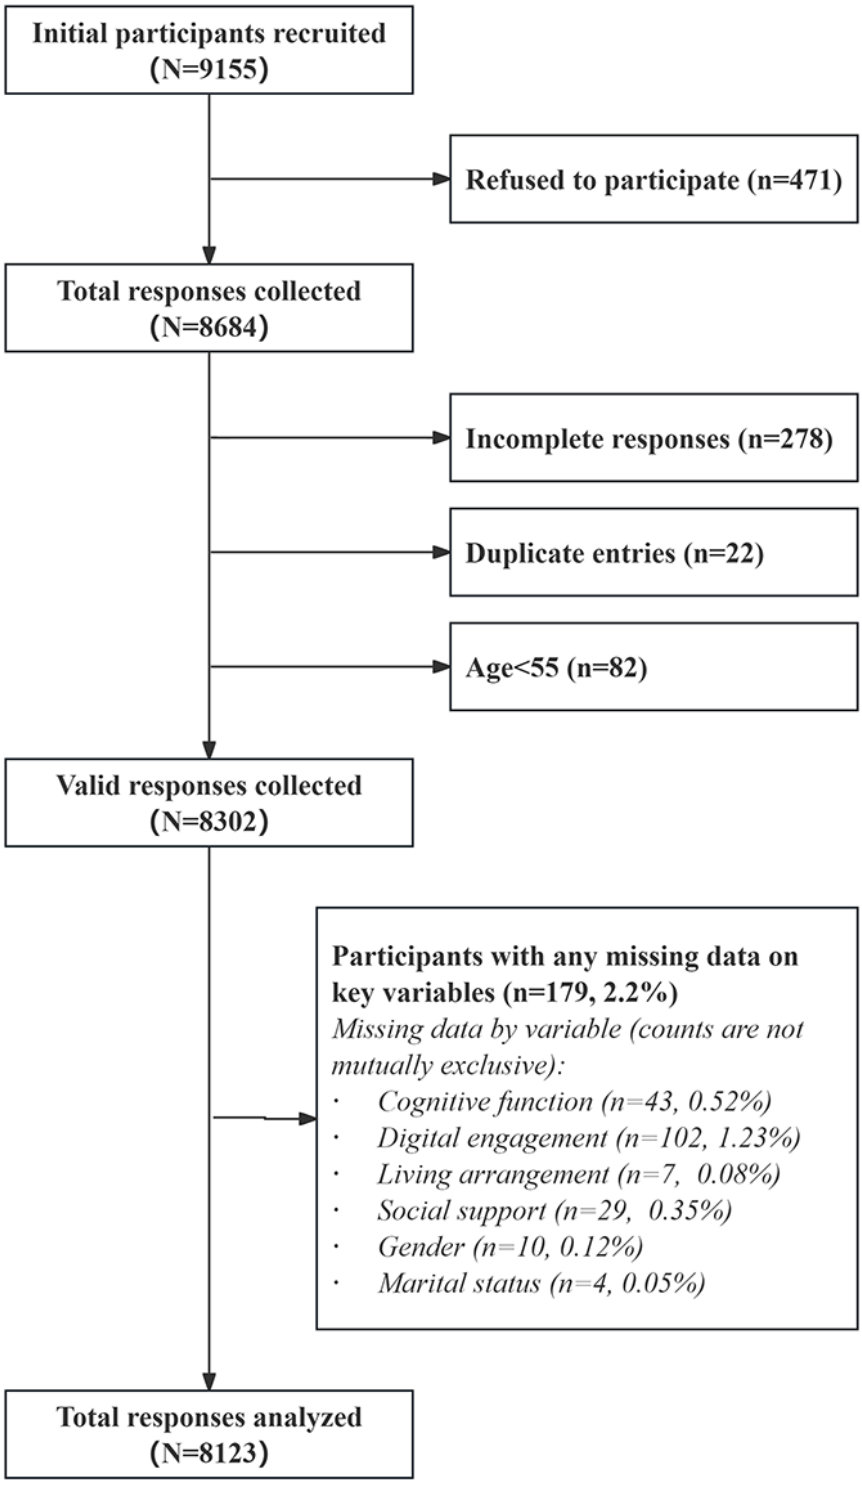
Fieldwork was conducted from June to November 2024 by trained surveyors in collaboration with local village committees or community service offices. Face-to-face interviews were

administered at participants' homes using standardized paper questionnaires. The interviews collected information on sociodemographic characteristics, digital technology use, digital literacy, cognitive function, and quality of life. All surveyors received centralized training to ensure consistent questionnaire administration and interpretation. Upon completion of each interview, field supervisors performed a thorough review of the questionnaires to check for completeness, internal consistency, and data accuracy before submission for entry.

Participants

Eligible participants were older adults who met the following inclusion criteria: (1) aged 55 years and older, (2) had resided in the sampled community or village for at least 6 months, and (3) were able to communicate effectively with investigators. Exclusion criteria included: (1) individuals temporarily absent from their households during the survey period, (2) those diagnosed with terminal illnesses, and (3) those who declined to participate. After excluding incomplete responses, duplicate entries, and respondents younger than 55 years, 8302 valid questionnaires remained. Among these, 179 participants (2.2%) had missing values on at least 1 analytic variable and were excluded from the main analyses. The final analytic sample consisted of 8123 participants (Figure 2).

Figure 2. Flow diagram of participant recruitment and data exclusion, resulting in a final analytic sample of N=8123.



Measurements

Cognitive Function

Cognitive function was assessed using the Mini-Cog test. The Mini-Cog test is a rapid, valid, and reliable screening tool for cognitive impairment [74]. The Mini-Cog Test includes a 3-word recall task (scored 0-3) and the clock drawing test (scored 0-2). The total score ranges from 0 to 5. The Mini-Cog test has demonstrated good screening performance in community-dwelling older adults in China [75]. In this study, the Mini-Cog total score was used as a continuous measure of cognitive function, with higher scores indicating better cognitive performance.

Digital Engagement

Digital engagement was measured using a self-reported scale developed to capture older adults' frequency of participation in various digital activities. The scale included eight items of

digital behaviors: (1) social communication (eg, using WeChat [Tencent] voice or video calls), (2) experience sharing (eg, posting on WeChat Moments, QQ Zone [Tencent], or Weibo [Sina Corporation]), (3) leisure and entertainment (eg, playing online games, listening to music, or watching videos), (4) online transactions (eg, transferring money, making payments, booking services, or trading stocks), (5) information seeking (eg, searching for travel information or reading news), (6) online learning or training, (7) online civic participation (eg, participating in online polls, petitions, or rights protection), and (8) political engagement (eg, online voting or leaving messages on government websites). Participants rated the frequency of each activity on a 5-point Likert scale ranging from 1 (never) to 5 (always). Higher scores indicated higher digital engagement. The scale demonstrated good internal consistency in this sample (Cronbach α=0.876). Although the scale covers multiple items of digital activities, this study conceptualized digital engagement as an overall behavioral tendency reflecting the breadth and extent of digital technology use in daily life. This approach is consistent with the technological reserve hypothesis and the concept of digital engagement, which emphasize cumulative and sustained engagement. Therefore, a composite digital engagement score was used in the analyses.

DHL

DHL was assessed using the eHealth Literacy Scale (eHEALS), a widely validated instrument developed by Norman and Skinner to measure individuals' self-perceived skills in locating, evaluating, and applying electronic health information to health-related problems [51]. The eHEALS consists of 8 items rated on a 5-point Likert scale (1=strongly disagree to 5=strongly agree), reflecting domains such as awareness of available online health resources, confidence in using the internet for health decision-making, and the ability to discern high-quality digital health content. Given the linguistic and cultural differences between the original instrument and the target population of older adults in mainland China, we used the simplified Chinese version (C-eHEALS) translated and validated by Ma and Wu [76]. The C-eHEALS has been confirmed to have good psychometric properties and can therefore be used to evaluate eHealth literacy in Chinese older populations [77]. In this study, the C-eHEALS demonstrated excellent internal consistency, with a Cronbach α coefficient of 0.986, indicating high reliability for use among Chinese older adults.

Social Support

Social support was assessed using the 3-item short version of the Perceived Social Support Scale (PSSS-3), which was developed and validated by Wu et al [78] specifically for use among the Chinese general population. This abbreviated scale was derived from the original 12-item Chinese version of the Multidimensional Scale of Perceived Social Support (MSPSS), originally adapted by Jiang [79] from the version developed by Zimet et al [80]. The PSSS-3 includes 1 item from each of the 3 core dimensions, family support, friend support, and significant others, selected based on the highest factor loadings in a large-scale national sample. The Cronbach α of PSSS-3 in this study was 0.868, demonstrating good internal consistency.

Living Arrangements

Living arrangements were measured as a binary variable indicating whether the older adult lived alone, and were assessed using the following question: "What are your current living arrangements?" Those who reported living alone were coded as 1, and those who reported living with others were coded as 0.

Control Variables

The prior study indicates that demographic and health factors have close links with cognitive function and suggests that these factors should be included in pertinent research [81]. In this study, gender, age, current place of residence, marital status, education, and number of chronic diseases were controlled as covariates.

Statistical Analysis

All analyses were performed using SPSS (version 27; IBM Corp). We first examined the extent and pattern of missing data for all analytic variables. The proportion of missing values for each variable ranged from 0.08% to 1.2% and the overall proportion of missing data was 2.2% (Figure 2). Little's Missing Completely at Random test was conducted using the missing value analysis procedure in SPSS 27. The test indicated that the missing values were independent of the observed or unobserved values (χ^2=14.893; *P*=.06). Given the low proportion and completely random patterns of missingness, we performed complete-case analyses based on listwise deletion.

Descriptive statistics summarized sample characteristics, with continuous variables reported as mean (SD) and categorical variables as frequencies and percentages. Pearson correlations examined associations among digital engagement, cognitive function, DHL, social support, and living arrangements. Multicollinearity was assessed by the variance inflation factor (VIF), with VIF>5 indicating collinearity. The relationships among variables were specified according to a DAG based on the technological reserve hypothesis (Figure 1) and analyzed using PROCESS models 4 and 8 with 5000 bootstrapped resamples. Effects were considered significant if the 95% bias–corrected CI did not include 0. All models controlled for age, gender, current place of residence, marital status, education, and number of chronic diseases. Continuous variables were standardized prior to analysis. Statistical tests were 2-tailed with α=.05.

Ethical Considerations

The study was reviewed and approved by the Medical Ethics Committee of Zhongda Hospital, Southeast University (approval number 2024ZDSYLL294-Y01). Written informed consent was obtained from all participants before they participated in the study, and they were provided with the opportunity to withdraw at any time during and after the survey. To protect privacy and confidentiality, electronic data were de-identified and stored on password-protected devices accessible only to the research team. No images or supplementary materials in this manuscript contain information that could identify individual participants. There was no compensation for the participants in our study survey.

Results

Demographic Characteristics of the Participants

The final sample consisted of 8123 older adults, with an average age of 71.03 (SD 8.39) years. Men accounted for 42.46% (3449/8123) of the participants. Among the participants, 3990 (49.12%) lived in urban areas, and 4133 (50.88%) lived in rural areas. Most respondents were married (6338/8123, 78.03%), and 51.73% (4202/8123) of the participants had attained a middle school education or above. Overall, 75.28% (6115/8123) of the participants reported at least 1 chronic condition. Summary statistics for main variables, including digital engagement, DHL, social support, living arrangements, and cognitive function, are presented in Table 1.

Table 1. Participant characteristics and descriptive statistics for study variables (N=8123).

Variables	Values
Sex, n (%)

Preliminary Correlation Analysis

Table 2 presents the Pearson correlation coefficients among the main variables. Digital engagement was significantly and positively correlated with cognitive function (r=0.365, P<.001), social support (r=0.081, P<.001), and DHL (r=0.575, P<.001), but negatively associated with living arrangements (r=–0.101, P<.001). Cognitive function was also positively correlated with social support (r=0.131, P<.001) and DHL (r=0.347, P<.001), and negatively correlated with living arrangements (r=–0.069, P<.001). VIFs indicated no multicollinearity among digital engagement (VIF=1.732), DHL (VIF=1.666), social support (VIF=1.027), living arrangements (VIF=1.823), and cognitive function.

Mediation Analysis

Guided by the DAG-specified conditional process model, we first used model 4 of the PROCESS macro for SPSS [82] to test Hypotheses 1 to 7. The total effect of digital engagement on cognitive function was 0.241 (95% CI 0.216-0.265), of which the direct effect accounted for 70.5% (β=0.170, 95% CI 0.143-0.196) and the combined indirect effects by DHL and social support accounted for 29.5% (β=0.071, 95% CI 0.061-0.082). The findings indicated a moderate but statistically meaningful mediation by DHL and social support.

Table 3 and Figure 3 present the results of the mediation analysis. As shown in model 3, the direct effect of digital engagement on cognitive function was significant (Model 3: β=0.170, 95% CI 0.143-0.196; *P*<.001), thus supporting Hypothesis 1. Digital engagement also demonstrated a significant and positive association with DHL (Model 1: β=0.400, 95% CI 0.379-0.420; *P*<.001), supporting Hypothesis 2. Additionally, DHL was significantly and positively related to cognitive function (Model 3: β=0.148, 95% CI 0.123-0.174; *P*<.001), supporting Hypothesis 3. Furthermore, digital engagement was positively and significantly correlated with social support (Model 2: β=0.129, 95% CI 0.103-0.155; *P*<.001), supporting Hypothesis 5. Social support, in turn, showed a significant and positive correlation with cognitive function (Model 3: β=0.091, 95% CI 0.071-0.112; *P*<.001), supporting Hypothesis 6.

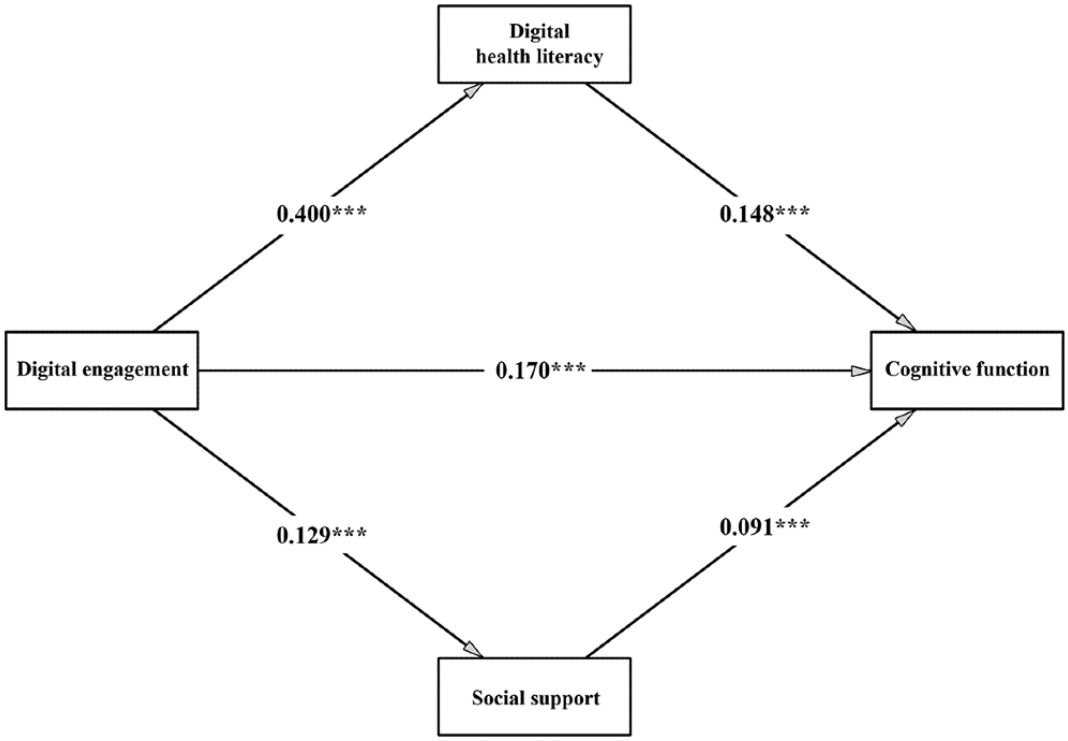
Figure 3. Mediation model of the association between digital engagement and cognitive function through digital health literacy and social support; values are standardized coefficients adjusted for covariates (PROCESS Model 4; N=8123; ***P<.001).



These findings suggest that DHL and social support play a partial mediating role in the relationship between digital engagement and cognitive function, with indirect effects of 0.059 (95% CI 0.049-0.069) and 0.012 (95% CI 0.008-0.016), respectively, supporting Hypotheses 4 and 7. Combining 2 mediation effects, the total indirect effect was 0.071 (95% CI 0.061-0.082). The bootstrap test results for indirect effects are reported in Table 4.

[d]SS: social support.

Moderated Mediation Analysis

To examine the moderated mediation effects involving living arrangements, we used Model 8 of the PROCESS macro for SPSS [82], using 5000 bootstrap resamples and a 95% bias-corrected CI. The results are reported in Table 5. The analysis revealed a significant and positive interaction effect between digital engagement and living arrangements on cognitive function (Model 6: β=0.109, 95% CI 0.052-0.166; P<.001), suggesting a moderating role of living arrangements. As illustrated in Figure 4, the beneficial association between digital engagement and cognitive performance was stronger among older adults who lived alone, relative to those who lived with others.

Table 5. Moderated mediation analysis testing moderation by living arrangements in the associations between digital engagement and digital health literacy, digital engagement and social support, digital engagement and cognitive function, adjusted for covariates (PROCESS Model 8; N=8123).

[b]DHL: digital health literacy.

[c]$F_{9, 8113}$=53.680; R^2=0.056.

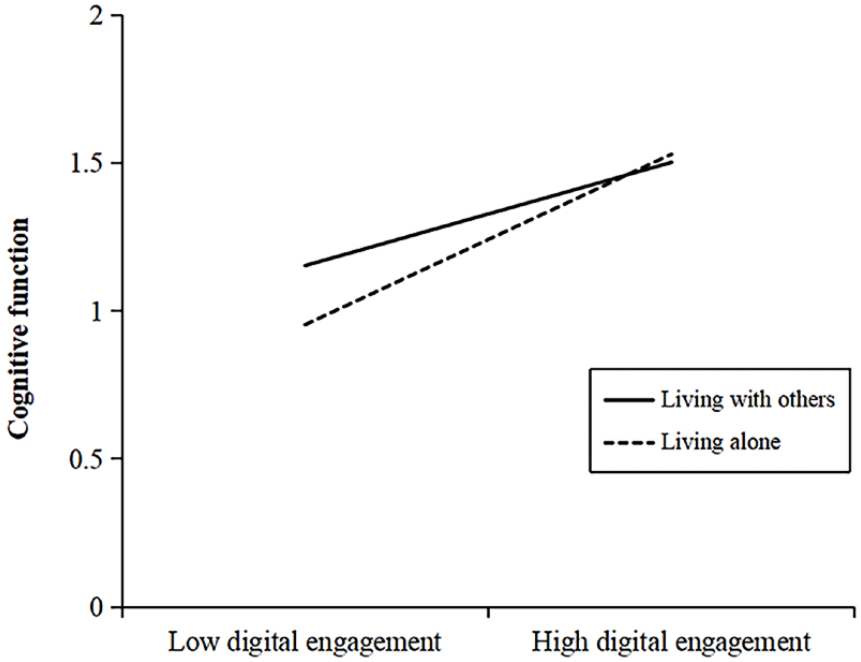
[d]$F_{11, 8111}$=178.558; R^2=0.195.

[e]β: standardized regression coefficient.

[f]Not applicable.

[g]DE×LA: the interaction term between digital engagement and living arrangements.

Figure 4. The moderating effect of living arrangements on the association between digital engagement and cognitive function. The difference in simple slopes indicated that the association between digital engagement and cognitive function was significantly stronger for individuals living alone than for those living with others (PROCESS Model 8, N=8123).



In addition to the interaction effect on the direct path, the results also revealed significant moderating effects of living arrangements on the first stages of both mediation pathways. Specifically, the interaction term between digital engagement and living arrangements significantly predicted DHL (Model 4: β=0.063, 95% CI 0.014-0.112; *P*=.01 and social support (Model 5: β=0.151, 95% CI 0.089-0.212; *P*<.001). As illustrated in Figures 5 and 6, the beneficial association of digital engagement with both DHL and social support was stronger among older adults who lived alone, relative to those who lived with others. These findings indicate that living arrangements moderate the associations of digital engagement with cognitive function, DHL, and social support, supporting Hypothesis 8.

Figure 5. The moderating effect of living arrangements on the association between digital engagement and digital health literacy. The difference in simple slopes indicated that the association between digital engagement and digital health literacy was significantly stronger for individuals living alone than for those living with others (PROCESS Model 8, N=8123).

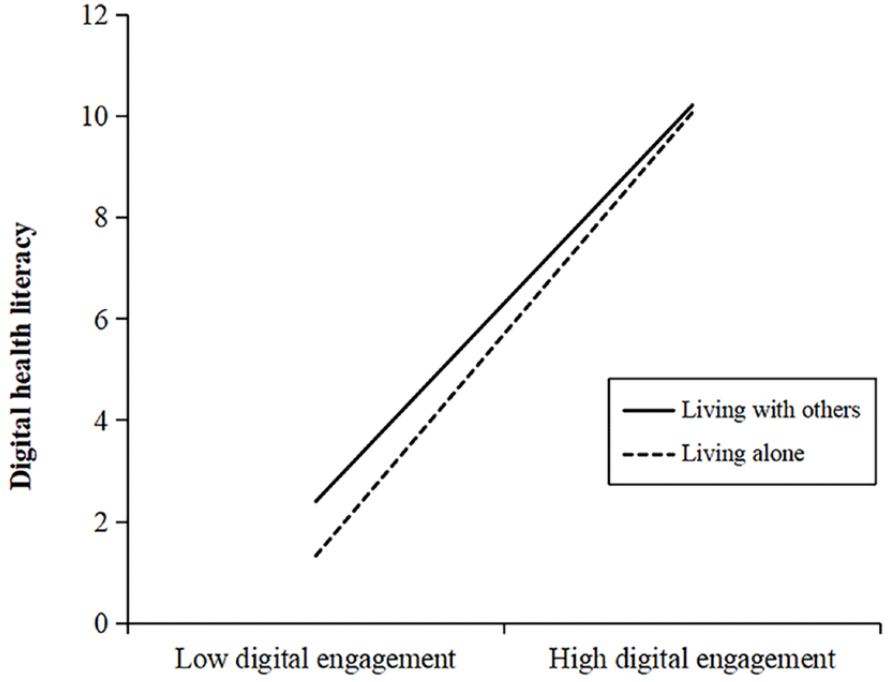


Figure 6. The moderating effect of living arrangements on the association between digital engagement and social support. The difference in simple slopes indicated that the association between digital engagement and social support was significantly stronger for individuals living alone than for those living with others (PROCESS Model 8, N=8123).

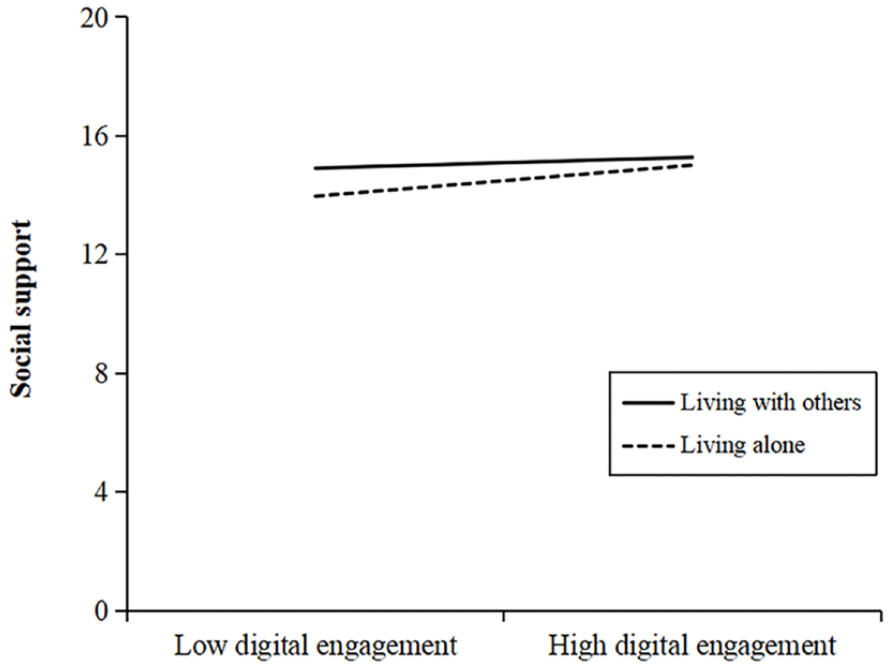

Table 6 reports the conditional indirect effects of digital engagement on cognitive function by each path. For the DHL mediator, the indirect effect of digital engagement on cognitive function was 0.057 (95% CI 0.048-0.068) among participants living with others and 0.067 (95% CI 0.054-0.080) among those living alone. The corresponding index of moderated mediation was 0.009 (95% CI 0.003-0.016), indicating a significantly stronger indirect effect by DHL for participants living alone. Similarly, for the social support mediator, the indirect effect was 0.010 (95% CI 0.007-0.013) for those living with others and 0.023 (95% CI 0.016-0.032) for those living alone. The index of moderated mediation for the social support pathway was 0.013 (95% CI 0.007-0.021). In all cases, the 95% CI values excluded zero, indicating that both indirect effects were significantly stronger among older adults living alone.

Table 6. Indices of moderated mediation for two conditional indirect effects of digital engagement on cognitive function by living arrangements (PROCESS Model 8; N=8123).

Conditional indirect effects path	Effects	SE	95% CI
DE[a]→DHL[b]→CF[c] (living with others)	0.057	0.006	0.048-0.068

[a]DE: digital engagement.

[b]DHL: digital health literacy.

[c]CF: cognitive function.

[d]SS: social support.

Discussion

Principal Findings

Guided by the technological reserve hypothesis and using a large, community-based sample of older adults in China, this study investigated the mechanisms underlying the association between digital engagement and cognitive function among older Chinese adults. We found that higher digital engagement was associated with better cognitive performance. DHL and social support partially mediated this association, and the combined indirect effects accounted for 29.5% of this association. Living arrangements moderated both the direct and indirect pathways, with stronger benefits among older adults living alone. These findings extend prior work on technology use and cognition in later life and broaden the application of the technological reserve hypothesis in the Chinese context.

The Association Between Digital Engagement and Cognitive Function

Digital engagement was significantly and positively associated with cognitive function. This supports the technological reserve hypothesis that digital technology use is a modifiable behavioral factor that can promote better cognitive outcomes [30]. It also aligns with prior work linking internet or computer use to cognition [83-88] and with recent studies in China demonstrating that internet use and digital activities enhance cognitive function [14,47]. By adopting the construct of digital engagement rather than a simple use-versus-nonuse dichotomy, our study advances the field by situating technology use within the everyday life context of older adults, emphasizing how they integrate information and communication technologies into their ongoing activities, social interaction, and information seeking [36]. This finding implies that encouraging sustained and meaningful digital engagement is a promising strategy for public health and aging policies aiming to strengthen cognitive function among older adults.

The Mediating Role of DHL and Social Support

Consistent with the cognitive-stimulation pathway posited by the technological reserve hypothesis, higher digital engagement was associated with higher DHL, which in turn related to better cognitive performance [28,30]. Notably, the DHL pathway accounted for the majority of the total indirect effect, indicating that health-related digital competencies may be a primary mechanism linking engagement to cognition. Specifically, engaging with digital technology improves DHL because digital skills are among the core skills of DHL [89,90]. In turn, higher DHL denotes a stronger capacity to seek, understand, appraise, and apply health information [91]. These processes involve engaging with cognitively complex information [30], helping older adults build cognitive reserve. This finding advances the eHealth Literacy Model, which posits that DHL is underpinned by cognition [92], and indicates that DHL also serves as a tool that shapes cognition through ongoing, cognitively complex digital activities. Accordingly, interventions should combine user-friendly interfaces with structured, progressive training in cognitively complex digital tasks, ensuring that everyday digital engagement serves as sustained cognitive stimulation. Practical examples include stepwise smartphone or tablet training delivered in community settings (eg, locating health information from reliable sources, evaluating credibility and misinformation, and applying information to everyday self-management tasks).

Social support mediated the association between digital engagement and cognition, consistent with the social-connectivity pathway [28,30]. This finding aligns with previous research showing that digital engagement has the potential to enhance cognitive function among older individuals by addressing feelings of loneliness and improving the social support they receive from relatives and friends [20]. Specifically, digital engagement enables cheap and easy communication between older adults in distant communities, increasing social connections, overcoming social and spatial barriers, and providing a convenient way to stay in touch with families, friends, and the outside world [62]. In turn, better social support is associated with better cognitive outcomes in older adults [65,93-96]. This finding underscores that interventions should help older adults form and maintain digital social ties so that online interactions translate into perceived social support and, ultimately, better cognitive outcomes. For example, programs could incorporate facilitated online peer groups and a “Digital Buddy system” to help older adults translate online interactions into perceived support [97].

The Moderating Role of Living Arrangements

Our study further revealed that living arrangements played a significant moderating role in the associations of digital engagement with cognitive function, DHL, and social support. Compared with older adults who live with others, those living alone experienced a significantly stronger positive effect of digital technology engagement on cognitive function, consistent with the previous studies [26,98]. This moderating effect was significantly present in both mediating pathways: older adults living alone gained greater benefits in terms of DHL and social support from digital engagement than those living with others. Specifically, older adults living alone, due to a lack of effective offline social interactions, are more reliant on virtual social networks facilitated by digital technologies [60]. This reliance partially compensates for the reduced social support associated with solitary living, thereby mitigating its negative impact on cognitive function [70]. Additionally, older adults who live alone are less likely to engage in proxy internet use [72] and thus rely more on themselves to use digital devices (eg, searching for health information online). Furthermore, since older adults living alone are less often burdened with caregiving responsibilities for grandchildren, they have more freedom and time to engage with digital technologies [26]. Our findings suggest that digital engagement serves as a more efficacious strategy for mitigating cognitive decline among older adults living alone compared to those living with others.

Our finding is broadly consistent with other international evidence. A cohort study in America reported that transitioning into Internet use was associated with better cognitive function and slower cognitive decline, and that these benefits were more pronounced among older adults living alone than among those living with others [84]. Additionally, a 2-country longitudinal study in Sweden and the Netherlands observed less decline in global cognition among baseline internet users after adjustment for living situation [86]. Beyond cognitive outcomes, findings based on the Survey of Health, Ageing and Retirement in Europe further indicate that internet use can attenuate the association between living alone and loneliness across different European welfare regimes, implying that digital engagement may buffer psychosocial vulnerabilities of solitary living [99]. Taken together, although the prevalence and social meaning of living alone differ across cultures, converging evidence supports that digital engagement may serve as a compensatory resource for older adults with constrained offline or household-based support.

This moderation finding has practical implications for intervention design. Digital inclusion initiatives to help older people adapt to digital technologies should prioritize this vulnerable group. An integrated community-based approach may be especially useful: individual digital coaching (eg, guided practice in health information seeking) coupled with structured

social support (eg, online group chats). Including a "living alone" priority within such initiatives may help maximize equity and potential cognitive benefits, while also addressing social isolation risks that have been recognized as a public health and policy concern.

Limitations and Future Research

Despite these contributions, several limitations should be acknowledged. First, the cross-sectional design precludes causal inferences. Although our models adjusted for a set of covariates, endogeneity, reverse causation, and unmeasured confounding cannot be fully ruled out. Thus, our results only show associations, not causality. Future studies should use longitudinal designs with extended follow-up periods to elucidate temporal dynamics and disentangle potential reverse causation. Second, reliance on self-reported measures introduces the risk of recall bias, especially among participants with cognitive impairments, despite our use of validated instruments to attenuate this issue. Third, digital engagement was operationalized as a composite measure. Thus, this study could not disentangle potentially differential effects of specific types of digital activities on cognitive function. Finally, due to data constraints, living arrangements were operationalized as solitary versus nonsolitary living, precluding differentiation among various household compositions (eg, living with a spouse, children, or extended family). Given the important role of family structures in the well-being of older adults in China, future research should refine classifications of living arrangements to better explore their moderating effects.

Conclusions

This study contributes to the understanding of cognitive aging in the digital environment from the perspective of the technological reserve hypothesis and digital engagement. First, it offers an innovative framework based on the technological reserve hypothesis for understanding the moderating and mediating mechanisms of DHL, social support, and living arrangements. Second, it advances previous assessment methods of digital technology application by using a comprehensive measure. Our results increase understanding of the mechanisms underlying the cognitive effects of digital technology use and provide insights for designing digital health interventions and public health policies.

Acknowledgments

The authors would like to express their sincere gratitude to all participants in this study, as well as to the staff of the community and village committees who facilitated the fieldwork. This study was supported by the Major Project of the National Social Science Fund of China (grant number 23&ZD188). The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Funding

No external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to restrictions under existing Data Use Agreements, but are available from the corresponding author on reasonable request.

Abstract

Background: The North Central London (NCL) Cancer Alliance carried out a quality improvement (QI) project to fill a distinct knowledge gap regarding the quality of clinical coded data in a primary care electronic health care record system across the whole cancer pathway.

Objective: This study aims to establish the quality of cancer-related clinical coding in NCL primary care, encompassing both quantitative measures (eg, coding completeness and diversity) and qualitative dimensions such as clinical relevance and workflow alignment.

Methods: This was a mixed methods QI project in which we combined an observational dataset review and qualitative data from stakeholder interviews, workshops, and discussions. In the dataset review, we evaluated completeness, diversity, validation, and granularity in cancer clinical coding along the patient cancer pathway, which was split into three domains: (1) patient characteristics and risk factors, (2) cancer screening attendance, and (3) living with cancer. It was conducted in NCL primary care electronic health record systems, covering a population of over 1.4 million adults across 5 boroughs.

Results: Cancer-related clinical coding in NCL primary care revealed significant gaps despite high completeness for ethnicity (912,679/1,055,083, 86.5%) and language (898,023/1,307,601, 68.7%). Employment status (29,848/1,229,644, 2.4%) and family history of cancer (183,424/1,236,580, 14.8%) were underrecorded, with wide variation in coding practices. Screening data showed good alignment with national datasets for cervical and bowel screening but fragmented and inconsistent breast screening data due to a lack of standardized codes. Cancer diagnosis coding was incomplete (4604/5260, 87.5% recorded), and treatment and staging data were almost entirely absent, limiting proactive management of long-term consequences. Stakeholder input highlighted inconsistent template use, limited data updates, and insufficient incentives as key barriers to better coding.

Conclusions: The QI project has provided a detailed insight into the many dimensions of cancer coding and sheds light on many factors that underpin variation and coding preference. We offer a number of recommendations. The prioritized ones include the need for a cancer clinical coding data framework for primary care supported by appropriate funding and incentivization; improvements in the breast screening pathway and its interface with primary care; improvements in the quality of secondary care information that is sent to primary care; and dissemination of the importance of coding of cancer activity in primary care.

Introduction

Overview

Clinical coding of cancer-related data in primary care supports accurate and timely data collection, analysis, and reporting of cancer diagnoses and treatments, which in turn facilitates high-quality patient care [1,2]. Consequently, incomplete or inaccurate clinical coding of cancer-related data has significant implications across the cancer pathway. For example, cancer prevention efforts, including information provision, vaccination, and screening, may be restricted if it is not possible to identify eligible individuals based on data available in primary care records (eg, age, sex, health behaviors, previous medical history) and follow up with those who have not engaged (eg, those who have not responded to previous cancer screening invitations) [3]. Missing data for cancer risk-factors, such as family history or previous medical history, may undermine appropriate referral of symptomatic patients for cancer investigation [4]. Similarly, missing data on precancerous conditions such as Barrett's esophagus or bowel polyps may prevent health care professionals from providing information and support to patients about managing their condition and personal risk and result in patients being excluded from relevant safety-netting efforts and surveillance pathways [5]. Meanwhile, the underreporting of cancer cases can lead to an underestimation of the true cancer burden within a population and limit the ability of primary care to support patients during cancer diagnosis and treatment [5,6]. Beyond clinical impact, poor coding may also contribute to financial losses for health care providers and hinder effective service planning at both practice and system levels [7].

Primary care cancer coding data are often variable and suboptimal, with a poor evidence base for improvement [8-10]. A systematic review by Thiru et al [11], concluded on the lack of standardized measures for data quality, which is supported by previous studies showing the heterogeneity of quality assessment methods in primary care coding [11,12]. Thiru et al [11], uncovered studies that assessed primary electronic patient record data and studies that reviewed survey and questionnaire data. They also found that data quality (reliability) was usually measured with rate comparisons and data validity was expressed under a range of terms (completeness, correctness, accuracy, consistency, and appropriateness), which were rarely defined [11].

Previous studies have identified the need for better communication about patients who have been diagnosed with cancer between primary and secondary care [13], and a UK study reported that 1 in 5 patients with cancer were not recorded to have a cancer diagnosis in primary care records [6]. In England, relatively robust audit systems and regulatory oversight exist to regulate coding for cancer diagnosis, cancer interventions, and procedures in secondary care, underpinned by financial incentives [14,15]. In contrast, equivalent governance mechanisms do not exist in primary care. Clinical entries in primary care rely on SNOMED CT (Systematized Nomenclature of Medicine – Clinical Terms), but there are no national standards or frameworks specifically guiding cancer coding across the whole pathway. Instead, coding behavior is shaped primarily by the Quality Outcomes Framework (QOF) [16], which provides financial incentives for documenting selected conditions and activities. For cancer, QOF incentivizes the coding of a cancer diagnosis and the completion of cancer care reviews (CCRs) following diagnosis—although CCRs were removed from general practitioner (GP) QOF contracts in April 2025 [16,17]. Importantly, QOF does not cover the full cancer pathway. Moreover, primary care coding systems often encourage diversity rather than consistency, such as having multiple codes to describe identical clinical events [10,18] (eg, "smoker," "cigarette smoker," "moderate cigarette smoker"). Lack of regulation and research evidence about cancer coding consistency and variation restricts the development of targeted quality improvement (QI) measures. Consequently, there is a need to understand how the quality of clinical coding data in primary care varies to influence outcomes across the cancer pathway. This holistic approach can inform suitable interventions for optimizing the quality of primary care coded data to deliver valuable improvements in cancer prevention, referral, diagnosis, and treatment outcomes [13].

Cancer Coding and Data Curation

The process of how patient information is recorded, updated, and monitored in electronic health records is sometimes called "data curation." Primary and secondary care data curation is influenced by multiple drivers, which in turn affect data quality. In the United Kingdom, the National Cancer Registration and Analysis Service (NCRAS) [19] provides guidance and support for clinical coding of cancer diagnoses and treatment in acute care. NCRAS has developed a set of coding standards that are incorporated in nationally commissioned datasets such as the Cancer Outcomes and Services Dataset and Systemic Anti-Cancer Therapy dataset, which provide guidance on the coding of cancer diagnoses and treatments. The National Health Service (NHS) primary care coding system is called SNOMED CT [20]. The SNOMED CT does not have standard clinical coding specifications for cancer data.

Acute and mental health trusts have standard procedures for regular quality inspections of their coded clinical data for inpatient and day-case episodes by approved clinical coding auditors, who aim to demonstrate compliance with national clinical coding standards [21]. The regulatory component is important, as it supports high-quality data collection that supports secondary uses of the data, such as collaborations with academic and research departments (eg, the "Getting It Right First Time" program to reduce unwarranted variation) [22]. There is no equivalent process for auditing the assignment of the terminology SNOMED CT, which is used in primary care.

Reasons for primary care coding incompleteness and inconsistencies are well documented and include time pressures, finding the right code, and motivation to code [12,23]. As part of the development work that led to this study, NCL Cancer Alliance conducted an online survey of GP respondents in London to understand barriers to good-quality clinical coding in primary care. The findings included lack of standardized coding practices, scarcity of dedicated staff time to code, and inadequate training around coding (for the full list of barriers see Table S2 in Multimedia Appendix 1 [24]).

Context for the Quality Improvement Project

The aim of this QI project was to assess the completeness and variation of clinical cancer coding in NCL primary care data and to understand the reasons for this. The output of this QI project was to develop a robust "case for change" [25] for relevant improvement solutions. The long-term goal of the project was to improve service planning, pathway delivery, and redress health inequalities. The QI project was carried out by the NCL Cancer Alliance team with support from researchers at the Queen Mary University of London.

Our objectives were to: first, examine the quality of clinical coding of cancer-relevant risk factors, processes, and outcomes, encompassing both quantitative measures (eg, coding completeness and diversity) and qualitative stakeholder perspectives (eg, barriers, enablers, clinical relevance, and workflow alignment); second, use data from the first objective to develop recommendations to support data improvement in primary care.

Methods

Overview

This was a mixed methods QI project combining an observational dataset review and stakeholder interviews, workshops, and discussions. The observational dataset and analysis were based on data searches designed in EMIS (Egton Medical Information Systems) Web by Enfield GP Federation. These were set up to take a snapshot of information held in GP records as it stood on October 31, 2023, so that results are consistent and comparable across practices. All participating GP federation teams then ran the searches between November 2023 and January 2024. The results were shared with the NCL Cancer Alliance, which completed the data analysis in April 2024. Preliminary insights from the early stages of qualitative data collection (eg, advice from group interviews) informed the quantitative analysis (eg, process barriers in breast screening to ethnicity codes recorded in 2 different parts of EMIS Web) and the development of the workshop themes and questions. The formal qualitative analysis was conducted after all qualitative data had been collected; this section of analysis was carried from October to December 2024 (Figure S1 in Multimedia Appendix 1 depicts the project timeline).

Setting and Participants

We gathered data on clinical coding from NCL primary care GP systems covering an adult population of >1.4 million. The qualitative data included email conversations, 2 semistructured interviews, and 2 workshops with key primary care stakeholders. The qualitative methods and analyses are reported according to the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Table S3 in Multimedia Appendix 1) [24].

Data Collection

We extracted GP data from the electronic health care system, EMIS Web [26], the sole GP electronic health care record provider for all GP practices in NCL. Data were obtained using built-in "searches" within EMIS Web. These are configurable protocols designed to retrieve coded patient information based on predefined clinical or demographic criteria, referred to as data domains (eg, ethnicity, smoking status, cancer diagnosis, or treatment history). Each search identifies patients meeting the selected criteria based on structured clinical codes. The output of these searches is presented in the form of "reports," which summarize the number of patients meeting each criterion and can be exported for further analysis. Figure S2 in Multimedia Appendix 1 provides an example of a search. We used the SNOMED CT [20,27] and EMIS Web clinical codes [28], which coexist in patients' records [29]. The NCL GP federations performed the searches; a GP federation is a group of general practices working collaboratively as an organizational entity to improve patient care, share resources, and enhance service provision within the local health economy [30].

Table 1 illustrates the number of GP practices across each GP federation or primary care network (PCN) in NCL and the completeness of report returns across the 26 searches that were built and run. A PCN in Islington that was not part of the Islington GP Federation (Islington North 2) did not participate in this project. A partial return is where some GP practices have generated results in a search and some have not due to there either being no patients who meet the criteria or technical constraints that prohibit the search from running for particular practices.

Table 1. Shows the number of general practitioner (GP) practices within each GP federation or primary care network (PCN) and the completeness of the reports that were requested.

Category	GP entity						
	Barnet[a], n	Camden[a], n	Camden Health Evolution[a], n	Enfield[a], n	Haringey[a], n	Islington[a], n	Islington North 2[b], n
Number of GP practices	48	23	9	30	34	23	8
Report status							
Complete	7	21	21	13	21	21	0
Partial	17	5	5	13	4	4	0
Did not return	2	0	0	0	0	0	26
Search generated null results	0	0	0	0	1	1	0

[a]Represents GP federations.

[b]Represents a PCN.

Three personalized cancer care metrics—cancer care plan given, end-of-treatment summary, and holistic needs assessment—were unintentionally omitted from the original data request. This gap was identified by the NCL Cancer Alliance after data had already been submitted by all boroughs. To partially address this, Enfield Federation, which had local access, conducted the relevant searches for its own borough (covering the 12 months up to October 2023). Due to timing and resource constraints, it was not feasible to repeat this process across the other boroughs. Enfield's data were compared with HealtheIntent cancer registries [31], which span the entire NCL adult population; while full coding quality could not be assessed, we were able to examine the relative frequency of these codes across populations.

Data Quality Assessment Method

We followed the approach taken by Pineda-Moncusi et al [32], who examined ethnicity data at a large scale and defined data quality across completeness, coverage, and granularity (most prevalent clinical codes used).

We drew on existing cancer data frameworks [33,34] to conceptualize different cancer pathway stages and identify relevant cancer codes. Within cancer alliances, there are established programs [35] spanning the entire pathway—from awareness and prevention through to living with and beyond cancer. Our aim in this study was to create a comprehensive and holistic dataset to review, thereby informing future recommendations. To do this, we built on this existing knowledge, incorporated earlier work from our team [36], and collaborated with our wider NCL Cancer Alliance team to scope data items across each pathway stage. Although we recognized that some of these items were unlikely to be routinely coded in primary care, there was no empirical evidence to confirm this; therefore, part of the purpose of this QI project was to assess the current state of coding. End-of-life care was deemed out of scope for this work. The Enfield GP Federation digital team built EMIS Web searches to cover each element of the pathway and shared these with other NCL GP federations' IT teams to run for each borough. Enfield GP Federation's IT team oversaw the communication, search development, search dissemination, and data submissions. Raw data were transferred to the NCL Cancer Alliance.

The data protection officer for NCL primary care assured that all data sharing complied with UK General Data Protection Regulation.

Qualitative Data Collection

A convenience sample of key stakeholders with expertise in clinical coding were invited (over email and through a GP bulletin) to attend an online group workshop through existing contacts (including GPs, project and program managers, IT staff, and academic researchers). They were told that they were being invited to discuss the quantitative findings relating to clinical coding. We conducted 2 semistructured group interviews and 2 workshops with 11 primary care stakeholders. We also reviewed email correspondence from the Enfield GP Federation team, which captured responses to queries arising from the initial round of quantitative data analysis. These communications provided a systematic method for clarifying data gaps and process-related issues and directly informed the development of key questions explored during the subsequent stakeholder workshops.

All interviews and workshops were held remotely over Microsoft Teams between April and August 2024 (Table S4 in Multimedia Appendix 1) and conducted by AB (female, GP clinical lead for Innovation and Integration at NCL Cancer Alliance). Sessions were also facilitated by 2 other members of the research team, GR (male, head of Data and Analytics, NCL Cancer Alliance) and KT (female, senior innovation consultant, NCL Cancer Alliance). Semistructured interview and workshop topic guides were developed by AB, KT, and GR. We presented key findings for discussion. All remote sessions were video recorded and transcribed using the Microsoft Teams record and transcription functions. Transcripts were not shared with stakeholders.

Analysis

Quantitative data were analyzed descriptively across the different boroughs to characterize coding patterns. In total, 26 searches were built and run. We analyzed these data domains: patient ethnicity, main language spoken, weight or BMI, alcohol consumption, smoking status, family history of cancer, employment status, environmental pollutants exposure, carer, cancer screening attendance, cancer fast-track referrals, presence of malignant neoplastic disease, treatment regimen, and attendance at CCR. To ensure transparency and facilitate replication as far as possible, we have included these extracted search terms in Textbox S1 in Multimedia Appendix 1.

Codes were descriptively analyzed for the following features (1) coding completeness, (2) coding diversity, (3) data validation, and (4) granularity of coding (Table 2).

Table 2. Definitions and methods used to assess clinical coding quality and completeness.

Definitions	Methods
Coding completeness[a]	Percentage of eligible patients with a relevant SNOMED CT (Systematized Nomenclature of Medicine – Clinical Terms) or EMIS (Egton Medical Information Systems) clinical code captured. This reflects the presence or absence of a code rather than the true or expected prevalence of the underlying condition.
Coding diversity[b]	Number of unique SNOMED CT or EMIS codes used to describe the same information (eg, patient's weight). This serves as a practical proxy for coding breadth, acknowledging limitations such as inaccessible child codes and variation in code list size.
Data validation	Comparison of coding completeness in EMIS Web with national or local reference datasets to assess missed or uncoded data. Calculated as EMIS Web completeness divided by completeness reported in the comparator dataset for the same coded item. Ratios may exceed 100% if EMIS Web demonstrates higher apparent completeness. Comparator datasets included HealtheIntent, Cancer Waiting Times, the National Cancer Registry, South East London Cancer Alliance data[c], and the NHS Futures Screening Dashboard.
Granularity of coding	Review of the most frequently used codes to assess specificity, for example the use of general codes such as "current smoker."

[a]Coding completeness describes the proportion of eligible patients in the denominator population who have a relevant code captured in their primary care record. This definition is intended to reflect the presence or absence of a code rather than to imply that the observed percentages represent the true or expected prevalence of the underlying clinical characteristic or diagnosis. For example, a coding completeness of 0.3% for malignant neoplastic disease reflects the proportion of the registered population with a relevant cancer code, not an assessment of whether this proportion is "correct" or "incorrect." To distinguish between the technical measurement of code capture and the interpretive question of whether coding levels are as expected, we also applied the concept of coding validation. Coding validation involves comparing observed coding completeness against external standards or datasets (eg, cancer wait times) to assess whether the recorded levels are appropriate and consistent with known population rates. In this way, completeness provides a descriptive measure of the presence of codes in primary care data, while validation enables assessment of their adequacy and alignment with clinical or epidemiological expectations.

[b]Coding diversity was defined as the number of unique codes captured in EMIS Web for each search. We recognize this is a practical proxy rather than a full measure, as EMIS Web does not easily expose all child codes, and many codes (eg, for rare conditions or languages) will naturally yield zero results. Some code lists are also inherently larger than others. A distinct count of unique codes therefore provides useful context on the breadth of coding options observed while acknowledging these limitations.

[c]South East London Integrated Care Board (ICB) and Cancer Alliance has its own population health dashboard that overlaps with the data and definitions in this study, meaning it is valid for comparison where we have no other published source. This dashboard is not publicly available.

Data completeness and validation analysis was carried out against all submitting GP practices' adult populations as of January 2024 (Table S5 in Multimedia Appendix 1). Practice populations are relatively stable month to month, so comparing October 2023 search results with the adult population in January 2024 is considered valid. Practices that did not submit data for a profile were excluded from the analysis to maximize data integrity (Table S6 in Multimedia Appendix 1).

Table 3 lays out the report names across the time frames for which the data was searched for, the denominator population, and the validation database used for comparison. Additionally: (1) data on body weight and BMI were assessed through a combined height and weight search); (2) smoking status was assessed through three separate searches; (3) family history of cancer was assessed based on any recorded code, rather than limiting analysis to the preceding 24 months (as the GP federations' IT team were aware this would be captured at one point in records); and (4) breast screening data were retrieved through four distinct searches: screening attendance, normal results, abnormal results, and cancer detected.

Table 3. Each report name shown against time period covered for each report, the denominator population, and the validation database used for comparison, including the validator time period.

Report name	Time period	Denominator population characteristics (age in years)	Validator database	Validator metric and time period
Ethnic origin	Recorded ever	>18	HealtheIntent	Ethnicity coding (April 2024)
Main language spoken	Recorded ever	>18	HealtheIntent	Main language spoken (April 2024)
Employment status	October 2021-October 2023	>18	No comparator	__[a]
Weight or BMI recorded	October 2021-October 2023	>18	South East London Cancer Alliance data completeness	Weight or BMI recorded (April 2024)
Current smoker (recorded in last 24 months)	October 2021-October 2023	>18	HealtheIntent	Current smoker status (April 2024)
Any smoking status (recorded in last 24 months)	October 2021-October 2023	>18	South East London Cancer Alliance data completeness	Any smoking status (April 2024)
Alcohol consumption record	October 2021-October 2023	>18	South East London Cancer Alliance data completeness	Alcohol consumption record (April 2024)
Family history of neoplasm	Recorded ever	>18	No comparator	—
Environmental pollutants	October 2021-October 2023	>18	No comparator	—
Fast track referral coding	New episode added in last 12 months	>18	Cancer Wait Times	Urgent suspected cancer referrals (2023)
Cancer–bowel: did not return screening kit	October 2023-2 years 6 months	60-74	No comparator	—
Cancer–bowel: screening uptake	October 2023	60-74	NHS Futures Screening Dashboard	Bowel screening uptake August 2023 (50-70 years)
Cancer–bowel: abnormal result	October 2023-2 years 6 months	60-74	No comparator	—
Cancer–breast: screened	October 2023-3 years 6 months	50-70 (female)	NHS Futures Screening Dashboard	Breast screening uptake August 2023 (50-70 years)
Cancer–breast: abnormal result	October 2023-3 years 6 months	50-70 (female)	No comparator	—
Cancer–breast: normal result	October 2023-3 years 6 months	50-70 (female)	No comparator	—
Cancer–breast cancer detected	October 2023-3 years 6 months	After screened for breast cancer (female)	National Cancer Registry	Breast cancer diagnosis via screening route February 2020 to July 2023 (3.5 years)
Cancer–cervical: adequate smear	October 2023-3 years 6 months	25-49 (female)	NHS Futures Screening Dashboard	Cervical screening uptake December 2023 (25-49 years)
Cancer–cervical: adequate smear	October 2023-5 years 6 months	50-64 (female)	NHS Futures Screening Dashboard	Cervical screening uptake December 2023 (50-64 years)
Malignant neoplastic disease	New episode added in last 12 months (as of October 2023)	>18	National Cancer Registry	Rapid Cancer Registration – New Diagnosis (2023)
Malignancy stage	New episode added in last 12 months (as of October 2023)	>18	National Cancer Registry	Rapid Cancer Registration – New Diagnosis (2023)
Treatment regimen	New episode added in last 12 months (as of October 2023)	>18	Cancer Waiting Times	Treatment starts (2023)
Cancer care review	New episode added in last 12 months (as of October 2023)	Cancer-diagnosed patients who had a care review	No comparator	—
Has a carer	Recorded ever	>18	No comparator	—

[a]Not applicable.

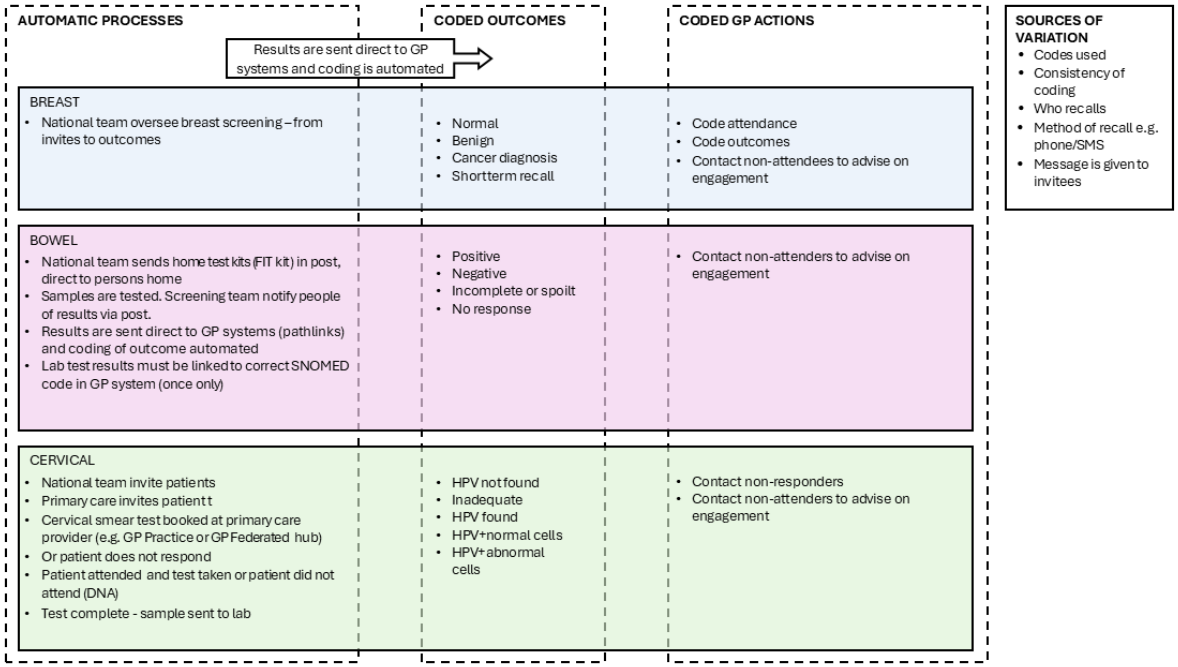
Missing Data

There were challenges with data collection in participating practices. Running searches at scale across several practices was technically difficult at times. These searches would often time out and fail, resulting in incomplete data collection. Despite repeated running of these searches to attempt to get a complete dataset, failures persisted (Table S3 in Multimedia Appendix 1 and its linked notes provide more detail on this process).

Barnet had the highest level of missing data across the 26 reports, although data gaps were present in all boroughs. The ethnic diversity of Barnet is broadly comparable to the rest of NCL, and given that data from Barnet were available for other nonethnicity reports, we do not believe these gaps materially skew the overall findings. Table S7 in Multimedia Appendix 1 illustrates the proportions of practices that submitted data across each of the 26 searches.

The searches did not examine comparable data across each screening pathway. Direct comparisons between breast, colorectal, and cervical screening were not feasible, as primary care is not uniformly responsible for screening data across the 3 screening pathways. As a result, a process mapping exercise was conducted to trace the pathways of each screening program into primary care, identifying recordable actions within primary care settings as shown in Figure 1.

Figure 1. Diagram showing how codes are generated for all cancer screening programs in primary care.



The qualitative data were analyzed by SB, a female behavioral science PhD student, and GB, a female applied health researcher. Both had previous experience conducting qualitative research. The analysis began in October 2024, after qualitative data collection had finished. SB listened to all video recordings and checked the transcripts for accuracy to become familiar with the study context and dataset before coding the data.

Qualitative data collection aimed to contextualize and validate quantitative findings rather than to achieve theoretical saturation. As this study adopted a QI focus, data collection was concluded once sufficient breadth of perspectives had been obtained and no new issues emerged that were relevant to the study objectives.

The analysis was conducted in Google Sheets using framework analysis [37]. Key excerpts from transcripts, email conversations, and comments posted in the chat during the workshops were copied into Google Sheets. All qualitative data were analyzed together. Raw data were arranged into columns. Each column represented a single code, and each row included raw data (eg, a verbatim quote labeled by data source and speaker) pertaining to that code.

An initial framework of 3 themes was developed deductively based on the findings of the quantitative analysis. SB coded the data into each theme before arranging the data into subthemes inductively. SB and GB met after 10%, 50%, and 100% of the data had been coded to discuss and revise the coding framework. A reflexive diary was kept and referred to throughout the analysis, which included field notes and impressions recorded by the researcher who conducted the interviews and workshops (AB) and the researchers who conducted the analysis (SB and GB). Regular meetings were held with the research team to clarify contextual details and discuss key interpretations. A reflexivity statement is available in Textbox S2 in Multimedia Appendix 1.

Ethical Considerations

This study was designed as a QI and health service enhancement initiative and therefore ethics approval was not applied for.

All data analyzed were fully deidentified at source, aggregated, and subject to small-number suppression (<5) in accordance with local information governance standards to protect patient confidentiality. The dataset was generated through local GP federations, with each federation running standardized searches and submitting aggregated data to Enfield Federation. Enfield Federation then securely transferred the data to the NCL Cancer Alliance for analysis.

The NCL primary care data protection officer reviewed and assured all data-sharing processes, confirming they aligned with the UK General Data Protection Regulation and the Caldicott Principles. A Data Protection Impact Assessment was not required, as the data used contained no identifiable information and presented no privacy risk.

Results

Principal Findings

We present our findings combining our descriptive analyses of clinical codes (quantitative findings) and the factors influencing coding (qualitative findings), in three themes: theme 1, precancer pathway, which includes codes relating to demographic characteristics, physical characteristics, risk factors (eg, family history), and cancer referrals; theme 2, cancer screening, which includes codes relating to screening invitations and uptake; and theme 3, postcancer diagnosis, which includes codes relating to staging, treatment, primary care surveillance, and follow-up.

In Table S8 in Multimedia Appendix 1, we include further details on data items included for each theme. Key findings are summarized for each theme before the results of the quantitative and qualitative analyses are presented.

Theme 1: Precancer Pathway

Overview

Completeness, code diversity, and validation of precancer codes are presented in Table 4 (Table S9 in Multimedia Appendix 1 provides additional detail on granularity).

Table 4. Descriptive analyses for data domains in theme 1 (precancer), showing completeness, code diversity, and validation of codes that were searched for in this theme.

Report name	Time period	Completeness and code diversity		Code validation	
		Completeness (% eligible coded), n/N (%)	Number of unique SNOMED CT[a] or EMIS[b] codes, n	Comparator source	EMIS completeness vs comparator, n/N (%)
Ethnic origin (coding)	Recorded ever	912,679/1,055,083 (86.5)	375	HealtheIntent	86.5/90.7 (95.4)
Main language spoken	Recorded ever	898,023/1,307,601 (68.7)	338	HealtheIntent	68.7/62.8 (109.4)
Employment status	24 months up to October 2023	29,848/1,229,644 (2.4)	87	No comparator for coding prevalence of this data item sourced	No comparator for coding prevalence of this data item sourced
Weight or BMI recorded	24 months up to October 2023	485,660/1,159,241 (41.9)	34	SELCA[c]	41.9/45.8 (91.5)
Current smoker (recorded in last 24 months)	24 months up to October 2023	90,029/1,236,580 (7.3)	47	HealtheIntent	7.3/14.9 (49)
Any smoking status (recorded in last 24 months)	24 months up to October 2023	530,720/1,185,812 (44.8)	117	SELCA	44.8/48.6 (92.3)
Alcohol consumption record	24 months up to October 2023	222,753/1,236,580 (18)	39	SELCA	18/29.2 (61.6)
Family history of neoplasm	Recorded ever	183,424/1,236,580 (14.8)	479	No comparator for coding prevalence of this data item sourced	No comparator for coding prevalence of this data item sourced
Environmental pollutants	24 months up to October 2023	494/1,113,575 (0.04)	45	No comparator for coding prevalence of this data item sourced	No comparator for coding prevalence of this data item sourced
Fast track referral coding	New episode added last 12 months up to October 2023	61,562/1,506,746 (4.1)	34	Cancer Waiting Times	61,562/78,989 (78)

[a]SNOMED CT: Systematized Nomenclature of Medicine – Clinical Terms.

[b]EMIS: Egton Medical Information Systems.

[c]SELCA: South East London Cancer Alliance.

The completeness of ethnicity coding was high, with 86.5% (912,679/1,055,083) of records containing an ethnicity code. A total of 375 distinct SNOMED CT codes were identified, with a 15.8% variation in coding completeness across boroughs. “Other White background - ethnic category 2001 census” made up 18.6% (170,190/912,679) of total codes captured in NCL. Language coding completeness was 68.7% (898,023/1,307,601) across the eligible population, which compares favorably with the comparator database coverage of 62.8% (929,987/1,482,024). A total of 338 unique codes were identified, with borough-level variation of 15.2% (Camden=75.3% and Enfield=60.1%). The top 2 most prevalent codes for language were “Main spoken language English” (527,227/898,023, 58.7%) and “Main spoken language NOS” (48,311/898,023, 5.4%). Employment status coding was minimal, with completeness at only 2.4% (29,848/1,229,644). The most frequently recorded codes related to unemployment (11,801/29,848, 39.5%) and work-related stress (5063/29,848, 17%), with a total of 87 distinct codes identified.

Coding completeness for BMI was 41.9% (485,660/1,159,241), with 34 individual codes used to describe weight and BMI. The SNOMED CT code for BMI accounted for 88.7% (430,736/485,660) of recorded entries. Overall, 44.8% (530,720/1,185,812) of the population had a recorded smoking status, including classifications such as current smoker and ex-smoker. Approximately 170 variations of smoking-related codes were identified. Data validation demonstrated near completion. Alcohol consumption was recorded in 18% (222,753/1,236,580) of patient records, with borough-level variation ranging from 13.9% (39,198/281,807) to 21% (64,255/281,807). A total of 39 different codes were identified. The “AUDIT-C” screening tool, which assesses excess alcohol consumption, was the prevalent code at 43.4% (96,619/222,753).

Family history of cancer across NCL showed that 14.8% (183,424/1,236,580) of records contained relevant codes, with 479 unique codes identified. There was no available comparator dataset for this parameter. The 2 most prevalent codes were “FH-Cancer” and “FH-Neoplasm” at around 17% each. Coding of environmental exposure was extremely limited, with a completeness rate of 0.04% (494/1,113,575), rendering the data unsuitable for analysis.

The incidence of suspected cancer referrals among eligible patients was 4.1% (61,562/1,506,746), with a 1% variation between the highest and lowest referring boroughs. The comparator database indicated a referral rate of 5.2% (78,989/1,506,746) for NCL residents. The analysis excluded deceased, temporary, and deregistered patients. The discrepancy between the study findings and comparator data was largely attributable to deceased patients.

Factors Influencing Clinical Coding of Precancer Data in Primary Care

Stakeholders reported 3 key factors that contribute to the quality and completeness of clinical coding of precancer data in primary care: opportunities to collect or update precancer data, motivations and capacity to collect and code precancer data, and the nature of the systems used to code precancer data.

Opportunities to Collect or Update Precancer Data

Many stakeholders reported that a key opportunity to capture precancer data is through registration forms and health check appointments. Some explained that registration templates and the commissioning of health check appointments vary by practice, leading to inconsistencies. There was agreement that standardized templates could improve this, although only for those registering subsequently, and it was noted that patients may not provide information if questions are not mandatory and the purpose of data collection is not transparent. While a few GPs suggested that mandating questions could improve data completeness, others were concerned that this could introduce barriers to registration. Family history is not routinely coded but may be documented in free text within clinical notes or referral forms. Environmental exposure data is not routinely collected or standardized within primary care records.

Some stakeholders advised that a lack of data completeness for information that changes over time, such as main language spoken or smoking status, is due to limited opportunities to update patient data after registration unless patients schedule appointments with primary care (eg, long-term conditions review, new medication appointments, e-consultations). It was suggested this could be improved by offering annual health check appointments, inviting patients to update their information, and the sharing of information collected in secondary care.

Motivations and Capacity to Collect and Code Precancer Data

Many GPs indicated that local and national financial incentive schemes (such as the QOF [38]) influence whether they collect and code precancer data at registration and during patient consultations. Some reported that variation in coding completeness between boroughs could be attributed to differences in locally commissioned services. There was agreement that clinical coding is demanding of staff time and capacity, and that improvements to the quality and completeness of clinical coding are unlikely to continue beyond the period of incentivization.

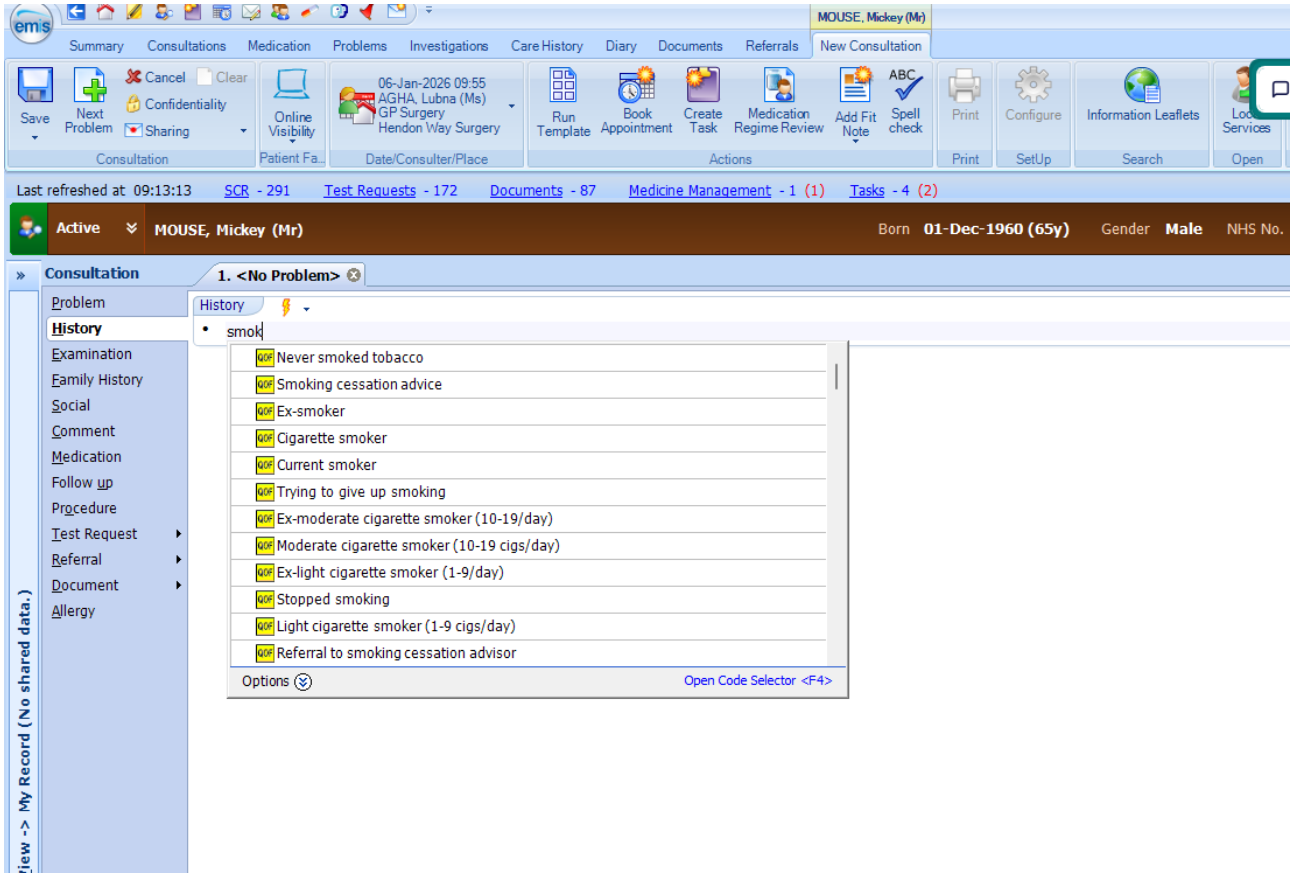
There was a general consensus that, in the absence of mandates and incentives, GPs are motivated to code precancer data that are relevant to the clinical workflow, such as arranging appointments (eg, need for interpreter, has a carer), assessing eligibility for local-level services (eg, smoking cessation, vaccination, information provision), or management of a patient's symptoms or a long-term condition. Some GPs admitted that they prefer to document precancer data in free text responses. This prevented interrupting the flow of conversation with patients, and, if needed, they could provide detail on more complex factors (eg, family history and exposure to environmental pollutants).

Nature of Systems Used to Code Precancer Data

GPs advised that coding will vary depending on whether patients register at GP practices using a paper or online form, whether registration data are coded into the system manually by staff or automatically, and which additional registration processing software practices have access to. It was also raised that there are multiple places within the system for data to be recorded. Furthermore, it was reported that some urgent suspected cancer referral forms may be available in the system but not trigger a SNOMED CT code. There was consensus that automated registration and data capture would improve the consistency and completeness of precancer data in primary care systems.

Several GPs suggested that the consistency of coding is made challenging by the array of codes available for specific types of precancer data such as smoking status, BMI, and family history, where there are different levels and layers, codes with similar or ambiguous meanings, and historic codes and prompts that cannot be removed (Figure 2). GPs admitted that codes higher up the list or those labelled with QOF prompts are most likely to be selected, and a program manager advised that coding prompts should be reserved for data that are most important to capture.

Figure 2. Screenshot of SNOMED CT (Systematized Nomenclature of Medicine – Clinical Terms) code options for term “smok” when typed into EMIS (Egton Medical Information Systems) Web, showing a drop-down menu of multiple code options that start with “smok.”.



Theme 2: Screening Pathway (Breast, Bowel, and Cervical Screening)

Completeness, code diversity, and validation of cancer screening data is presented in Table 5 (Table S10 in Multimedia Appendix 1 provides additional detail on granularity).

Table 5. Descriptive analyses for data domains in Theme 2 (screening), showing completeness, code diversity, and validation of codes that were searched for in this theme.

Report name	Time period	Completeness and code diversity		Code validation	
		Completeness (% of eligible patients with code captured), n/N (%)	Number of unique SNOMED CT[a] or EMIS[b] codes in search, n	Data validation comparator source	EMIS data completeness as a proportion of comparator, n/N (%)
Cancer–bowel (aged 60-74 years; did not return screening kit)	Run date (October 2023)-2 years 6 months	65,762/188,939 (34.6)	4	No comparator for coding prevalence for kit DNRs[c], only uptake and coverage	No comparator for coding prevalence for kit DNRs, only uptake and coverage
Cancer–bowel (aged 60-74 years; screened)	Run date (October 2023)-2 years 6 months	112,939/184,323 (61.3)	10	NHS[e] Futures Screening Dashboard	61.3/62.2 (98.6)
Cancer–bowel abnormal result	Run date (October 2023)-2 years 6 months	2308/184,323 (1.3)	5	No comparator for coding prevalence for abnormal screening results, only uptake and coverage	No comparator for coding prevalence for abnormal screening results, only uptake and coverage
Cancer–breast (aged 50-70 years; screened)	Run date (October 2023)-3 years 6 months	79,321/175,986 (45.1)	30	NHS Futures Screening Dashboard	45.1/57.2 (78.8)
Cancer–breast (aged 50-70 years; abnormal result)	Run date (October 2023)-3 years 6 months	1646/114,606 (1.4)	7	No comparator for coding prevalence for abnormal screening results, only uptake and coverage	No comparator for coding prevalence for abnormal screening results, only uptake and coverage
Cancer–breast (aged 50-70 years; normal result)	Run date (October 2023)-3 years 6 months	71,043/165,126 (43)	3	No comparator for coding prevalence for normal screening results, only uptake and coverage	No comparator for coding prevalence for normal screening results, only uptake and coverage
Cancer–breast cancer detected	Run date (October 2023)-3 years 6 months	913/167,315 (0.5)	35	National Cancer Registry	913/731 (124.9)
Cancer–cervical (aged 25-49 years; adequate smear)	Run date (October 2023)-3 years 6 months	205,730/356,955 57.6%	103	NHS Futures Screening Dashboard	57.6/57.7 (99.8)
Cancer–cervical (aged 50-64 years; adequate smear)	Run date (October 2023)-5 years 6 months	97,233/139,233 (69.8)	98	NHS Futures Screening Dashboard	69.8/71 (98.3)

Breast Screening

Coding for breast cancer screening uptake was recorded in 45.1% (79,321/175,986) of screening-eligible patients, with a 12% deficit compared with the comparator database. A total of 30 unique codes were used to document breast screening activity. The number of breast cancer diagnoses following abnormal results exceeded those in the comparative dataset. The most frequently used code was “Mammography normal,” accounting for 39.2% (31,109/79,321) of coded entries. The qualitative data (semistructured interviews and workshops) verified much of the persistent quality issues in the breast screening service, particularly its interface with primary care. This data also highlighted problems such as significant delays in breast screening attendance and nonattendance notifications; delivery of notifications by letters that contain multiple patients on a single sheet and therefore require manual separation; and counterintuitive patient reminders. For instance, proactive reminders for women upon turning age 50 years can cause confusion, because screening invitations may not be issued until age 53 years, with no flexibility for earlier appointments.

Bowel Cancer Screening

Codes for bowel cancer screening suggested an uptake of 61.3% (112,939/184,323). The proportion of screening-eligible patients who did not return test kits was 34.6% (65,762/188,939). Coding of abnormal results was documented in 1.3% (2308/184,323) of cases. The fecal immunochemical test (FIT), which underpins bowel screening, was consistently coded as "Bowel cancer screening program faecal occult blood test" within EMIS Web. The most frequently used codes were for normal and abnormal fecal occult blood (FOB) test results. The qualitative data (semistructured interviews) showed us that the bowel screening processes and coding practices were clearly defined for patients who undergo screening (aligned to QOF-funded activity). However, variability exists in recall, reminder, and engagement activities for nonresponders. Those who did not participate in screening were often coded using a non-SNOMED CT term, "No response to BCSP invitation."

Cervical Screening

Cervical screening data in the eligible population, coded as having had a smear, were 57.6% (205,730/356,955; in the 25 to 49 years age group) and 69.8% (97,233/139,233; in the 50 to 64 years age group). Both numbers aligned with the comparator database at over 99% (57.6%/57.7%) and 98% (69.8%/71%). A total of 98-103 individual codes were used to describe cervical screening coverage among the 2 eligible age cohorts. The qualitative data (semistructured interviews with GP federation's IT team) revealed that cervical screening processes were also clearly defined and aligned with the funding route (QOF). Variability existed in the recall and engagement activities for nonresponders. Reports for cervical nonengagement and recall were not developed because it was understood that data would not exist.

Factors Influencing Clinical Coding of Cancer Screening Data in Primary Care

Stakeholders explained that the coding of cancer screening data in primary care is influenced by primary care staff motivations and the ease of coding screening results in the system.

Relevance of Coding Cancer Screening Data to Clinical Workflow

Primary care staff described varied practices in whether cancer screening attendance was recorded. While some mentioned manual efforts or automated systems for reminding patients about upcoming screening appointments or contacting patients when they were notified of nonattendance, many admitted that they did not code screening attendance and follow up for those who did not attend. In discussing reasons for this, GPs and program managers indicated that coding was motivated by mandates and incentives (QOF) that are often only short term.

Many GPs agreed that recording screening data or contacting those who did not attend was not clinically relevant to primary care workflow and believed it was under the remit of national teams that run the programs. A few also noted that they did not have the most up-to-date information to monitor and facilitate screening attendance as they had received incorrect system prompts around screening attendance and were not aware of changes to screening eligibility. While some GPs and program managers noted local-level efforts to support and improve cancer screening attendance, there was general consensus that this is dependent on practice capacity to follow up those patients and is challenging due to competing priorities.

Ease of Coding Screening Results in Primary Care

GPs and program managers raised that coding breast cancer screening data is time consuming and demanding because paper results are sent to primary care with 2 patients' results per page, meaning they must be cut in 2 before being filed. Some recounted making requests for results to be sent electronically to streamline this process but had accepted that the system cannot be changed. GPs and program managers reported that the multitude of coding options for breast and cervical cancer screening results (eg, cervical screening, smear, cervical smear) contribute to coding inconsistencies. There was agreement that standardized coding could improve this. In contrast, stakeholders reflected that processing bowel cancer screening results is straightforward because the codes on the screening results letters are easy to match to those on the system (SNOMED CT). However, some highlighted that FOB codes (which relate to guaiac fecal occult blood testing [gFOBt] that is no longer used in the bowel screening program) [39] are still being used to code FIT screening results. Some reported that there is unified understanding in primary care that these legacy codes relate to FIT results and that incentive schemes for screening data still acknowledge these codes. However, one GP raised that legacy FOB codes may not be acknowledged in data searches for symptomatic FIT results.

Theme 3: Postcancer Diagnosis

Overview

Completeness, code diversity, and validation for postcancer codes are presented in Table 6 and in Table S12 in Multimedia Appendix 1 (Table S11 in Multimedia Appendix 1 provides additional detail on granularity).

Table 6. Descriptive analyses for data domains in Theme 3 (postcancer diagnosis), showing completeness, code diversity, and validation of codes that were searched for in this theme.

Report name	Time period	Completeness and code diversity		Code validation	
		Completeness (% of eligible patients with code captured), n/N (%)	Number of unique SNOMED CT[a] or EMIS[b] codes in search	Data validation comparator source	EMIS data completeness as a proportion of comparator, n/N (%)
Malignant neoplastic disease	New episode added last 12 months up to October 2023	6,044/1,506,746 (0.4)	677	National Cancer Registry	4604/6319 (73)
Malignancy stage	New episode added last 12 months up to October 2023	6/64,977 (0.01)	4	National Cancer Registry	6/3536 (0.2)
Treatment regime (if coded)	New episode added last 12 months up to October 2023	315/942,260 (0.03)	35	Cancer Waiting Times	315/10,574 (3)
Cancer care review	New episode added last 12 months up to October 2023	3953/1,236,580 (0.3)	1	No comparator for coding prevalence of this data item sourced	No comparator for coding prevalence of this data item sourced
Has a carer	Recorded ever	14,513/1,229,644 (1.2)	17	No comparator for coding prevalence of this data item sourced	No comparator for coding prevalence of this data item sourced

[a]SNOMED CT: Systematized Nomenclature of Medicine – Clinical Terms.

[b]EMIS: Egton Medical Information Systems.

The proportion of newly diagnosed cancers coded in EMIS was 73% (4604/6319) of the expected figure. The EMIS searches excluded deceased patients; further data comparison suggests that deceased individuals could account for 11.8%-14% of new cancer diagnoses in the Rapid Cancer Registration Database, reducing the initial coding gap from 27% to approximately 13%.

Cancer staging data showed a total completeness of 0.2% (6/3536) when compared with the validation database. One borough recorded no staging codes. Cancer treatment coding showed a total completeness of 3% (315/10,574) when compared with the validator.

CCRs were coded for 66% (3953/5982) of eligible patients, aligning with the 73% (4604/6319) of new cancer diagnoses recorded in primary care. A single SNOMED CT code is used to document CCRs. A total of 1.2% (14,513/1,229,644) of patients aged 18 years and older had a recorded carer status. The code “Has a carer” accounted for 80.1% (11,631/14,513) of these entries. Beyond CCRs, other personalized cancer care quality indicator data are shown separately in Table S12 in Multimedia Appendix 1. Cancer care plans, end-of-treatment summaries, and holistic needs assessments were recorded in 1%-2% of patients with cancer across NCL.

Factors Influencing Clinical Coding of Postcancer Diagnosis Data in Primary Care

Stakeholders suggested that coding of patients’ cancer diagnoses and treatment data is influenced by the relevance of information to the clinical workflow in primary care, the quality of information sharing from secondary care, and the complexity and consistency of the systems used for coding.

Relevance of Coding Postcancer Diagnosis Data to Clinical Workflow

A few GPs mentioned that coding of cancer diagnoses will improve when incentivized through the QOF. However, some highlighted that coding information about treatment plans organized by secondary care is not perceived as relevant or a priority in daily practice. One GP also reflected that they sometimes felt reluctant to request information from patients during CCR appointments given that patients have already had to discuss their diagnoses in secondary care.

Quality of Postcancer Diagnosis Information Sharing

GPs suggested that cancer diagnosis information is not always shared by secondary care or that it may be sent with some delay. They also reported that information may be missing for patients who are diagnosed and treated privately or those who are diagnosed at an advanced stage whereby primary care is only notified of a cancer diagnosis through the receipt of postmortem information. When cancer diagnosis information is received, there is consensus among GPs that letters from secondary care are long and complex, meaning staff have to scrutinize the whole letter to find and extract the key information. Many agreed that diagnosis information and SNOMED CT codes that require coding should be placed at the top of these letters for easy translation into primary care records. Some GPs also lack trust

in the accuracy of information received from secondary care due to finding previous errors in patient records. For this reason, a few expressed concerns about linked data between primary and secondary care if errors could not be redacted within primary care.

Consistency and Complexity of Systems Used for Coding Postcancer Diagnosis Data

GPs reported that there are multiple places within primary care–based systems (EMIS) where cancer information can be coded or entered as free text, as well as several different coding options that prevent consistent coding of cancer diagnoses. There was agreement that standardized templates were needed. GPs also reported that *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) codes used in secondary care letters are not aligned to SNOMED CT codes used in primary care, which causes ambiguity. Additionally, some explained that practices vary in their capacity to ensure the quality of coding, such as whether formalized coding teams are used and given adequate resources, time, and training to correctly code information received from secondary care.

Discussion

Summary

This QI project provides a detailed assessment of cancer-related clinical coding in NCL primary care across a population of 1.4 million adults. Our findings show that although some demographic data such as ethnicity and language are well captured (coding completeness), many other important codes across the cancer pathway—especially those relating to social determinants of health, cancer treatments, and postdiagnosis care—remain inconsistently coded or significantly absent from primary care records.

Coding quality was strongly influenced by the presence of national or local incentives (such as QOF), which drove completeness for certain indicators like ethnicity, cancer diagnosis, and CCRs. In contrast, areas not linked to performance payments or formalized data capture processes, such as cancer treatment, staging, and screening follow-up, showed substantial gaps. These differences signal that current coding behavior in primary care is shaped by system design, contractual levers, and administrative capacity.

Further qualitative insights helped contextualize these patterns, showing that GPs often prioritize coding activities relevant to their daily clinical workflow or incentivized tasks. Key barriers to good coding included complex and inconsistent coding systems, limited opportunities to update data, and limited structured information sharing from secondary care.

Overall, the findings demonstrate that improving cancer coding quality in primary care requires more than local process changes; it will require a coordinated national approach that includes clearer coding standards, automation, and alignment of incentives.

Interpretation

Our findings align with existing literature relating to cancer data coding in primary care. For example, our observation that ethnicity coding was high at 86.5% (912,679/1,055,083), is consistent with other studies using patient electronic records. This is similar to 78.2% ethnicity coding reported in NHS primary care records in 2022 [40]. These high levels may be related to incentive schemes (QOF) to improve completeness in England [41]. Similarly, 68.7% (898,023/1,307,601) completeness for language coding aligns with findings that emphasize the need for comprehensive demographic information to support better patient health outcomes [42].

The minimal recording of employment status (29,848/1,229,644, 2.4%) and the moderate completeness of BMI data (485,660/1,159,241, 41.9%) underscore challenges in capturing socioeconomic and health metrics. These gaps are consistent with literature indicating that certain health data, such as employment status, are often underreported in primary care settings [43]. Our findings on smoking status (530,720/1,185,812, 44.8%) and alcohol consumption (222,753/1,236,580, 18%) coding completeness, which show significant borough variation, also reflect widespread underrecording of these factors in patient records [44]. This may reflect discomfort in approaching conversations about lifestyle factors as well as lack of time or resources, particularly in more deprived areas [12,45].

The variation in cancer screening data across pathways, particularly the fragmented coding for breast screening, highlights the complexities in capturing screening information. Rafi et al [46] also found that a wide range of codes were used to document a family history of breast cancer in primary care, leading to inconsistencies in data quality and the potential for misclassification of risk. This finding may relate to primary care's role and responsibilities in screening, where their involvement varies significantly across different cancer types [47]. While primary care plays a structured role in bowel and cervical screening (underpinned by funding and agreed processes nationally), breast cancer screening activity is not delivered or incentivized in primary care.

New cancer diagnoses were also undercoded, at 87% (4604/5260) completeness. This aligns with findings from the Netherlands, where only 60.6% of cancer cases were coded according to the national registry [9]. Undercoding is linked to reliance on unstructured secondary care letters and a lack of coding incentives [8,9]. Cancer treatment and staging data were also undercoded, and there was not any existing evidence to compare against.

The recording of CCRs (3953/5982, 66% of eligible patients) closely mirrors the proportion of coded diagnoses, suggesting a correlation between diagnosis coding and care review documentation. However, concerns exist that high completeness rates reflect a "tick-box" approach driven by financial incentives for coding "cancer care review" [48]. Documentation of broader personalized cancer care indicators, such as care plans and holistic needs assessments, was minimal (1%-2%), highlighting gaps in comprehensive cancer care documentation. This aligns with studies calling for broader, patient-centered metrics to sustain confidence in cancer registries [49]. National CCR templates embedded in GP electronic records [50] support additional quality indicator completion alongside CCRs,

promoting standardization [51]. The lack of broader care indicators being coded suggests that these templates are not embedded in daily practice.

While this project was conducted in NCL, the findings have broader relevance across other similar primary care settings. Although population demographics vary between regions, the core structures, processes, and incentives that shape GP coding behaviors are largely consistent across the NHS and similar international health care systems. Primary care operates within a standardized framework of national policies, contractual obligations, and clinical systems, meaning that the challenges and opportunities identified in this study are likely to be mirrored elsewhere. As such, our findings provide valuable insights for informing coding improvement initiatives beyond our study region, with potential applicability across primary care systems nationally.

Limitations

Two boroughs were excluded due to nonengagement; however, the dataset remained robust with high completeness in other areas, minimizing bias. The findings should be interpreted cautiously for nonsubmitting practices. Additionally, our quantitative data searches were completed by GP Federation's IT team, but their searches could not fully align with our specifications. This left gaps in key cancer care metrics, such as patients with cancer on stratified follow-up pathways or active surveillance; alternative data sources such HealtheIntent (the ICBs' provider for linked datasets across the NHS in NCL until September 2025), helped fill in some gaps.

Conclusions

The QI project has provided a unique and detailed insight into the many dimensions of cancer coding across the whole pathway in primary care and sheds light on many factors that underpin variation and coding preference.

We have developed recommendations based on our findings aimed at primary care providers, commissioners, ICBs' digital teams [52], cancer screening teams and the National Cancer team [53].

Implications for Practice

Textbox 1 outlines practical recommendations to enhance primary care data management, integration with secondary care, and overall service quality. The focus is on standardizing coding practices, improving information flow, and leveraging data for informed decision-making and patient care improvements.

Textbox 1. Implications for practice.

Strengthen data infrastructure in primary care

- Develop a structured data framework using SNOMED CT (Systematized Nomenclature of Medicine – Clinical Terms) with a minimum dataset and distinct code sets, aligning with secondary care processes. This will enable better use of primary care data for analysis, epidemiology, and health care improvement.

Enhance breast screening integration with primary care

- Transition to electronic breast screening outcome reports for general practitioners (GPs), standardize national breast screening activity codes within SNOMED CT, and define and resource primary care's role in patient follow-up and nonattendance intervention. These changes will improve the accuracy and efficiency of breast screening data and ensure clear responsibility for patient engagement.

Improve secondary care information for primary care

- Standardize hospital discharge letters to clearly indicate new diagnoses, multidisciplinary team outcomes, and care plans, ensure clinical coding aligns with SNOMED CT; prioritize consistent implementation of end-of-treatment summaries; and link secondary care data directly to primary care [27-29]. This recommendation aligns with the national strategy [54,55]. This will reduce duplication, enhance continuity of care, and improve data quality for patient management.

Standardize primary care coding practices

- Employ coding professionals in primary care, align screening activity codes, update bowel screening codes to reflect the transition from fecal occult blood to fecal immunochemical tests, and educate the workforce on the value of high-quality coding. These steps will improve consistency, accuracy, and the usefulness of coded data for patient care and service planning.

Optimize patient registration processes

- Automate the integration of coded demographic, behavioral, and risk factor data from National Health Service Digital's updated registration forms (Patient Registration Form 1) [56] into primary care systems and allocate resources for implementation. This will ensure more complete and accurate patient information from the outset.

Improve Quality Outcomes Framework rules and transparency

- Make Quality Outcomes Framework rule changes trackable over time and provide clearer navigation and updates [57,58]. This will help those involved in service improvement and research to understand and respond to coding changes more effectively.

Implement primary care coding audits

- Introduce National Health Service England–funded coding audits, assess data quality and completeness, flag nonrecommended codes, and cross-reference with national datasets. This will improve coding accuracy, highlight inconsistencies, and enhance data reliability.

Develop an analytics dashboard

- Create a live dashboard to track trends, profile data, and support quality improvement, leveraging the London Health Data Service (launched in June 2025) [59]. This will provide real-time insights into primary care data, supporting better decision-making and service planning.

Facilitate knowledge sharing

- Identify regions with superior data completeness and share successful quality improvement initiatives across London. This will promote best practices and drive improvements in data quality and patient care across the system.

Funding

This study did not receive external funding from any public, commercial, or not-for-profit sources. The Enfield Federation was commissioned to build the data searches, run these across NCL GP practices, and extract the data. SB's time was funded by the NCL Cancer Alliance to support the qualitative analysis. GB acknowledges funding from Barts Charity. No funding body was involved in study design, data collection, analysis, interpretation, or manuscript preparation.

Acknowledgments

The authors thank the Enfield general practitioner (GP) Federation data team, General Practice Provider Alliance, North Central London (NCL) GP practices, all workshop participants, patient partners, the internal NCL Cancer Alliance team working group, the NCL Integrated Care Board digital team, and all stakeholders who reviewed and engaged in this study.

We used ChatGPT (free version; OpenAI) [60] to support the manuscript writing process. It was used to optimize sentence structure, readability, and reduce text burden. All content, analyses, and interpretations were developed, verified, and approved by the authors. ChatGPT was not used for data generation, analysis, or creation of original scientific content. The artificial

intelligence (AI) use for this manuscript falls under Domain 1 of the “Recommendations for a Classification of AI Use in Academic Manuscript Preparation” document.

The project was delivered as part of service improvement and evaluation led by the NCL Cancer Alliance.

Data Availability

The datasets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

AB conceived and led the project, collated a significant portion of the mixed methods data, supported analysis, and drafted the initial manuscript. GR conducted data collation and analysis, identified comparative data sources, and contributed substantially to manuscript development. KT provided project support and made significant contributions to the manuscript. SB analyzed the qualitative data and drafted the corresponding sections. GB provided overall guidance and methodological support, particularly in qualitative data collection and analysis. She advised on this study’s structure and contributed significantly to manuscript development. All authors contributed to the analysis, interpretation of findings, and manuscript revisions. All authors reviewed and approved the final version for submission. AB is the guarantor of this study.

Conflicts of Interest

None declared.

Abstract

Background: Cystoscopy remains the gold standard for diagnosing bladder lesions; however, its diagnostic accuracy is operator dependent and prone to missing subtle abnormalities such as carcinoma in situ or misinterpreting mimic lesions (tumor, inflammation, or normal variants). Artificial intelligence–based image-analysis systems are emerging, yet conventional models remain limited to single tasks and cannot produce explanatory reports or articulate diagnostic reasoning. Multimodal large language models (MM-LLMs) integrate visual recognition, contextual reasoning, and language generation, offering interpretive capabilities beyond conventional artificial intelligence.

Objective: This study aims to rigorously evaluate state-of-the-art MM-LLMs for cystoscopic image interpretation and lesion classification using clinician-defined stress-test datasets enriched with rare, diverse, and challenging lesions, focusing on diagnostic accuracy, reasoning quality, and clinical relevance.

Methods: Four MM-LLMs (OpenAI-o3 and ChatGPT-4o [OpenAI]; Gemini 2.5 Pro and MedGemma-27B [Google]) were evaluated under blinded, randomized procedures across two tasks: (1) free-text image interpretation for anatomic site, findings, lesion reasoning, and final diagnosis (n=401) and (2) seven-class tumor-like lesion classification (n=113) within a multiple-choice framework (cystitis, polyps, papilloma, papillary urothelial carcinoma, carcinoma in situ, non-urothelial carcinoma, and none of the above). Three raters independently scored outputs using a 5-point Likert scale, and classification metrics (accuracy, sensitivity, specificity, Youden J index (Youden J), and Matthews correlation coefficient [MCC]) were calculated for lesion detection, biopsy indication, and malignancy endpoints. For optimization, model performance was compared between zero-shot and text-based in-context learning prompts that were prefixed with brief descriptions of tumor features.

Results: The 401-image test set spanned 40 subcategories, with 322 (80.3%) containing abnormal findings in the image interpretation task. OpenAI-o3 demonstrated strong reasoning, with high satisfaction for anatomy (339/401, 84.5%) and findings (305/401, 76%), but lower satisfaction for lesion reasoning (211/401, 52.5%) and final diagnosis (193/401, 48.2%), indicating increasing difficulty with higher-order synthesis. Mean Likert score differences (OpenAI-o3 minus Gemini 2.5 Pro) were +0.27 for findings (adjusted *P* value: q=0.002), +0.24 for lesion reasoning (q=0.047), and +0.19 for final diagnosis. For clinically relevant endpoints in the full set, OpenAI-o3 achieved the most balanced performance, with lesion detection accuracy of 88.3%, sensitivity of 92%, specificity of 73.1%, Youden J of 0.650, and MCC of 0.635. In 7-class tumor-like lesion classification, OpenAI-o3 achieved accuracies of 73.5% for biopsy indication and 62.8% for malignancy, with a balanced sensitivity-specificity

trade-off, outperforming other models. Notably, OpenAI-o3 performed best on prevalent malignant lesions. ChatGPT-4o and Gemini 2.5 Pro showed high sensitivity but low specificity, whereas MedGemma-27B underperformed. In-context learning improved OpenAI-o3 microaverage accuracy (40.7%→46.0%; MCC 0.311→0.370) but yielded only slight specificity gains and minimal accuracy change in other models, likely constrained by the absence of paired image-text context.

Conclusions: MM-LLMs demonstrate meaningful assistive potential in generating interpretable cystoscopy free-text rationales and supporting biopsy triage and training. However, performance in difficult differential diagnoses remains modest and requires further optimization before safe clinical integration.

(J Med Internet Res 2026;28:e87193) doi:10.2196/87193

KEYWORDS

multimodal; large language model; AI; cystoscopy; diagnostic reasoning; finding description; biopsy indication; bladder tumor; artificial intelligence

Introduction

Cystoscopy is one of the most frequently performed procedures in urology [1]. Its effectiveness heavily depends on the urologist's experience, attention to detail, and interpretive skill, making it both technically and diagnostically challenging [2]. Interobserver variability is common, and lesion characterization (tumor vs inflammation vs normal variant) is not always straightforward, often requiring clinical correlation. Bladder cancer, the ninth most common cancer globally [3], relies heavily on cystoscopy as the cornerstone for diagnosis, treatment, and surveillance. However, studies report false-negative rates ranging from 10%-40%, with white-light cystoscopy missing up to one-third of carcinoma in situ (CIS) cases and frequently overlooking small tumors [4]. Accordingly, cystoscopic interpretation is a nuanced clinical process.

Artificial intelligence (AI)-assisted cystoscopic diagnosis and decision-making can be decomposed into distinct tasks: lesion detection (present vs absent), lesion classification, margin segmentation, descriptive reporting, biopsy triage, final diagnosis, and ultimately full report generation. Each task places different demands on algorithms, ranging from visual localization to semantic reasoning and clinical judgment. Previous work in cystoscopy has predominantly framed the problem as image classification or segmentation [5-9], often using specialized vision pipelines that localize or outline lesions but provide limited clinical context and have uncertain generalizability across morphology-diverse appearances.

Evidence from other endoscopic domains provides a useful benchmark. Task-tuned computer-aided detection systems in colonoscopy, for example, improve clinically meaningful endpoints such as polyp or adenoma detection in randomized and real-world settings; however, these gains are achieved by narrowly optimized, single-purpose models rather than by systems capable of broader interpretive reasoning [10-14].

Against this background, multimodal large language models (MM-LLMs) hold substantial potential [15]. By jointly processing images and text, MM-LLMs can, in principle, "see and say": integrate visual features with medical knowledge, generate free-text rationales, and condition decisions on clinical context [16]. Early reports suggest encouraging aggregate performance, but also reveal marked variability across lesions and tasks, indicating a role as assistive rather than autonomous readers at present [17].

Key gaps remain. First, it is unclear how state-of-the-art (SOTA) MM-LLMs perform on morphology-diverse, clinically difficult cystoscopic images curated as a stress test by domain experts. Second, the alignment between their free-text reasoning and expert judgment has not been systematically examined. Third, the practical utility of in-context learning (ICL) in cystoscopy—without task-specific fine-tuning—remains uncertain [18].

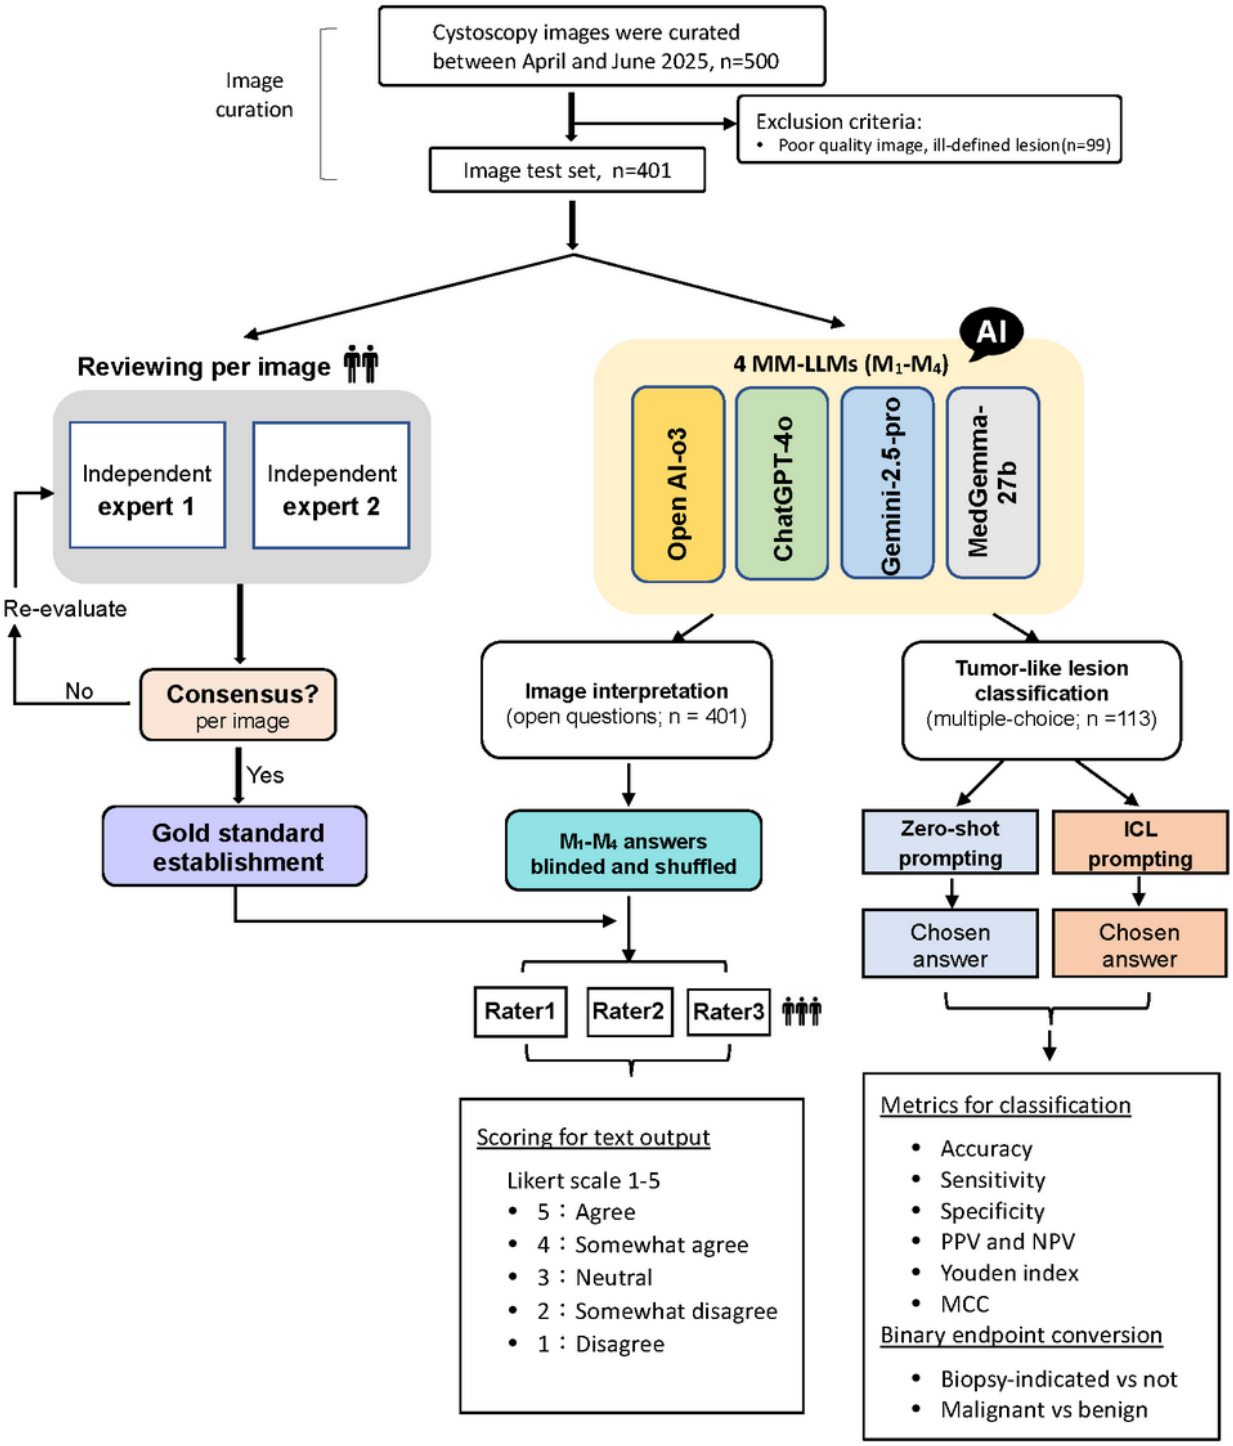
To address these gaps, our goal was to characterize the current capabilities and limitations of MM-LLMs in cystoscopic interpretation and to outline directions for model strengthening and additional adaptations required for safe clinical adoption.

Methods

Overview

Building on this objective, we (1) constructed a clinician-defined stress test that reflects real-world interpretive difficulty and spans benign and malignant lesions; (2) implemented a rater-blinded, model-anonymized evaluation across 2 complementary tasks—free-text image interpretation (4 open-ended questions plus a binary lesion detection query) and structured 7-class lesion classification; (3) mapped model outputs to clinically actionable binary endpoints (biopsy indication and malignancy); and (4) quantified the incremental benefit of ICL over zero-shot prompting. The overall study workflow is provided in Figure 1.

Figure 1. Study flow diagram. Evaluation pipeline for cystoscopic image interpretation and tumor-like lesion classification using 4 multimodal large language models (MM-LLMs). ICL: in-context learning; MCC: Matthews correlation coefficient; NPV: negative predictive value; PPV: positive predictive value.



Curation of a Diverse Image Test Set

Inclusion Criteria and Diverse Lesion Coverage

We evaluated vision-enabled LLMs for cystoscopic image interpretation and tumor-like lesion classification. To stress-test model generalization, the test set was curated to maximize the diversity of morphological patterns rather than mirror clinical prevalence. Images were included only if they mapped to a prespecified schema of lower urinary tract presentations—normal anatomy, intraluminal nonmucosal conditions, and focal mucosal lesions—with finer-grained sublabels (eg, verumontanum, trabeculation, and papillary urothelial carcinoma [pUC]). To extend beyond routine cases, we deliberately sampled uncommon entities encountered in

practice, including endometriosis, miscellaneous deposits, fistulas, and erosion-related changes. This approach yielded a corpus with broad lesion coverage suitable for rigorous stress-testing cystoscopic interpretation.

Sources and Image Preprocessing

Images were curated between April and June 2025 from five sources: (1) an industry archive of intra-operative images captured on Karl-Storz endoscopes, (2) reference atlases (eg, Springer's *Diagnostic Cystoscopy* [19] and other urologic textbooks), (3) deidentified cystoscopy images obtained from websites, (4) open-access repositories accompanying PubMed-indexed papers and public datasets, and (5) Creative Commons–licensed surgical or teaching videos hosted on YouTube (Google). A total of 500 images were curated, and 99 were excluded due to poor image quality or an ill-defined lesion. The distribution of image sources and the memorization-test results, which were used to evaluate potential data-leakage risk from overlap with the 4 models' pretraining corpora, are summarized in Table S1 in Multimedia Appendix 1. Raw images were center-cropped to a square aspect ratio, resized to 800×800 pixels, and saved as JPEG files. This standardized pipeline harmonized the field of view and resolution across heterogeneous sources and ensured uniform inputs for all downstream model evaluations.

Multimodal LLMs

The evaluated MM-LLMs comprised 3 general-purpose models and 1 open-weight, medical-specific baseline. Two reasoning-optimized models—OpenAI-o3 [20] and Google Gemini 2.5 Pro [21]—were selected for their native image processing capabilities and emphasis on multistep reasoning. These represent the SOTA reasoning MM-LLMs available before July 2025. ChatGPT-4o (OpenAI) was included as a general-purpose, nonreasoning MM-LLM optimized for everyday assistance and among the earliest widely deployed models capable of accepting image input. MedGemma-27B (Google) [22] was intentionally included as a local and open-weight baseline—an open-source medical model (~27B parameters) suited for on-premises deployment and potential clinical fine-tuning. Because its parameter count and training budget are substantially smaller than the proprietary models (undisclosed), MedGemma-27B serves as a baseline rather than a capacity-matched comparator. Collectively, these systems span closed-source production platforms and an open-weight medical baseline, enabling a balanced, transparent comparison.

Study Design

Establishment of the Gold Standard

The reference standard diagnoses were determined through a multiphase, consensus-based process. Two urological experts, each with more than 25 years of clinical experience, independently reviewed all cystoscopic images, blinded to each other's assessments. The initial interexpert agreement was satisfactory (Cohen κ=0.81). In cases of disagreement, a consensus meeting was convened to establish a single unified diagnosis, integrating both normal anatomical features and pathological findings.

Image Interpretation and Lesion Classification Tasks

For a comprehensive evaluation, we designed 2 complementary tasks that reflect distinct components of diagnostic reasoning. The first, the image interpretation task, evaluated each model's capacity for domain-specific interpretation, logical reasoning, descriptive accuracy, and clinical judgment. The second, the lesion classification task, assessed the model's discriminative performance in differential diagnosis. Together, these 2 tasks provided a systematic assessment of MM-LLMs in both free-form interpretation and constrained classification settings, thereby capturing complementary dimensions of clinical decision-making.

Image Interpretation Task

The task used a structured, stepwise, open-ended question format. Each model was primed with a role-based instruction ("Suppose you are a urologist") and prompted with 4 sequential open-ended questions addressing anatomical site (Q1), findings (Q2), lesion reasoning (Q4), and final diagnosis (Q5). Q3 was not an open-ended interpretation item; it was a binary lesion-detection query (present or absent) embedded in the Q1→Q5 chain-of-thought to assess abnormal-versus-normal detection and was automatically graded against the gold standard. Free-text outputs for Q1, Q2, Q4, and Q5 were independently assessed by 3 raters (urology residents with 2-5 years of cystoscopy experience) using a 5-point Likert scale (1=disagree, 2=somewhat disagree, 3=neutral, 4=somewhat agree, and 5=agree).

Blinded and Randomized Evaluation Procedures

A dedicated evaluation software was developed to ensure complete rater blinding and randomization of both image presentation and model output order (Figure S1 in Multimedia Appendix 1).

- Image-level randomization: the display order of images was randomized once and shared across all raters. Each evaluation screen presented only 1 cystoscopic image at a time.
- Structured display: the upper panel displayed the image and its gold-standard answers to 5 reference questions (4 open-ended and 1 binary detection). The lower panel simultaneously presented anonymized text responses from the 4 MM-LLMs.
- Model-level randomization and anonymization: for each image, the order of model outputs was independently shuffled to minimize position bias. Model identities were fully anonymized to raters.
- Scoring process: raters independently scored the free-text responses using the 5-point Likert scale. The binary lesion-detection item (Q3) was automatically graded against the reference standard and was not rated by humans.

Lesion Classification Task

The lesion classification task was conducted to evaluate the models' discriminative capacity. It simulates a clinical scenario in which a urologist has already identified a tumor-like lesion and requires a differential diagnosis. A subset of tumor-like lesion images was used for this analysis. The task involved a 7-class multiple-choice framework comprising cystitis, polyps,

papilloma, pUC, CIS, nonurothelial carcinoma (non-U Ca), and none of the above (NOTA). Models were tested under 2 prompting strategies: zero-shot prompting and ICL. In the ICL condition, a text-based description of tumor-related features was incorporated into the prompt. This task aimed to assess each model's discriminative performance, adaptability to structured clinical classification, and robustness across prompting paradigms.

A subset of tumor-like lesion images was used for this task. The 7-class classification included cystitis, polyps, papilloma, pUC, CIS, non-U Ca, and NOTA. Models were tested under 2 settings—zero-shot prompting and ICL with added tumor-feature descriptions—to assess discriminative performance.

Clinically Relevant Binary Endpoint Conversion

To mirror real-world cystoscopic decision-making when tumor-like lesions are encountered, the 7-class classification task was collapsed into 2 clinically oriented binary endpoints. The first, the biopsy-indication endpoint, represented immediate clinical decision-making: pUC, CIS, non-U Ca, papilloma, and polyps were labeled as "biopsy indicated," whereas cystitis and NOTA were labeled as "biopsy not indicated." The second, the malignancy endpoint, classifies pUC, CIS, and non-U Ca as malignant, and cystitis, polyps, papilloma, and NOTA as nonmalignant. This mapping preserved the full 7-class framework for granular analysis while providing pragmatic outcomes aligned with bedside triage. Notably, papilloma—though histologically benign—was categorized as "biopsy indicated" to reflect the routine need for histologic confirmation.

Prompt Design

The complete and exact prompt designs are detailed in the Multimedia Appendix 1.

Prompt Design With Open-Ended Questions for Image Interpretation

We used a role-based, zero-shot prompt tailored to cystoscopy. The prompt primed domain reasoning ("Suppose you are a urologist") and briefly contextualized the procedure, followed by stepwise instructions to encourage explicit intermediate reasoning. The query comprised five domains: (1) anatomic site (free text), (2) endoscopic findings (free text), (3) presence or absence of a pathological lesion (binary), (4) lesion diagnostic reasoning and justification if present (free text), and (5) final diagnosis (free text).

Prompt Design for Tumor-Like Lesion Classification Task With Multiple-Choice Diagnostic Framework

We compared 2 prompting strategies for cystoscopic diagnosis of tumor-like lesions: zero-shot and ICL. Both adopted a role-based instruction ("Suppose you are a urologist"). The zero-shot prompt presented a single forced-choice 7-class label set. In contrast, the ICL prompt prefixed brief text-based descriptions of the 7 lesion classes before the same multiple-choice query. Models were instructed to provide the best diagnosis from the given options and include a concise rationale grounded in endoscopic morphology.

Outcome Measures and Statistical Analysis

For each image-question-answer instance, the 3 raters' Likert-scale ratings were averaged to obtain a single consensus score. The distribution of these scores across the test set was summarized using the mean and SD to describe the central tendency and variability of model performance. To compare performance among models, pairwise differences in scores were analyzed using paired *t* tests. Results were reported as mean differences with 95% CIs. Given the ordinal nature of Likert-scale data, Wilcoxon signed-rank tests were conducted as a sensitivity analysis. To account for the multiplicity of pairwise comparisons across the top 3 performing models, the Benjamini-Hochberg procedure was applied to control the false discovery rate and mitigate type I error. Consequently, statistical significance for all intermodel comparisons was defined as a false discovery rate–adjusted *P* value (q value)<.05. Subgroup analyses of final diagnosis were conducted according to cystoscopic finding categories and anatomic sites, following the same statistical procedures.

For interpretability, the mean Likert-scale score for each item was further converted into a binary satisfaction outcome: satisfactory if the mean score was >3 and unsatisfactory if ≤3. The satisfaction rate (percentage of satisfactory responses) was reported and used as a binary outcome in subsequent analyses.

The performance metrics for the classification tasks—including binary domains (lesion detection: present vs absent, biopsy indication: yes or no, and malignancy: yes or no) and the 7-class lesion classification—were derived from confusion matrices. Reported metrics included accuracy, sensitivity, specificity, positive predictive value, negative predictive value, Youden J, and the Matthews correlation coefficient (MCC) [23]. Youden J represents the overall diagnostic effectiveness of a test, defined as (sensitivity + specificity – 1), and reflects the balance between true-positive and true-negative rates. The MCC quantifies the overall agreement between predicted and actual classifications by incorporating all 4 components of the confusion matrix (true or false positives and negatives). Metric comparisons were conducted using the chi-square test.

For the 7-class task (n=113), models were instructed to select exactly 1 forced-choice label from the prespecified options. Outputs failing to provide a single permissible choice (eg, refusals such as "I could not answer this question") were coded as invalid. To ensure a consistent head-to-head comparison and minimize selection bias, the primary (strict) analysis used an intent-to-treat approach: invalid outputs were retained in the denominator and treated as incorrect predictions. However, because an invalid output does not necessarily reflect an incorrect diagnosis and may instead represent abstention—potentially safer than guessing in a human-in-the-loop workflow—we conducted a secondary sensitivity analysis, recalculating performance metrics conditional on valid responses only. All statistical analyses were conducted using SAS software (version 9.4; SAS Institute Inc).

Ethical Considerations

The Research Ethics Committee A of National Taiwan University Hospital determined that this study was exempt from

human participant research (NTUH-REC 202507210W). Informed consent was waived because this study involved a secondary analysis of deidentified cystoscopic images with no patient contact or intervention; for publicly available or published images, consent for the original collection followed the source publication, and the exemption permitted secondary analysis without additional consent. All images were deidentified, stored on access-controlled institutional systems, and reported only in aggregate. No participants were recruited, and no compensation was provided; all figures were reviewed to ensure no individual is identifiable.

Results

Distribution of the Whole Test Set and the Tumor-like Lesion Subset

Among 401 cystoscopic images, most originated from the bladder (n=329), followed by the prostate (n=41) and urethra (n=31). Abnormal findings were present in 322 (80.3%) images. The most common categories were tumor or neoplasm (n=126), structural or outlet abnormalities (n=76), inflammatory or reactive changes (n=69), deposits or foreign bodies (n=43), and vascular lesions (n=8); 79 (19.7%) images showed normal anatomy (Table 1). Table 1 provides the detailed distribution of finding subcategories, reflecting diagnostic diversity and difficulty.

Table 1. Detailed distribution of cystoscopic finding subcategories in the whole test dataset (N=401). This table provides a comprehensive breakdown of all observed cystoscopic findings across 3 hierarchical levels (normality, categories, and subcategories) and anatomic sites (bladder, prostate, and urethra). Values are presented as n (intracategory %); percentages represent the proportion of each subcategory within its respective parent category. The inclusion of both benign and malignant findings illustrates the heterogeneity of endoscopic presentations and underscores the diagnostic complexity represented in the dataset.

Anatomic site	Bladder	Prostate	Urethra	Total

[a]CIS: carcinoma in situ.

[b]IC: interstitial cystitis.

The tumor-like lesion subset included 113 visually and pathologically similar images spanning both benign and malignant lesions: cystitis (n=18), polyps (n=7), papilloma (n=12), pUC (n=20), CIS (n=17), non-U Ca (n=17), and NOTA (n=22) (Table 2).

Table 2. Distribution of the tumor-like lesion subset (n=113) used for the 7-class lesion classification task, representing a focused subset of the whole test dataset. The tumor-like lesion subset comprised 18 cystitis (15.9%), 7 polyps (6.2%), 12 papilloma (10.6%), 20 papillary urothelial carcinoma (pUC; 17.7%), 17 carcinoma in situ (CIS; 15%), 17 non-urothelial carcinoma (non-U Ca; 15%), and 22 none of the above (NOTA; 19.5%).

Lesion type	Value, n (%)
Cystitis	18 (15.9)
Polyps	7 (6.2)
Papilloma	12 (10.6)
pUC[a]	20 (17.7)
CIS[b]	17 (15)
Non-U Ca[c]	17 (15)
NOTA[d]	22 (19.5)
Total	113 (100)

[a]pUC: papillary urothelial carcinoma.

[b]CIS: carcinoma in situ.

[c]Non-U Ca: non-urothelial carcinoma.

[d]NOTA: none of the above.

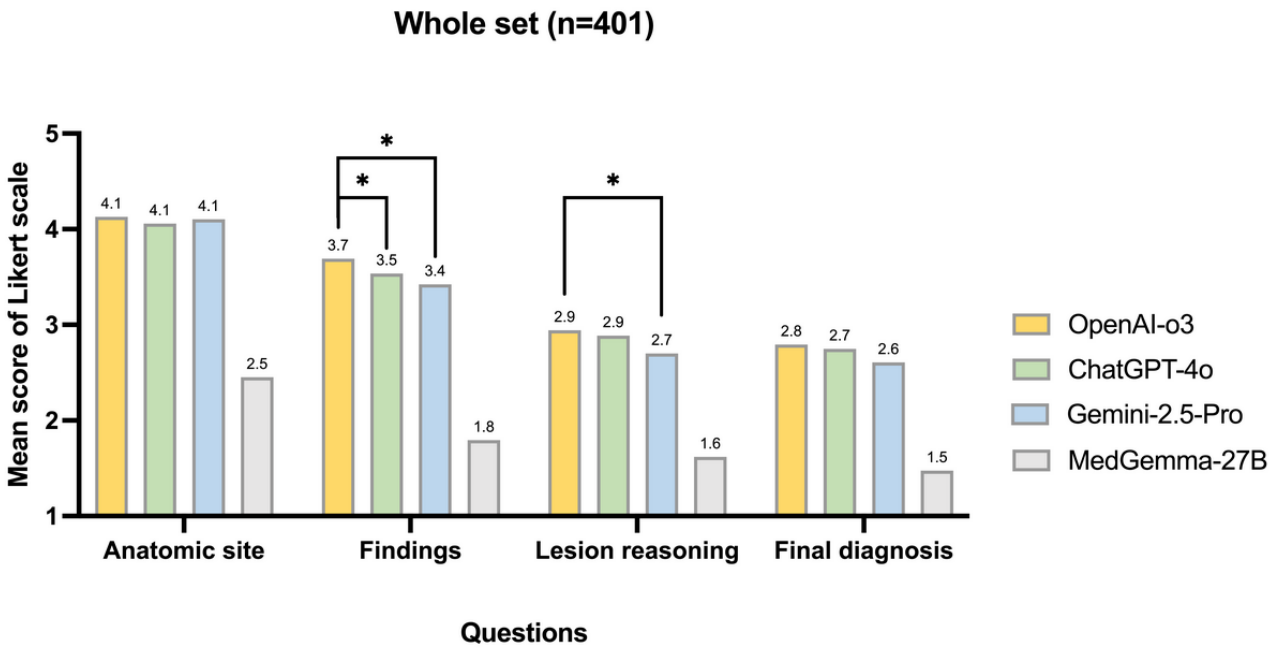
Comparative Mean Scores of LLMs in Image Interpretation

Among the whole test set (n=401), MM-LLMs demonstrated progressively lower performance as task complexity increased (Table 3 and Figure 2). Mean Likert-scale scores declined from anatomic site recognition (≈ 4.1) to findings (≈ 3.4-3.7), lesion reasoning (≈ 2.7-2.9), and final diagnosis (≈ 2.6-2.8). OpenAI-o3, ChatGPT-4o, and Gemini 2.5 Pro achieved comparable accuracy in anatomical localization, while OpenAI-o3 showed the highest overall consistency and clarity in lesion description. Statistically significant differences emerged in the findings, lesion reasoning, and final diagnosis domains, in which OpenAI-o3 outperformed Gemini 2.5 Pro and the medical-specific MedGemma-27B. Notably, MedGemma-27B lagged substantially behind the general-purpose MM-LLMs across all categories, suggesting that its limited training scope constrained both descriptive precision and diagnostic reasoning. These results indicate that reasoning-optimized general-purpose MM-LLMs currently outperform open-source, domain-specific models in free-text cystoscopic interpretation tasks.

Table 3. Performance of 4 multimodal large language models (MM-LLMs) in cystoscopic image interpretation, presented as mean Likert scores and SDs across open-ended questions and final-diagnosis subgroups.

Question and subgroup	Value	OpenAI-o3, mean (SD)	ChatGPT-4o, mean (SD)	Gemini 2.5 Pro, mean (SD)	MedGemma-27B, mean (SD)
Whole test set (n=401)					
Questions					
Q1: anatomic site	401	4.13 (1.24)	4.06 (1.20)	4.10 (1.21)	2.45 (1.37)
Q2: findings	401	3.69 (1.23)	3.54 (1.25)	3.42 (1.30)	1.80 (1.03)
Q4: lesion reasoning	401	2.94 (1.57)	2.89 (1.49)	2.70 (1.48)	1.62 (1.11)
Q5: final diagnosis	401	2.79 (1.59)	2.75 (1.51)	2.61 (1.51)	1.48 (0.93)
Q5. final diagnosis					
Subgrouping by findings					
Tumor or neoplasm	126	3.12 (1.44)	3.32 (1.36)	3.07 (1.51)	2.06 (1.18)
Inflammation or reaction	69	2.34 (1.21)	2.82 (1.30)	2.87 (1.29)	1.19 (0.45)
Deposits or foreign bodies	43	2.77 (1.59)	2.97 (1.52)	2.64 (1.64)	1.07 (0.26)
Structure or outlet	76	1.71 (1.13)	1.45 (0.69)	2.45 (1.67)	1.03 (0.10)
Vascularity	8	2.42 (1.05)	2.75 (0.71)	2.75 (0.87)	1.29 (0.70)
Normal	79	3.79 (1.76)	2.92 (1.81)	1.76 (1.13)	1.49 (1.04)
Subgrouping by anatomic site					
Bladder	329	3.04 (1.56)	3.06 (1.46)	2.64 (1.47)	1.56 (1.00)
Prostate	41	1.45 (1.02)	1.24 (0.62)	2.95 (1.79)	1.09 (0.31)
Urethra	31	2 (1.34)	1.48 (0.91)	1.80 (1.27)	1.12 (0.38)

Figure 2. Comparative mean scores of multimodal large language models (MM-LLMs) for cystoscopic image interpretation across 4 question domains in the whole test set. Asterisks denote statistically significant pairwise differences among the top 3 models. *q<0.05, where q is the false discovery rate (FDR)-adjusted *P* value.



Mean-score pairwise comparisons among models (mean-score deltas) are provided in Table S2 in Multimedia Appendix 1. A 0.2-point difference on the 5-point Likert score corresponds approximately to a 5-point difference on a 100-point scale. The matrix of column-row differences confirmed OpenAI-o3's edge across open-question domains. Versus Gemini 2.5 Pro, OpenAI-o3 scored higher by +0.27 on findings (q=0.002), +0.24 on lesion reasoning (q=0.047), +0.03 on anatomic site, and +0.19 on final diagnosis (not significant). Against ChatGPT-4o, OpenAI-o3 held a small but consistent advantage on findings

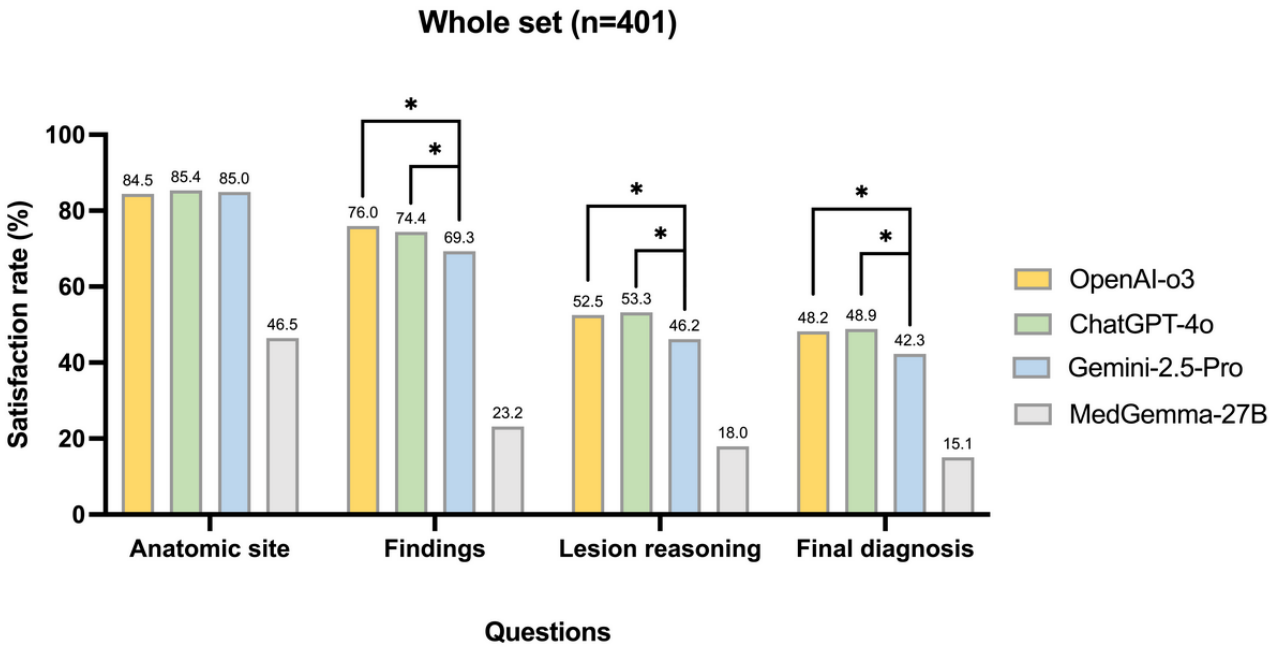
(+0.15, q=0.004) with near-parity on anatomic site, lesion reasoning, and final diagnosis (+0.07, +0.06, +0.04; not significant). All general-purpose models substantially outperformed the medical-specific MedGemma-27B; OpenAI-o3's margins were +1.68 (anatomic site), +1.90 (findings), +1.32 (lesion reasoning), and +1.32 (final diagnosis), all q<0.001. Taken together, these deltas indicate that OpenAI-o3 is the most reliable free-text interpreter, with the largest, statistically robust gains in content-heavy domains (Findings → Reasoning → Diagnosis). The significance pattern of the Wilcoxon signed-rank tests was consistent with that of the paired *t* tests.

Intraclass correlation coefficients demonstrated excellent interrater reliability across both model and question domains. Of the 16 intraclass correlation coefficient values, 14 ranged from 0.82 to 0.94, indicating high consistency among raters (Table S3 in Multimedia Appendix 1).

Model Satisfaction Rates

Satisfaction rates for each question across models closely paralleled mean scores of the Likert scale (Figure 3). Overall, satisfaction ranked anatomic site > findings > lesion reasoning ≈ final diagnosis, consistent with mean-score trends. Anatomic site showed uniformly high satisfaction for the top 3 models (339/401, ≈85%), while MedGemma-27B was much lower (184/401, 46%). For findings, OpenAI-o3 (305/401, 76%) and ChatGPT-4o (297/401, 74%) outperformed Gemini 2.5 Pro (277/401, 69%) and MedGemma-27B (92/401, 23%; all q<0.01). In lesion reasoning, OpenAI-o3 (211/401, 53%) and ChatGPT-4o (201/401, 53%) outperformed Gemini 2.5 Pro (184/401, 46%; q=0.003 and q=0.002 vs Gemini 2.5 Pro, respectively), while MedGemma-27B again had the lowest performance (72/401, 18%). For final diagnosis, satisfaction was lowest overall but remained higher for OpenAI-o3 and ChatGPT-4o (192/401, ≈48%) than for Gemini 2.5 Pro (168/401, 42%) or MedGemma-27B (60/401, 15%).

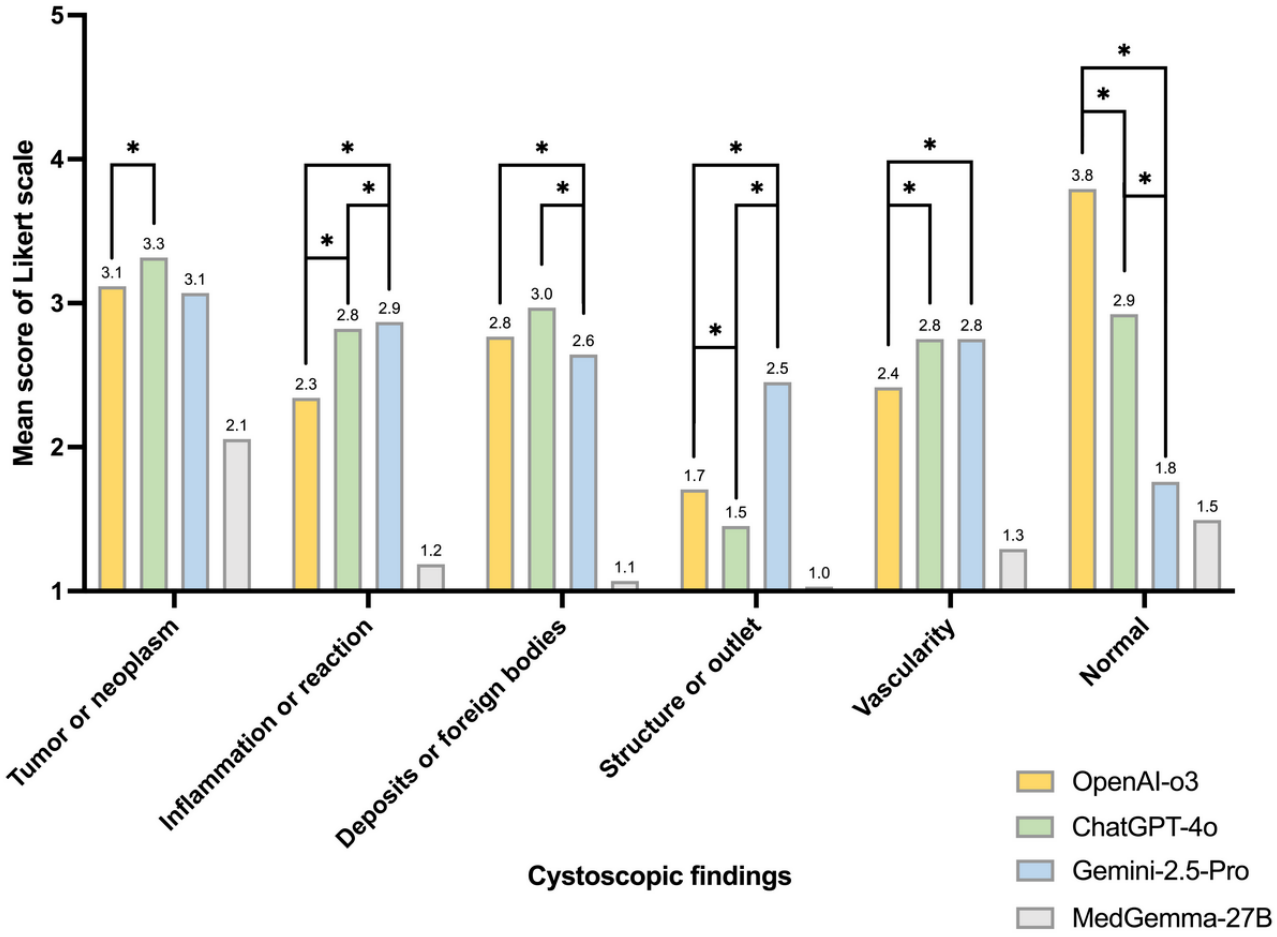
Figure 3. Comparative satisfaction rates (% of cases with mean score >3) of multimodal large language models (MM-LLMs) for cystoscopic image interpretation across 4 question domains. Asterisks denote significance for pairwise comparisons between the top 3 models. *q<0.05, where q is the false discovery rate (FDR)-adjusted *P* value.



Subgroup Analysis of Final Diagnosis

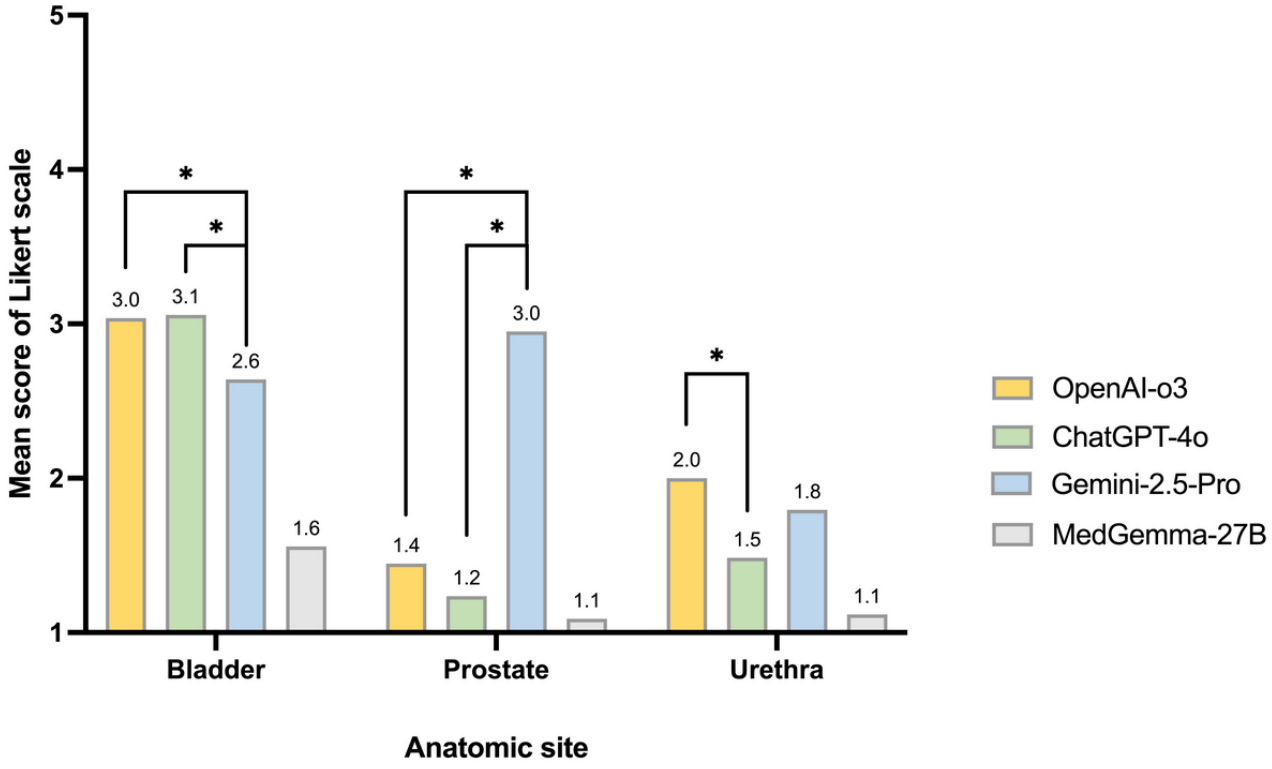
When mean scores for final diagnosis were stratified by finding category (Figure 4 and Table 3), the largest intermodel differences occurred in the normal and structure or outlet groups. OpenAI-o3 achieved the highest score for normal findings (3.79), significantly outperforming ChatGPT-4o (2.92) and Gemini 2.5 Pro (1.76; q<0.001). Conversely, Gemini 2.5 Pro scored best for structure or outlet findings (2.45), exceeding OpenAI-o3 (1.71) and ChatGPT-4o (1.45; q<0.001). For tumor or neoplasm, ChatGPT-4o slightly surpassed OpenAI-o3 (3.32 vs 3.12; q=0.02), with Gemini 2.5 Pro showing comparable performance (3.07). Inflammation or reaction and vascularity categories both favored ChatGPT-4o and Gemini 2.5 Pro over OpenAI-o3, whereas deposits or foreign bodies showed minimal differences among models.

Figure 4. Subgroup analysis of mean final diagnosis scores across 6 cystoscopic finding categories (tumor or neoplasm, inflammation, deposits, structure, vascularity, and normal) for 4 multimodal large language models (MM-LLMs). Asterisks denote significance for pairwise comparisons between the top 3 models. *q<0.05, where q is the false discovery rate (FDR)-adjusted *P* value.



Performance also varied by anatomic site (Figure 5 and Table 3). Gemini 2.5 Pro performed best in the prostate (2.95), significantly exceeding OpenAI-o3 (1.45) and ChatGPT-4o (1.24; q<0.001). In the bladder, OpenAI-o3 (3.04) and ChatGPT-4o (3.06) outperformed Gemini 2.5 Pro (2.64; q<0.001). For the urethra, OpenAI-o3 (2) exceeded ChatGPT-4o (1.48; q=0.02), with Gemini 2.5 Pro intermediate (1.80). These site-specific trends suggest complementary strengths: Gemini 2.5 Pro performs relatively better in structure-dominated prostate views, whereas OpenAI-o3 and ChatGPT-4o perform best in bladder-focused interpretation.

Figure 5. Subgroup analysis of mean final diagnosis scores across 3 anatomic sites (bladder, prostate, and urethra) for 4 multimodal large language models (MM-LLMs). Asterisks denote significance for pairwise comparisons between the top 3 models. *q<0.05, where q is the false discovery rate (FDR)-adjusted *P* value.



Clinically Relevant Binary Endpoints

For the lesion-detection task in the whole test set, OpenAI-o3 achieved the highest overall performance, with an accuracy of 88.3%, a Youden J of 0.650, and an MCC of 0.635, followed by ChatGPT-4o and Gemini 2.5 Pro, while MedGemma-27B performed the lowest (Table 4). OpenAI-o3 demonstrated the most balanced profile (sensitivity 92% and specificity 73.1%), whereas ChatGPT-4o showed higher sensitivity but lower specificity (94.4% vs 44.2%). Gemini 2.5 Pro exhibited an extreme trade-off—maximal sensitivity (99.7%) but very low specificity (10.3%). MedGemma-27B produced the weakest results overall (accuracy 45.6%, Youden J –0.103, and MCC –0.081).

Table 4. Binary classification performance of 4 multimodal large language models (MM-LLMs) in clinically relevant cystoscopic endpoints (strict analysis).

[a]MM-LLM: multimodal large language model.

[b]VRR: valid response rate. Valid response rate = (total - invalid) / total. Invalid denotes outputs failing to provide a single permissible choice.

[c]Acc: accuracy.

[d]Sen: sensitivity.

[e]Spe: specificity.

[f]PPV: positive predictive value.

[g]NPV: negative predictive value.

[h]Youden J: Youden J Index.

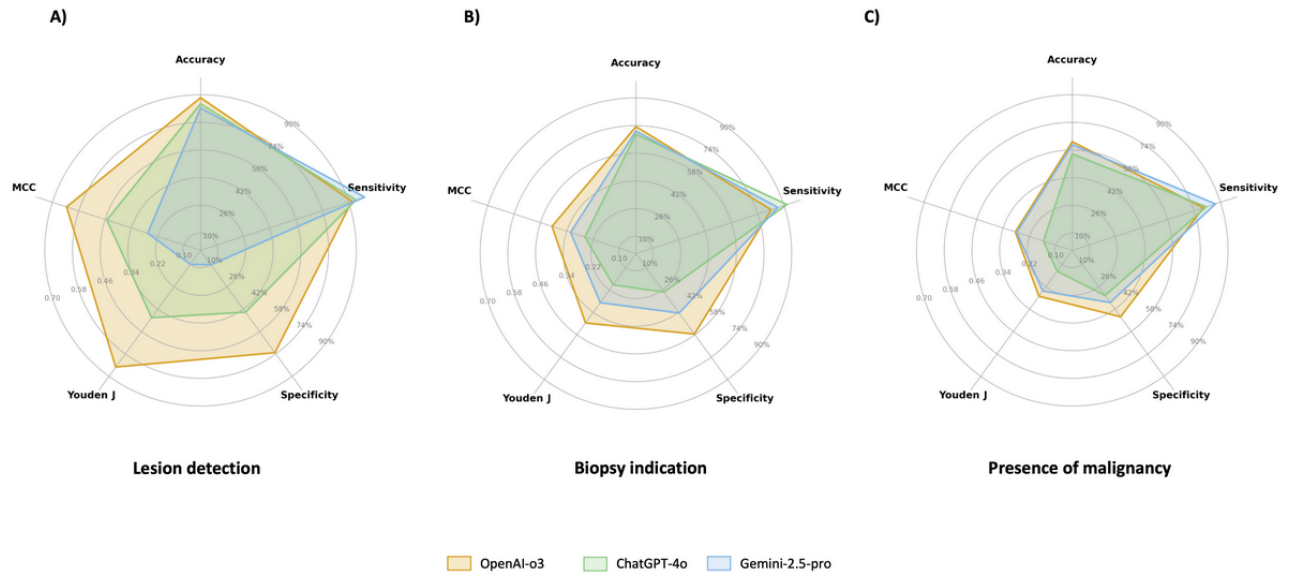
[i]MCC: Matthews correlation coefficient.

In the tumor-like lesion subset (n=113), OpenAI-o3 again achieved the highest Youden J and MCC performance for both biopsy-indication and malignancy endpoints, followed by Gemini 2.5 Pro and ChatGPT-4o, with MedGemma-27B lowest. For biopsy indication, OpenAI-o3 reached 73.5% accuracy (Youden J=0.397 and MCC=0.407), demonstrating the best specificity-sensitivity balance. ICL modestly improved specificity and accuracy (Table 4). For malignancy detection, OpenAI-o3 similarly performed best (accuracy 62.8%), followed by Gemini 2.5 Pro and ChatGPT-4o, whereas MedGemma-27B underperformed (Tables S4-S5 in Multimedia Appendix 1).

Overall, OpenAI-o3 demonstrated the most balanced diagnostic performance across all 3 binary endpoints, consistently achieving the highest Youden J, largely attributable to its superior specificity (Figure 6). For lesion detection, specificity reached 73.1%, significantly outperforming ChatGPT-4o

(44.2%; q<0.001) and Gemini 2.5 Pro (10.3%; q<0.001; Figure 6A). In biopsy indication, specificity was 57.5%, again higher than ChatGPT-4o (27.5%; q<0.001) and Gemini 2.5 Pro (42.5%; q=0.047; Figure 6B). In malignancy prediction, OpenAI-o3 maintained the highest specificity (47.5%) compared to ChatGPT-4o (32.2%; q=0.042) and Gemini 2.5 Pro (37.3%; q=0.21; Figure 6C). In contrast, MedGemma-27B demonstrated limited generalizability despite its medical-domain optimization.

Figure 6. Radar charts illustrating diagnostic performance across 3 cystoscopic endpoints in classification tasks. Panels represent (A) lesion detection (presence vs absence), (B) biopsy indication (yes vs no), and (C) presence of malignancy (yes vs no). Five key metrics are visualized: accuracy, sensitivity, specificity, Youden J index, and Matthews correlation coefficient (MCC).



Seven-Class Tumor-Like Lesion Classification

For the 7-class classification (n=113), OpenAI-o3 remained the top-performing model, although overall accuracy was modest, improving only slightly with ICL (microaverage accuracy from 40.7% to 46% and MCC from 0.311 to 0.370) (Table 5). Class-level performance was heterogeneous. In the zero-shot setting, malignant categories (pUC and CIS) achieved relatively balanced sensitivity and specificity, whereas benign lesions (cystitis, polyps, and papilloma) showed high specificity but low sensitivity. Notably, non-U Ca were not recognized. ICL mainly adjusted the sensitivity-specificity balance—enhancing detection of polyps, papilloma, and NOTA while slightly reducing sensitivity for cystitis and CIS. However, non-U Ca remained unrecognized.

Table 5. Confusion matrix outlining the performance of OpenAI-o3 in 7-class tumor-like lesion classification under zero-shot and in-context learning prompting (strict analysis).

	Actual							Total

[a]pUC: papillary urothelial carcinoma.

[b]CIS: carcinoma in situ.

[c]Non-U Ca: non-urothelial carcinoma.

[d]NOTA: none of the above.

[e]Invalid: model outputs failing to provide a single permissible choice.

[f]ICL: in-context learning.

[g]AVG: microaverage.

[h]PPV: positive predictive value.

[i]NPV: negative predictive value.

[j]Youden J: Youden J Index.

[k]MCC: Matthews correlation coefficient.

The other 3 models performed suboptimally and showed limited responsiveness to ICL (Tables S6-S8 in Multimedia Appendix 1). In the zero-shot setting, microaveraged accuracy ranked as follows: 36.3% (Gemini 2.5 Pro); 31.9% (ChatGPT-4o), 28.3% (MedGemma-27B), with Youden J and MCC both 0.164-0.257. Under ICL, accuracy was similar or slightly lower—34.5% (Gemini 2.5 Pro), 31% (ChatGPT-4o), and 27.4% (MedGemma-27B)—with minimal shifts in Youden J and MCC (0.153-0.236). Class-wise patterns were consistent: malignant categories (pUC, CIS, and non-U Ca) showed the most balanced sensitivity-specificity trade-offs, whereas benign entities (cystitis, polyps, and papilloma) had low sensitivity but high specificity.

Analysis of the NOTA Category

The NOTA category represents a unique "negative exclusion" challenge. Previous research indicates that LLMs often exhibit a bias toward positive selection, struggling to confidently select "None of the Above" even when accurate [24,25]. Our results show that this bias is pervasive, affecting models across different architectures (Tables S6-S8). Despite being a reasoning-optimized model, Gemini 2.5 Pro aligned with the general-purpose ChatGPT-4o and the medical-specific MedGemma-27B in exhibiting a "high specificity, low sensitivity" pattern. Specifically, Gemini 2.5 Pro and ChatGPT-4o achieved high specificity (>97%) but low sensitivity (9.5%-27.3%) across prompting strategies. The open-weight MedGemma-27B exhibited the most severe manifestation of this bias: while its specificity remained high (98.9%), its sensitivity was only 13.6% in the zero-shot setting and collapsed to 0% under ICL prompting. This indicates that for models unable to effectively leverage negative logic, added textual context may inadvertently reinforce positive selection bias.

A distinct divergence was observed between the 2 reasoning-optimized models. In contrast to Gemini 2.5 Pro, OpenAI-o3 demonstrated superior handling of exclusion (Table 5). It achieved a significantly higher baseline sensitivity of 45.5% in the zero-shot setting. Moreover, while ICL yielded negligible or detrimental effects for the other 3 models, OpenAI-o3's sensitivity surged to 63.6% under ICL prompting. This suggests that OpenAI-o3's specific implementation of chain-of-thought reasoning is critical for overcoming the standard positive selection bias, allowing for robust diagnosis through exclusion where other reasoning and general models failed.

Sensitivity Analysis: Conditional on Valid Responses

In the tumor-like lesion classification task, invalid (refusal) outputs were uncommon: valid-response rates were ≈100% for OpenAI-o3, Gemini 2.5 Pro, and MedGemma-27B, whereas ChatGPT-4o had the highest invalid rate (7.1%) in zero-shot prompting. While excluding invalid responses can inflate performance (introducing optimistic bias) relative to the strict analysis, invalid outputs can be interpreted clinically as abstention, which may be safer than guessing in a human-in-the-loop workflow because it prompts clinician confirmation. Accordingly, we report conditional-on-valid performance to better reflect accuracy when the model provides a valid output (Table S9 in Multimedia Appendix 1).

ChatGPT-4o showed the largest strict vs conditional-on-valid differences, consistent with its lower valid-response rate (Table 4 vs Table S9 in Multimedia Appendix 1). Accuracy and Youden J increased from 69% and 0.193 to 74.3% and 0.267 for biopsy indication and from 55.8% and 0.137 to 60% and 0.205 for malignancy. Seven-class changes were small, most notably higher sensitivity for NOTA (from 13.6% to 15%) and cystitis (from 11.1% to 14.3%), with microaverage sensitivity rising from 31.9% to 34.3%.

ICL-focused takeaway across models was that text-only ICL chiefly reweighted sensitivity-specificity rather than boosting overall accuracy; modest gains in benign or NOTA recognition were offset by reduced sensitivity in key malignant classes.

Discussion

Principal Findings

This study is the first to benchmark SOTA MM-LLMs for cystoscopic interpretation under a clinician-defined stress test with rare and diagnostically difficult lesions. The rigorous, blinded design enabled objective assessment of interpretive reasoning and classification. Outputs were also mapped to actionable binary endpoints and used to quantify the incremental effect of text-based ICL over zero-shot prompting, thereby revealing both strengths and current limitations of MM-LLMs in real-world clinical tasks.

Overall, OpenAI-o3 demonstrated superior performance, followed by ChatGPT-4o and Gemini 2.5 Pro, with MedGemma-27B showing the most limited capabilities. The results revealed a progressive decline in model performance as diagnostic complexity increased—from anatomical recognition to higher-order diagnostic synthesis. While models showed meaningful strength in visual recognition and descriptive reporting, performance in challenging differential diagnosis

remained modest, suggesting that current MM-LLMs function best as assistive rather than autonomous diagnostic tools at present.

Image Interpretation and Lesion Classification Tasks

The free-text interpretation task assessed 4 domains of increasing complexity—anatomic site, findings, lesion reasoning, and final diagnosis—simulating real-world diagnostic synthesis that integrates visual recognition with clinical reasoning. Task satisfaction declined with increasing complexity, from anatomic localization (~85%) to definitive diagnosis (~45%). OpenAI-o3 and ChatGPT-4o consistently outperformed Gemini 2.5 Pro and MedGemma-27B, though with distinct profiles: OpenAI-o3 produced concise, accurate descriptions with coherent diagnostic impressions and high specificity for normal anatomy, while ChatGPT-4o showed greater sensitivity for inflammatory and vascular findings. In contrast, Gemini 2.5 Pro often overcalled minor irregularities but performed better on prostate lesions, likely reflecting prostate-predominant pretraining. These discrepancies indicate that MM-LLM behavior depends not only on recognition accuracy but also on underlying reasoning logic, diagnostic thresholds, and domain-specific pretraining.

Regarding clinical decision endpoints, the goal of cystoscopy is to identify abnormal lesions—particularly malignancies—so that biopsies are performed when necessary while avoiding unnecessary procedures that increase cost and risk. Thus, lesion detection, biopsy indication, and malignancy presence were defined as key clinical endpoints. OpenAI-o3 achieved the most balanced performance across sensitivity, specificity, and Youden J, outperforming ChatGPT-4o and Gemini 2.5 Pro, especially in specificity, by accurately distinguishing normal from malignant cases—supporting appropriate biopsy decision-making. These findings highlight the importance of calibrating operating points to clinical priorities and suggest that MM-LLMs, particularly OpenAI-o3, can aid cystoscopic decision-making when optimized for an appropriate specificity-sensitivity balance.

The 7-class lesion classification task evaluated each model's ability to distinguish visually and pathologically similar tumor-like lesions. Models performed best on prevalent malignant lesions (pUC) but struggled with benign mimickers (polyps and papilloma) and rare entities (non-U Ca), often misclassified as pUC—reflecting limited pretraining exposure to uncommon classes. As shown in Table 5, 14 of 17 non-U Ca cases (82.4%) were predicted as pUC, a much more prevalent bladder tumor. One plausible explanation is that LLMs exhibit a tendency to choose majority or high-frequency labels in multiple-choice settings. When pretraining class distributions are imbalanced, the token sequences corresponding to common options (eg, "pUC") can carry higher previous probabilities, biasing the model toward these answers irrespective of correctness. This phenomenon is often described as majority-label bias or common-token bias [26].

On the other hand, the frequent misclassification of papilloma as pUC highlights the inherent challenge of distinguishing these entities based solely on cystoscopic appearance—a difficulty shared by human experts. Rather than indicating model failure, these confusion patterns reflect the substantial macroscopic overlap between papilloma and low-grade pUC. While visual distinction remains experimental, our study addressed this clinical reality by grouping both entities under the "Biopsy Indicated" category in the binary endpoint analysis. In that context, the models successfully flagged these lesions for histologic confirmation, aligning with standard safety protocols despite the specific classification ambiguity. CIS, a flat, high-grade, non-invasive UC subtype, was handled well by OpenAI-o3, achieving strong results (accuracy 86.7, sensitivity 52.9, specificity 92.7, and Youden J 0.46) despite diagnostic difficulty. Overall, OpenAI-o3 showed the most balanced performance, particularly excelling in benign and NOTA classifications, achieving higher specificity than ChatGPT-4o and Gemini 2.5 Pro.

Performance Disparity and the Role of the Open-Weight Baseline

Although MedGemma-27B is a medical-specific model, its performance trailed behind the general-purpose proprietary models (OpenAI-o3, ChatGPT-4o, and Gemini 2.5 Pro). This gap can be attributed to 2 primary factors: domain-specific data misalignment and model scale. First, contrary to the expectation that a medical model should inherently outperform general models, MedGemma's training distribution did not encompass the specific modality of cystoscopy. While its multimodal components (SigLIP encoder) were rigorously pretrained on diverse medical datasets—including chest X-rays, dermatology images, ophthalmology images, and histopathology slides—endoscopic imagery was notably absent from its pretraining corpus. Consequently, the model faced a "zero-shot" challenge in a domain it had not explicitly learned, whereas the massive general-purpose models likely benefited from broader exposure to endoscopic images present in their web-scale training data.

Second, as a local and open-weight baseline, MedGemma-27B (≈27B parameters) operates with significantly constrained capacity compared to the proprietary SOTA architectures. It lacks the extensive parameter count, training budget, and chain-of-thought optimization that allow models such as OpenAI-o3 to generalize across unseen tasks. Therefore, our intent is not to claim parity with these massive systems, but to establish a transparent performance floor for open-weight deployment. Despite the lower accuracy in this zero-shot setting, MedGemma-27B remains a critical benchmark for institutions requiring on-premise, privacy-preserving solutions. Its performance represents the current starting point for future adaptation, such as LoRA fine-tuning or retrieval-augmented prompting, rather than a direct competitor in raw reasoning capability.

Comparing With Previous Studies

Guo et al. [17] reported comparable findings when evaluating ChatGPT-4V (OpenAI) and Claude-3.5 (Anthropic) on 603 cystoscopic images, achieving accuracies of 82.8% and 79.8% but with marked variability across conditions. Both models performed well for cystitis and bladder tumors but poorly for BPH and normal structures, indicating that general-purpose LLMs detect major lesions with high sensitivity but struggle

with subtle findings. Similar variability has been observed in gastrointestinal endoscopy, where ChatGPT-4V showed mixed accuracy across lesion types and underperformed relative to tuned CNN models [27]. Recent work suggests that general multimodal models such as Gemini 2.5 Pro may even surpass specialized AI in certain "edge cases" [28]. Unlike task-specific systems, these models can simultaneously classify images and generate descriptive reasoning and management suggestions, offering value for clinical interpretation and education.

Enhancing MM-LLM Performance in Medical-Specific Domain

Several in-domain strategies can improve general-purpose MM-LLMs without training from scratch, including ICL, contrastive pretraining, and retrieval augmentation.

In our study, text-only ICL with brief cystoscopic tumor descriptions had minimal impact, except for OpenAI-o3. Specificity rose slightly, and sensitivity improved for rare benign lesions, but this was offset by reduced sensitivity for malignant classes (pUC and CIS)—a trade-off in which stricter thresholds reduce false positives and unnecessary biopsies, but risk missed cancers. These findings indicate that text-only ICL confers minimal benefit for image-dominant tasks. Notably, OpenAI-o3 showed a modest gain in micro-average accuracy (0.41-0.46), driven mainly by NOTA, likely reflecting its reasoning-oriented architecture and more flexible use of ICL as contextual support.

A likely reason for the limited effect is insufficient visual grounding: text-only cues do not anchor the model's attention to class-defining morphology. In fine-grained visual discrimination (eg, cystoscopic lesion typing), semantic hints (eg, "papillary fronds" and "flat erythematous base") may not map reliably to visual features unless those associations were learned during pretraining; without image exemplars, the model's visual reasoning remains underconstrained.

Beyond text-only prompts, few-shot image-text exemplars (multimodal ICL) can strengthen grounding and improve accuracy. Presenting paired lesion images with diagnoses exposes prototypical visual features and tightens the link between morphology and class semantics. Across histopathology imaging, image-text ICL has enabled ChatGPT-4V to approach or surpass task-specific classifiers with only 5-10 examples per class, markedly narrowing the gap between zero-shot and fully supervised models [29].

In parallel, contrastive-learned encoders (eg, MedCLIP) [30] and multimodal retrieval augmentation [31] can enrich representations and factual grounding, mitigating data scarcity and hallucination. In summary, improving MM-LLM image classification in medical domains is multifaceted, and combining hybrid ICL (image + text), contrastive pretraining, and retrieval augmentation offers a practical path to greater accuracy, robustness, and interpretability in cystoscopic diagnosis.

Clinical Implications

MM-LLMs offer greater flexibility than task-specific endoscopy AI by combining visual recognition with contextual reasoning and narrative explanation. They can interpret morphology-diverse findings and integrate relevant clinical text, supporting a more context-aware understanding. Our results suggest potential applications in education and workflow support, including serving as virtual tutors for trainees and automating report generation to reduce workload and standardize documentation. However, their moderate diagnostic accuracy, particularly for rare or subtle lesions, limits their current use as autonomous diagnostic tools. Future efforts should focus on vision-conditioned ICL, multimodal retrieval-augmented training, and video-based modeling to enhance interpretive stability and diagnostic confidence [30,31]. Integration with patient-level data, cystoscopy-specific benchmark datasets, and human-in-the-loop oversight will be critical to ensure clinical safety and responsible implementation.

Limitations

This study has several methodological strengths, including an unbiased and rigorous evaluation framework. The dual-task design enabled simultaneous assessment of reasoning transparency, adaptability, and accuracy—helping distinguish superficial pattern recognition from genuine clinical understanding. However, several limitations should be acknowledged. First, our ICL implementation was text-based only: models received brief written descriptions of tumor features without any paired visual exemplars. As a result, this study evaluated "text-based ICL" rather than full multimodal ICL, and the absence of a few-shot image or image-text examples likely constrained the models' multimodal capabilities. The modest gains observed with ICL in our experiments may therefore underestimate the potential benefit of visual or hybrid (image + text) ICL. Future work should directly compare text-based, visual, and hybrid ICL strategies and explore complementary approaches such as contrastive-learned encoders and multimodal retrieval augmentation for cystoscopic diagnosis. Second, because the raw test images were drawn from heterogeneous sources, residual confounding from source-related differences and image-quality artifacts cannot be fully excluded. Although we applied a strict 3-layer quality control pipeline—image exclusion criteria, standardized preprocessing, and human verification of diagnostic utility—to mitigate these effects, some bias related to image source heterogeneity may remain. In addition, our evaluation relied on static images; incorporating temporal cues from cystoscopy videos may improve recognition of subtle or evolving lesions and reduce misclassification. Third, our dataset has an enriched abnormality prevalence (80.3%), substantially higher than that of typical clinical populations (20%-30%). Consequently, the reported positive predictive value and negative predictive value are inflated and not generalizable; they should be interpreted as dataset-specific rather than as estimates for real-world screening or hematuria-clinic settings.

Conclusions

Using a clinically challenging, stress-test image set and a rigorous blinded evaluation framework, this study comprehensively assessed MM-LLMs for cystoscopic interpretation and lesion classification. Among the evaluated models, OpenAI-o3 demonstrated the most balanced and clinically coherent performance, followed by ChatGPT-4o and Gemini 2.5 Pro. These findings highlight the meaningful

assistive potential of MM-LLMs in generating interpretable free-text rationales, supporting biopsy triage, and facilitating training. However, their performance in truly difficult differential diagnoses remains modest and requires further optimization before safe clinical integration.

Acknowledgments

We would like to extend our heartfelt gratitude to our colleagues for their invaluable contributions to this work. ChatGPT (OpenAI) was used only for language editing and grammar correction; it was not used for content generation or any data-related tasks.

Data Availability

The datasets generated and/or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

YCS and CYW contributed equally as first authors. SWH and CYT contributed equally as corresponding authors. Conceptualization was performed by CYT and SWH. Data curation was carried out by YCS and CYW. Formal analysis was conducted by CYW, YCS, SWH, and CYT. Visualization was undertaken by CYT and CYW. The original draft was written by CYW and YCS, and SWH and CYT completed manuscript review and editing. Supervision was provided by CYT and SWH.

Conflicts of Interest

None declared.

Abstract

Background: Interoperability has been a challenge for half a century. Led by an informatics view of the world, the quest for interoperability has evolved from typing and categorizing data to building increasingly complex models. In parallel with the development of these models, the field of terminologies and ontologies emerged to refine granularity and introduce notions of hierarchy. Clinical data models and terminology systems vary in purpose, and their fixed categories shape and constrain representation, which inevitably leads to information loss.

Objective: Despite these efforts, semantic interoperability remains imperfect. Achieving it is essential for effective data reuse but requires more than rich terminologies and standardized models. This methodological study explores the extent to which the SNOMED CT (Systematized Nomenclature of Medicine – Clinical Terms) compositional grammar can be leveraged and extended to approximate a formal descriptive grammar, allowing clinical reality to be expressed in coherent, meaningful sentences rather than preconstrained categories.

Methods: Building on a decade of semantic representation efforts at the Geneva University Hospitals, we developed a framework to identify recurring semantic gaps in clinical data. We addressed these gaps by systematically modifying the SNOMED CT Machine Read` Concept Model and extending its Augmented Backus-Naur Form syntax to support necessary grammatical structures and external vocabularies.

Results: This approach enabled the semantic representation of over 119,000 distinct data elements covering 13 billion instances. By extending the grammar, we successfully addressed critical limitations such as negation, scalar values, uncertainty, temporality, and the integration of external terminologies like Pango. The extensions proved essential for capturing complex clinical nuances that standard precoordinated concepts could not represent.

Conclusions: Rather than creating a new standard from scratch, extending the grammatical capabilities of SNOMED CT offers a viable pathway toward high-fidelity semantic representation. This work serves as a proof-of-concept that separating the rules of composition from vocabulary allows for a more flexible and robust description of clinical reality, provided that challenges regarding governance and machine readability are addressed.

Introduction

Status of Health Care Interoperability

Achieving semantic interoperability remains a central challenge in biomedical informatics and health data integration. While technical interoperability ensures that systems can exchange data in compatible formats, semantic interoperability guarantees that exchanged information is unambiguously interpretable across heterogeneous systems and contexts. This objective requires the explicit representation of meaning through formal models, ontologies, and standardized vocabularies, enabling computational reasoning and automated integration of clinical data.

Significant efforts have been invested in developing tools and frameworks to bring semantics to the complex field of health data. In Switzerland, the Swiss Personalized Health Network and its 3-pillar strategy defined a strong semantic representation of data as the first and mandatory pillar [1]. At the European level, the European Health Data Space initiative has further emphasized the importance of standardized, interoperable health data to enable secure sharing and secondary use across member states [2]. Similarly, in the United States, the Office of the National Coordinator for Health IT promotes this goal through the US Core Data for Interoperability, a standardized set of data elements required for nationwide health information exchange [3]. For years, the field of semantic interoperability has been supported by clinical data models, considered technical standards, and classifications and terminologies, called semantic standards.

The multiplication of semantic standards has prompted the need for ontology alignment, or ontology matching, to establish semantic correspondences between heterogeneous terminologies and domain ontologies. Classical systems such as AgreementMaker leverage a combination of lexical similarity, structural consistency, and description logic reasoning to ensure coherent mappings between ontologies [4]. More recent approaches, such as BERTMap, apply contextual language models to improve recall and precision in complex clinical terminologies [5].

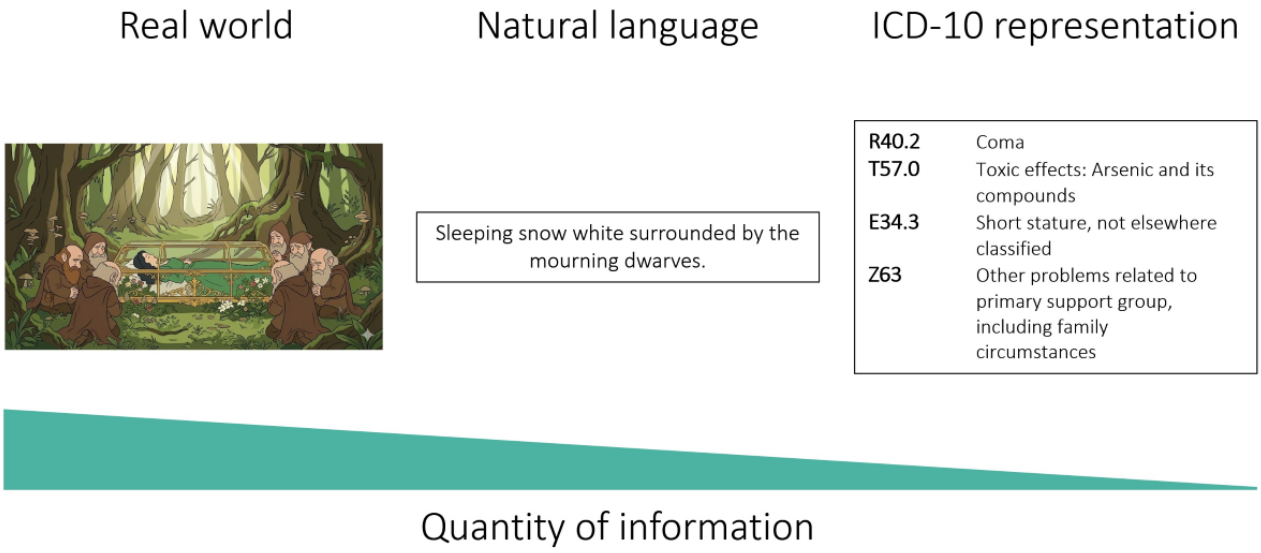
Compositional grammar (CG) models provide a structured means of representing the internal semantics of clinical expressions. Clinical concepts are inherently compositional and thus require formalisms that can represent their components and relationships. Frameworks such as the SNOMED CT (Systematized Nomenclature of Medicine – Clinical Terms) CG define syntactic and semantic rules for postcoordinated expressions (PCEs), ensuring internal consistency and machine interpretability [6].

Semantic interoperability also relies on formal logic–based models, typically expressed in Description Logics (DL), which underpin the Web Ontology Language. These models enable key reasoning tasks such as classification, consistency checking, and inferencing [7]. Building on this foundation, knowledge graphs have emerged as a flexible paradigm for integrating heterogeneous biomedical data, representing entities and their relationships within a unified semantic space.

Several international standardization bodies have developed complementary frameworks to support semantic interoperability. Health Level Seven Fast Healthcare Interoperability Resources (FHIR) provides a resource-oriented model for data exchange, including semantic bindings to standard terminologies such as SNOMED CT, Logical Observation Identifiers Names and Codes (LOINC), and Unified Code for Units of Measure, and offers Resource Description Framework and Web Ontology Language representations for semantic web integration [8]. The Observational Medical Outcomes Partnership (OMOP) Common Data Model, developed within the Observational Health Data Sciences and Informatics initiative, harmonizes observational health data using standardized vocabularies and facilitates analytical interoperability [9]. Cross-domain efforts, including ISO (International Organization for Standardization) 23903 and the World Wide Web Consortium's Health Care and Life Sciences group, promote semantic harmonization through formal metadata and linked data principles [10].

Each of these models has its strengths and weaknesses, and no system fits all purposes [11-13]. Creating a data model ultimately involves defining a finite set of categories, making choices that inherently shape what can and cannot be represented. These reflect the intended purpose of the model, but fitting data into these finite sets inevitably modifies it, making reuse based on model-specific categories less granular [14]. Semantic standards similarly have specific purposes, and granularity can vary dramatically depending on the focus of the classification. The *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) can be useful in representing disease, but cannot represent surgical interventions. Representing data using only single codes from a classification will inherently result in information loss that will be tied to the focus and granularity of the terminology. Figure 1 depicts this loss using a commonly known situation and its representation in natural language, then in *ICD-10* codes.

Figure 1. Information loss when using single standards to represent reality.



SNOMED CT and Natural Language

In this landscape, the CG of SNOMED CT, combined with its broad coverage, makes it a strong candidate for semantic interoperability [15]. With its knowledge graph–like structure, it allows intelligent code retrieval through its expression constraint language and gives users the ability to create PCEs to represent absent concepts. This relies on 2 elements. The CG, an Augmented Backus-Naur Form (ABNF) syntax, is used to create composed expressions that can be parsed and evaluated automatically [16]. The Machine Readable Concept Model (MRCM) defines which concepts (domain) can be refined with which relation (attribute) to which values (range). Combining these resources with the editorial guide, which defines attributes-naming conventions, ensures that new expressions comply with SNOMED CT's rules and grammar [17].

However, while designed for postcoordination and full expressivity of clinical concepts, it is rarely used to its full capacity and is intended for SNOMED CT concepts only [18,19]. It lacks granularity in some fields, such as strains of SARS-CoV-2, while others, such as genomic sequences, are not covered at all. Using SNOMED CT to represent clinical structured data within its expected parameters is eventually restrictive and insufficient to cover everything. Each attribute has a very specific range, domain, definitions, and permitted use cases, known as domain-specific modeling, and extending it eventually becomes necessary [20].

Like natural languages, SNOMED CT can be described as consisting of 3 fundamental components: a vocabulary of words, a grammar defining the rules for their combination, and the resulting sentences. Natural languages, however, allow the creation of any sentence respecting their grammar, regardless of their meaning, and regularly integrate words from other languages. A sentence such as "The 'entrepreneur' dropped his children off at 'kindergarten' before going to a 'karaoke'" uses words from French, German, and Japanese, which have been fully integrated into the English language. It is possible to draw inspiration from this structure to form a similar, computer-processable language, and applying this philosophy to SNOMED CT could improve its usability to fully represent clinical data semantically. The field of medical informatics already possesses rich vocabularies such as SNOMED CT, which serve as the source of machine-readable "words," each with its own specific strengths and weaknesses. They must then be combined according to well-defined grammar rules to form expressions, for which the SNOMED CT CG provides a comprehensive base.

Beyond SNOMED CT

Despite long-standing efforts to construct a comprehensive medical terminology, a single complete solution remains elusive, often resulting in the use of fragmented assemblies of various systems [21]. What remains necessary is a unifying set of rules to govern composition.

The solution should be formal, as semantic representation requires clear rules for machine readability that define how building blocks assemble into structured expressions. It must be descriptive rather than prescriptive. While grammars guide expression, they should not restrict what can be said a priori but rather ensure reality can be described clearly and consistently. Importantly, the solution must be dynamic, evolving through continuous iteration. Clinical reality is complex and ambiguous, with new findings emerging faster than they can be formally incorporated. Enabling the construction of meaningful expressions even without predefined concepts allows rapid adaptation to this complexity. To the best of our knowledge, such a formal descriptive grammar (FDG) does not exist yet.

This study proposes a first step in this direction by leveraging SNOMED CT to represent clinical data while ensuring machine readability. We summarize requirements gathered through 10 years of manual semantic representation and describe an implementation based on extending SNOMED CT's CG, syntax, and MRCM. This approach aims to represent clinical data regardless of source, output terminology, or intended use case.

While the results presented reflect the current state, they remain open-ended and extensible.

Methods

Overview

This work was developed in parallel to the semantic representation of structured data in the Geneva University Hospitals (HUG) data lake over the past decade. It builds upon the methodological framework introduced in *Semantics in Action: a Guide for Representing Clinical Data Elements* [22] and *Scalar Values in SNOMED CT: a Proposed Extension* [23], which proposes a structured and iterative approach for semantically representing clinical data. Counts of represented metadata elements are derived from the Clinical Data Warehouse without individual data extraction.

Framework

The guide's competency-building framework and rule-creation cycle were followed, incorporating both manual expert encoding and consensus-based refinement of representation rules through regular focus groups to define the FDG. The method used was gradually complexified in focus groups as more rules became necessary.

The teaching framework focuses on the use of SNOMED CT and follows a 3-part approach. First, SNOMED International's (SI) introductory training courses and documentation are taken to familiarize newcomers with the basics of standard-based semantic representation [24]. This allows new team members to start work on a simpler 1-dimensional representation, such as a problem list value set [25]. Next, internal documentation and continued practice give trainees a deeper understanding of real data and local specificities, allowing them to represent more complex data. Finally, more advanced courses, such as the SNOMED CT authoring courses, are taken by long-term core team members [26]. These, along with the practical experience gained by taking part in the training, give the ability to supervise newcomers and to participate in the rule creation cycle described below. New team members are always supervised closely by experienced team members and progressively increase the complexity of their tasks as required. Following this framework ensures that team members participating in the discussions around the rules of representation have a common training and vision.

Over time, complex situations encountered during the process made it clear that SI's rules were too restrictive to allow for complete representation. Initially, only a few internal unwritten rules were agreed upon, but it quickly became evident that, to avoid losing track of erratically evolving rules and changes, a framework was necessary to harmonize the process and maintain coherence. The rule-creation cycle was developed during weekly focus groups, which bring together the team members who participate in the semantic representation effort. They are made up of a core of 4 team members with heterogeneous professional backgrounds, including health care professionals (medical, nursing, midwifery), more technical training (IT, bioinformatics), and administrative knowledge (billing). These can then be joined by others depending on the team's setup at that time, such as students, new team members, or other colleagues with an occasional interest in a specific topic. The core members all have proficient experience with semantic representation and specifically with SNOMED CT, and are certified by SI through courses such as the authoring certification. The core of the team represents a small, soft-funded group, and the rest of the group has a high turnover rate. Added to this are limited time and resources, which means that there is a strong need to prioritize how and where said resources are applied. Data collections with high clinical value and a high number of instances, such as laboratory procedures and patient formularies, were tackled first. For the same reasons, work is parallelized as team members are each assigned separate tasks. For these reasons, no formal interannotator agreement studies are carried out.

Instead, specific topics are discussed during focus groups, and only when outcomes are unanimously agreed upon are they validated. Focus group topics consist of questions or complex situations each member has identified, and the rule-creation cycle is applied to each. First, existing guidelines and approaches are thoroughly reviewed and applied if they can solve the issue. If no existing solution is deemed satisfactory, an extension to the current rules is necessary, and is put into practice once consensus is reached through rounds of discussions. It is evaluated both for coherence with regard to previous rules and for clarity and semantic accuracy. Satisfactory outcomes are added to the list of grammar rules, which are revisited until deemed sufficiently tested. As this method applies only to situations for which the current set of rules available through SI or other groups is deemed insufficient or not applicable, they were not formally compared to each other on the same cases.

Reaching SNOMED CT's Limits

SNOMED CT was selected as the foundational semantic standard for this representation effort due to its comprehensive set of concepts, its adherence to a formal ABNF syntax, and its robust compositional rules that facilitate precise concept modeling. We prioritize the use of single SNOMED CT concepts first whenever they are sufficient to faithfully represent the data's content. When single concepts fall short, we use postcoordination, leveraging the constraints defined by the MRCM to its full capacity, constructing complex clinical expressions.

If neither approach can adequately capture the semantic content, extending it becomes inevitable as a representation gap is formally identified. This is where SNOMED CT's inherent extensibility is crucial for addressing domain-specific requirements. To resolve such gaps, we systematically explore possibilities for modifying the underlying grammar. The primary strategy involves altering existing MRCM rules, specifically through domain or range extensions, as referenced in [27]. Should this be insufficient, we analyze the need to include new SNOMED CT attributes within the representation framework. Finally, if essential semantic concepts are entirely absent from SNOMED CT, an external terminology is integrated, which consequently requires corresponding modifications to the ABNF syntax governing the semantic expressions.

The results detail the principal extensions implemented, which enable semantic coverage for a large percentage of the structured data within the HUG's data lake. The modified SNOMED CT ABNF syntax and MRCM collectively form the contribution of this paper and are available in Multimedia Appendices 1 and 2.

Ethical Considerations

Access to the HUG database is granted on an individual basis by the institution's Chief Data Officer and Medical Director and is reviewed and renewed every 6 months. This authorization permits access for the purpose of viewing and extracting aggregated metadata. No individual-level patient data are ever extracted, processed, or analyzed. All results presented in the manuscript consist exclusively of irreversibly aggregated counts derived from metadata and do not allow identification or reidentification of individuals. Consequently, this work does not constitute research involving human beings or health-related personal data within the meaning of the Swiss Human Research Act (SR 810.30) and falls outside its scope [28]. In accordance with the Swiss Human Research Act and the Swiss Federal Act on Data Protection, neither ethics committee approval nor patient consent was required; therefore, no waiver was sought from the cantonal or hospital ethics committee [29].

Results

Overview

Several problematic situations were encountered, which required progressively drifting away from SNOMED CT's official rules. These are common properties or patterns that occur across all or most natural languages, known as linguistic universals, a concept derived from Chomsky's universal grammar [30]. They are encountered often while representing data, and most can be addressed only partly by applying SNOMED CT's rules, grammar, and concepts. These gaps in the capacity to represent reality include negation, numeration, or scalar values, and displacement, which includes uncertainty and temporality. Most are included in some way in SNOMED CT's design, although rarely implemented in practice, and are therefore solvable by expanding the CG. This is done with domain and range extensions, and the addition of new attribute rules [31], which allow better representation.

Other situations, however, are not intended by SNOMED CT and necessitate breaking the mold to make the CG more inclusive. This is done by integrating other terminologies to fill gaps within SNOMED CT that cannot be handled even with postcoordination, such as SARS-CoV-2 strains. The different situations encountered and solutions devised are detailed below with an example for each. The complete list of MRCM modifications is available in Multimedia Appendix 1, and the modifications done for each property are detailed in Textbox 1.

Textbox 1. Modifications done for each property.

Negation

- 45169001 |Without (attribute)|
- 5185003 |Except for (attribute)|
- 408729009 |Finding context (attribute)|
- 408730004 |Procedure context (attribute)|

Scalars

- 103373006 |With size (attribute)|
- 410671006 |Date (attribute)|

- 246205007 |Quantity (attribute)|
- 246262008 |Score (attribute)|

Uncertainty

- 408729009 |Finding context (attribute)|
- 408730004 |Procedure context (attribute)|

Temporality

- 255234002 |After (attribute)|
- 288556008 |Before (attribute)|
- 371881003 |During (attribute)|
- 103335007 |Duration (attribute)|

Scalar Values

Scalar values are physical quantities that can be described by a single pure number accompanied by a unit of measurement [32]. Scalars are one of the first domains encountered that were not present in sufficient detail in SNOMED CT. Scalars appear in myriad places in clinical data, whether as laboratory results, scores, sizes, or measurements, and hold great importance for accurate representation of clinical reality [8,18]. In SNOMED CT, integers were previously included as concepts, which have since been removed and replaced by Unicode text expressions preceded by a hash [33]. There remain concepts that contain numerical values in labels, such as quantitative result cutoffs, but not in any attribute relationship, as they are not fully defined [34].

A better representation of scalar values is achieved with new attributes, using existing accepted standards, when possible, such as the ISO 8601 format for dates, which is largely used, including by SNOMED CT [35] (Figure 2). The advantages of representing scalars directly in formal grammar expressions are vast. This greatly improves querying capacity, using queries with numeric operators, such as "all heart rates with a value of >150 bpm."

Figure 2. Scalar value representation example.

Negation

Negation is the act of denying or contradicting something, or the expression of its absence or opposite. The ability to represent negation is a key part of any language. Without it, this sentence could not be written. It does, however, pose many challenges when attempting to include it in a knowledge representation, particularly with regard to inference in hierarchical structures [36]. SNOMED CT's approach to negation through its context model exists outside the DL, as the absence of something is still linked to the focus concept by an "Associated" attribute [37], which is logically incoherent. Other ways of representing negation in SNOMED CT can also lead to errors of inference and classification [36], with children concepts being less restrictive than their parents. In fact, SI goes as far as to recommend "handling negation outside of SNOMED CT ... rather than try and represent it within the terminology" [38].

However, SNOMED CT abounds with concepts containing negation in some form or another. The limitations described above apply to the approved attribute relations that are used in fully defined concepts. For the cases not already covered, plenty of concepts exist that represent negation in one way or another, such as unapproved attributes and qualifiers, which are used to extend the MRCM when necessary. Extending attribute domains and using new attributes such as "Except for" and "Without" has proven highly useful. For hernia repairs, for example, SNOMED CT only specifies when the procedure is done with a mesh. However, no concepts describe the absence of mesh during a procedure, which was needed (Figure 3). These modifications allow us to cover many instances of negation encountered and are currently deemed sufficient.

Figure 3. Negation representation example.

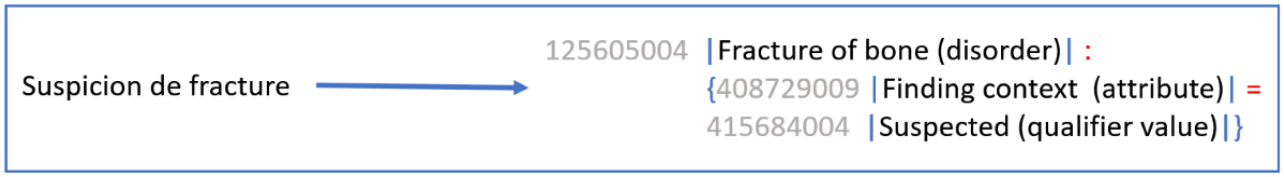
Uncertainty

Uncertainty describes a situation in which something is not known or not certain. This has an important place in representing medical data, as many situations in clinical care contain uncertainty. It is inherent in every patient encounter. It starts with the patient's history, such as not knowing when a symptom began, and continues through the diagnostic process, from forming a differential diagnosis to choosing which tests to order.

Natively, SNOMED CT represents uncertainty in the same way as negation, with the "Finding context" attribute with values such as "Known possible." As with negation, however, SI states that "attempts to capture probabilistic or uncertain knowledge are out of the scope of SNOMED CT" [39], despite containing approved attribute relations for describing such situations. It is also present in primitive concept labels such as "Uncertain diagnosis."

Similarly to negation, the extensions made to cover uncertainty are expanding the domain of the "Finding context" and "Procedure context" attributes to include "<<Clinical finding" and "<<Procedure," respectively. This allows for representing Findings and Procedures with a refinement concerning uncertainty (Figure 4).

Figure 4. Uncertainty representation example.



Temporality

Temporality is the state of existing within or having some relationship with time. It is a vital property to consider when analyzing patient data. Indeed, knowing if a certain procedure, laboratory test, or diagnosis happened before, during, or after another is critical and has a defining influence on how information is interpreted. This also includes notions such as duration of processes or procedures, evolution over time, and chronicity.

SNOMED CT already has an extensive coverage of temporality and has proven capable of adequately representing many cases encountered in practice, such as "Temporally related to" (with its descendants After, During, and Before). These apply to various domains such as Situations, Clinical findings, and Observables entities, and therefore already cover many situations. However, despite their extensive coverage, gaps remain in the representation of temporality.

Extensions include extending the range of the Before and During attributes to match that of After. Procedures are added to these attributes' domains. Some larger gaps include dates, which are resolved using the "Date" attribute, and duration of procedures, with the "Duration" attribute (Figure 5), which both use scalar values as necessary.

Figure 5. Temporality representation example.

External Vocabularies Integration

Overview

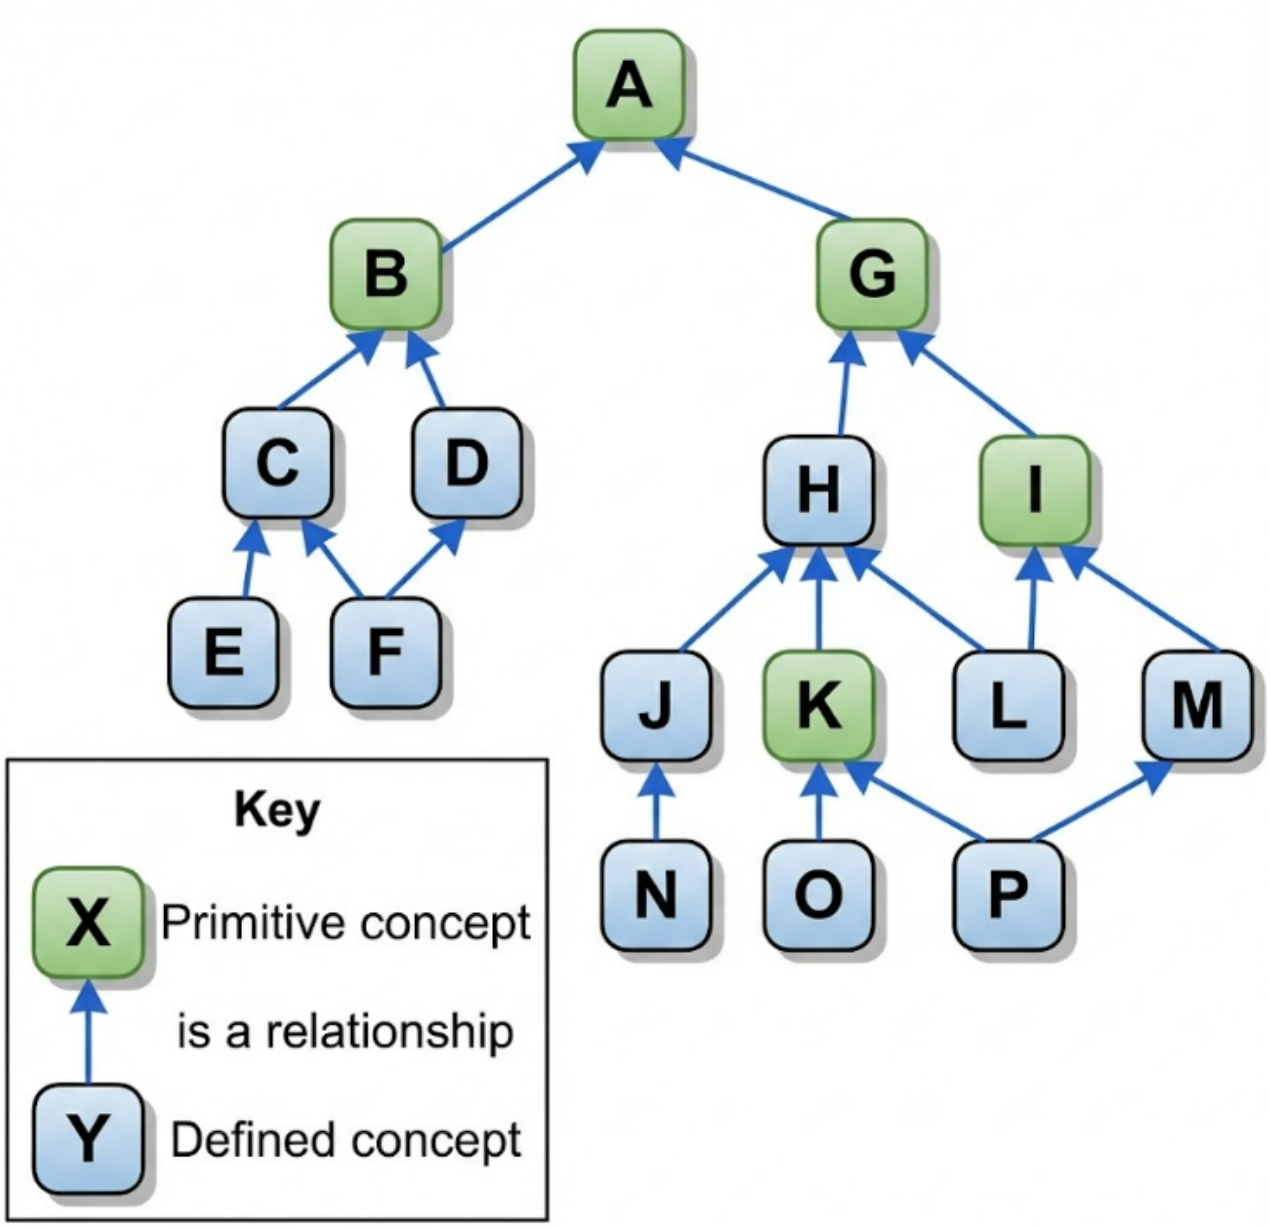
While the situations mentioned up to now are certainly a welcome improvement in terms of scope of representation, they describe modifications compliant with SNOMED CT extension capabilities. Other types of encountered gaps, which concern specific group of concepts absent from SNOMED CT, are not resolvable in this way. Representing these concepts, therefore, necessitates the inclusion of external terminologies. While using different standards together can hinder interoperability, as it can limit the possible exchange and secondary usage of data, it has become unavoidable. Integrating various formats and standards to make them compatible has been identified as a challenge in the field of medical informatics [40]. In fact, SNOMED CT itself was born from the fusion of SNOMED RT and Clinical Terms V3, so what is proposed here is only an extension of its original philosophy [41]. However, it should be remembered that multiple maps exist between SNOMED CT and terminologies such as ICD-10 and Orphanet [42], as well as the effort to harmonize LOINC and SNOMED CT [43,44]. These should be consulted first to ensure that the desired term does not already have a SNOMED CT equivalent. Ontology alignment efforts and thesauri such as Unified Medical Language System should also be consulted to verify equivalences.

Once this verification is done, external vocabularies can be evaluated for integration. How they are evaluated is subject to rules. We have defined five selection criteria: (1) the terminology must first cover an identified gap in SNOMED CT coverage; (2) it must be concept-based, so cannot be a thesaurus; (3) it must be hierarchical and contain at least some graph-like properties; (4) it must have versioning capabilities; and (5) it must be a well-recognized standard widely accepted by relevant users. Once chosen, the steps described below should be followed to fully integrate them, increasing the scope of representation. This includes adding them virtually to a SNOMED CT hierarchy by attributing a parent, verifying MRCM rules, and modifying the ABNF syntax.

Content Analysis and Proximal Primitive Parent Attribution

To include an external terminology, it is necessary to clearly identify when and where it would be used. The content of the identified terminology should be analyzed in parallel with SNOMED CT to define where it could fit in the SNOMED CT hierarchies. Ideally, an entire terminology should be linked to one parent concept, but if different parts of the terminology fit in different hierarchies, this should be documented, and clusters of codes should be defined if needed. The defined clusters are then attributed to a proximal primitive parent. This task is described in the SNOMED CT authoring course for concept creation and consists of defining the closest parent of the cluster of codes in SNOMED CT that is not fully defined [45]. To do so, the closest parent is assigned, and its genealogy is reviewed to find the first primitive concept (Figure 6 [46]).

Figure 6. Proximal primitive parent attribution.



Modifying the MRCM and ABNF

Once the clusters of codes are attributed to a parent, MRCM rules covering those parents must be reviewed to ensure they are still valid. If necessary, they can then be updated, or new rules created, to include the cluster in the range or domain, if they fit an approved definition. This helps in keeping coherence when creating new PCEs, but must be done carefully, as integrations that happen too high in the hierarchy can influence multiple existing MRCM rules.

A syntax modification is then necessary to allow for integration of external concepts into SNOMED CT PCEs. The ABNF syntax is therefore modified to signal when another terminology is used and to allow validation of PCEs. The tilde symbol (~) is used to signal the start and end of the use of external concepts. Another ~ is used to separate the identifier of the vocabulary and the concept used. These new terminology concepts can, in theory, be inserted into any part of an expression, whether as the focus concept (~Terminology~id~:SCT=SCT), attribute (SCT:~Terminology~id~=SCT), value (SCT:SCT=~Terminology~id~), a combination of these, or even used alone. This modification has been validated using a modified ABNF parser on newly created expressions. The modified ABNF syntax is available in Multimedia Appendix 2.

Implementation

When the COVID-19 pandemic hit, genomic sequencing quickly led to a characterization of the SARS-CoV-2 virus in specific strains, with scientific and vernacular names given by organizations such as Nextstrain [47], Pango [48], and the World Health Organization [49]. These strains took on a crucial importance with the advent of more contagious or less lethal variants such as Delta or Omicron [50]. This close focus on specific variants is well represented in classifications such as the Pango nomenclature [51]. However, in SNOMED CT, the representation of those strains is lacking, with a unique code to

characterize the SARS-CoV-2 virus. This situation is used as a use case to demonstrate the inclusion of an external vocabulary through the proposed method. In this scenario, Pango is chosen to refine the organism hierarchy for SARS-CoV-2 lineages. Therefore, a new attribute group with a domain, range, and definition must be validated. Since SNOMED CT already has a category of codes that defines strains but does not include SARS-CoV-2, the Pango nomenclature is added as children of this code. A new MRCM rule is then defined to refine the Organism hierarchy with the "Microbiological strain" attribute, as shown in Figure 7.

Figure 7. External terminology representation example.

Using this method, a total of 5 terminologies other than SNOMED CT are added to expand the scope of representation. These are Pango, Nextstrain, Sequence Ontology [52], RadLex [53], and the Common Terminology Criteria for Adverse Events (CTCAE) [54].

Discussion

Principal Results

Overview

This work addresses the difficult balance between expressivity and standardization with a first step in the direction of an FDG for semantic representation of clinical data, using SNOMED CT as the base. It provides a formal, extensible set of rules for constructing meaning that can draw from diverse vocabularies as needed. This modular approach means new terminologies can be integrated as they become relevant without limiting what can be said, but providing a clear structure for how to say it.

After 10 years of representing structured data in the HUG datalake, the FDG now provides semantic representations for 119,941 distinct data elements using 39,168 unique expressions. These expressions cover over 13 billion data instances from 1.7 million patients. Notably, 18,370 of these unique expressions are PCEs, validating the approach as nearly half of all unique expressions created are complex PCEs. This clearly demonstrates that precoordinated concepts alone are profoundly insufficient to capture clinical reality at scale. Moreover, 4500 PCEs use the extensions presented in this paper, for a total of nearly 500 distinct extended PCEs, underscoring their usefulness.

This approach differs from existing interoperability efforts. While FHIR provides a flexible structural framework to define custom data models (FHIR profiles), its focus is not on prescribing semantic content, leaving users to define their own semantic frameworks. In comparison to FHIR extensions, the approach is similar, but we connect the external terminology to SNOMED CT to maintain semantic coherence. To the best of our knowledge, this is not allowed in FHIR extensions, which do not specify the relation of the extension to the resource it extends. Crucially, neither FHIR nor OMOP supports the definition of PCEs, a capability central to our solution for expressing complex clinical nuances. In comparison to ontology alignment frameworks, our approach does not align ontologies but allows their combined use to compose concepts absent in both. Furthermore, a key difference lies in the methodology; our solution focuses entirely on the semantic description of data where it resides, avoiding the necessity of data movement or physical transformation inherent in many FHIR or OMOP-based implementations. Because our primary intent is semantic description and not structural or physical data modeling, a direct, formal comparison between these solutions is not appropriate.

The decision to build upon and extend SNOMED CT is grounded in the need for a robust and logical foundation, which its unique extensible grammar and syntax provide. This work shows that extending a powerful existing standard can be a path toward semantic interoperability. Four large domains of clinical reality, identified as lacking in SNOMED CT and known as challenging fields to represent, have been partially solved using this approach. Despite allowing for the representation of a large amount of data elements that were out of reach of current SNOMED CT rules, there remain gaps in representation that have not yet been resolved. Each category described previously has seen its coverage improved, but as things stand, complete coverage of these domains is still out of reach.

A statistical analysis of the extensions used shows that the 4500 PCEs created using extensions represent less than 4% of data elements and 3% of instances (Table 1). However, a deeper analysis shows that while seemingly sparse overall, extensions are very useful for certain data types. Laboratory procedures and medical devices, for example, are two collections in which 27% (250,617,656/935,678,204) and 23% (1,140,820/4,926,815) of instances, respectively, were represented with extensions. Other collections, such as formularies, have nearly 4000 extensions used.

Table 1. Detailed statistics of representation by category of data using extensions.

Source	IDs encoded, n	Extensions used, n (%)	Instances encoded	Extension instances, n (%)
Administrative stay	1172	2 (0.17)	78,020,550	131,832 (.17)
Anesthesiology	2139	11 (0.51)	117,419,522	1,275,337 (1.09)
Medical devices	699	235 (33.62)	4,926,815	1,140,820 (23.16)
Formularies	51,322	3925 (7.65)	1,641,633,208	119,941,273 (7.31)
ICU[a]	6934	157 (2.26)	6,656,119,500	367,548 (.005)
Laboratory	7231	72 (1)	935,678,204	250,617,656 (26.78)
Observations	2784	1 (0.03)	2,440,891,370	1003 (.00004)

[a]ICU: intensive care unit.

Closer examination shows clearly that the extensions have proven extremely useful to fill certain specific gaps within SNOMED CT. In these cases, the gaps identified were SARS-CoV-2 strains for laboratory procedures, sizes for medical devices, and occupations for formularies. Looking in even further detail, the 4500 PCEs created represent 488 distinct expressions. However, certain specific expressions have proven very useful. Extending representation of negation was a big part, with the Without and Except for attributes used a combined 88 times, and sizes for medical devices used 178 times.

Machine-Readable Interoperability

A primary concern regarding the modification of established standards is the potential loss of machine readability. Our implementation presents a dichotomy in this regard. The modifications made strictly to the MRCM, such as domain and range extensions for scalars or negation attributes, remain compliant with SNOMED CT's structure. These are natively processable by standard terminology servers like Snowstorm, provided the modified MRCM is loaded [55].

However, the integration of external vocabularies required modifications to the ABNF syntax (specifically the use of the tilde delimiter), which constitutes a divergence from the standard CG. Consequently, standard parsers and expression constraint language query engines cannot currently process these specific expressions without adaptation. We have validated that these expressions can be parsed using a modified ABNF parser, and we are currently adapting open-source tools to accommodate this syntax. Until these tools are widely available, this specific aspect of the grammar hinders immediate interoperability with the existing global standards ecosystem.

This technical gap is compounded by a governance challenge, as the number of integrated terminologies increases, so does the need for robust documentation to prevent ambiguity. A formal glossary or registry is therefore required to track which terminologies are in use, their specific versions, and the rules governing their application. For clarity, versioning could even be embedded directly within an expression, for example: ~CTCAE~v5.0~4028512~. A more sustainable formalism could use Uniform Resource Identifiers to designate terminology releases. This could be implemented without modifying the ABNF.

Challenges Encountered

Scalars are a massive chapter, and representing certain situations, such as ranges, has not been resolved yet. Allowing for scalar values in the range of most hierarchies also requires defining new attribute relations for each use case encountered. Negation is resolved by exclusively using and extending existing SNOMED CT concepts, as this is sufficient for our needs and maintains internal consistency within the grammar. However, this is not the only valid approach. More complex scenarios could be addressed by incorporating a formal negation operator, such as the widely accepted "¬" symbol, as described by Schulz et al [37]. Similarly, reification offers another method for handling negation within SNOMED CT, though it lacks a directly queryable negation indicator [36,37]. This would require additional ABNF syntax modification, and the impact it would have on DL means that this has not been implemented.

Other challenging situations fall into different categories but account for only a small fraction of all data elements, such as rare, complex labels within otherwise well-resolved categories. These include highly specific laboratory procedures that represent less than 1% (1,475,290/250,521,754) of all laboratory procedure instances. They could likely be addressed by incorporating more specialized terminologies. However, because these cases are anecdotal, the effort required to search for and integrate additional terminology is not justified for now.

Data-element categories with no widely adopted standard and no suitable SNOMED CT codes for creating new PCEs are another challenge. An example is triage-sheet questions, which include 350 distinct labels across 4 million instances, a negligible portion of the overall dataset. Work is ongoing to find solutions, primarily through new MRCM rules, such as

defining an appropriate relationship between Observable Entities and Clinical Findings (current options like “Precondition” or “Has realization” are inadequate), or between Environments and Procedures.

Finally, some grammatical constructions are poorly supported by current grammar rules. A key case is the presence of “or” in problem-list entries. For concepts containing “or,” we currently apply a rule that the label is represented only if both concepts share a sufficiently close semantic parent; otherwise, it remains unmapped. Some labels can be resolved this way, such as Intervention de gynécologie ou d’obstétrique = Operation on female genital organs (procedure). But others are too semantically broad or distant, with no precise match, such as Pneumonie ou pneumopathie, where the shared parent Disorder of lung (disorder) is considered too vague and would cause excessive information loss. In total, our database contains 2895 labels with “or,” representing 17.5 million instances. Among these, 834 (28%) labels have been successfully resolved, covering 10 (57%) million instances.

Limitations

This work presents limitations. For reasons mentioned previously, no interannotator agreement was carried out on the work done. The goal was initially to develop the approach for internal use only. Since it evolved gradually in parallel to our improving capabilities, there was never a “before” and “after” to evaluate. Also, since the team is made up of a set core of 3-4 members, it was considered more useful for us to evaluate our work in focus group discussions. There was never a need internally for a more explicit evaluation because problems are reviewed so often. Finally, while the intention is to generalize the way people use SNOMED CT to represent data, one of the founding principles of SNOMED CT is that there are many ways to express the same thing. As the most important outcome is semantic accuracy, maintaining the meaning of the data element, if two expressions mean the same thing but are written differently, they are still both correct. The expected outcomes were therefore never exactly matched. Such subtleties would not appear in a formal interannotator agreement, reducing its interpretability, an important point, which, in our opinion, diminished the potential impact of such an evaluation.

The byproduct of an inclusive grammar, as described in this work, is that it will inevitably make reuse more difficult. There will be links created that should not work, and inconsistencies in DL. The primary limitation of this implementation lies in the operational integration of external vocabularies with standard SNOMED CT tools. While separation of grammar and vocabulary was identified as a crucial need for an FDG, its implementation in the proposed approach is incomplete. The MRCM we chose to keep and extend constitutes a set of rules that are semantic, not merely grammatical. Currently, the terminologies added to the grammar are attributed a SNOMED CT code as a parent, to allow initial querying. But the new codes themselves cannot be directly accessed yet. For this to function, the integrated terminologies need to be definitively added to SNOMED CT. There are ways to do this in theory, such as creating a new concept with a valid SNOMED CT concept identifier for each, but they have not yet been explored in detail or implemented. Applying these solutions would greatly enhance reuse capabilities, improving interoperability and consistency of results. Modifying the ABNF syntax and parser is a first step in this direction.

The results only cover the sources that have been selected for representation so far. As the project continues, new sources will be analyzed, extracted, and represented. Therefore, it is not possible, to date, to give a clear image of the progress compared to the complete data warehouse. However, the choice of the sources to be added first has been designed to cover first the core of the electronic health record, before smaller sources. Additionally, new problems will inevitably appear, which will need to be addressed, and new rules will have to be added. As this work focuses primarily on structured data, it is not possible to confront our semantic coverage to the full information content of the electronic health record, but this is being addressed through automatic annotation of free text using natural language processing in a similar manner.

Finally, the approach was tested only in our environment and is currently used nowhere else. The end goal, however, is, of course, to apply it elsewhere to test its reproducibility, as the complexity and variability of the approach mean it may not be immediately applicable in different settings.

Governance and Implementation

Key recommendations can be derived from this work to address the limitations discussed above. To safely adopt these extensions, institutions should establish a minimum governance structure consisting of a multidisciplinary committee of domain experts and SNOMED CT–certified terminologists. This body acts as a gatekeeper, validating new representation rules through a consensus-based cycle only when standard SNOMED CT concepts or official maps (eg, LOINC and Orphanet) are proven insufficient. Key steps toward alignment with SI include maintaining a formal local registry of all grammar extensions and prioritizing the use of standard extension mechanisms (MRCM) over syntax modifications to preserve compatibility with the broader ecosystem. In terms of maturity, the MRCM extensions for scalar values, temporality, uncertainty, and negation are stable and ready for immediate reuse in standard terminology servers (eg, Snowstorm). Conversely, the ABNF syntax modifications required for integrating external vocabularies remain experimental; they currently necessitate custom parsing tools and can be adopted as a proof-of-concept pending the evolution of standard tooling.

Future work

Steps have been taken to start implementing the strategy in different institutions, as interest has been strong, and collaborations are currently ongoing, but are at a preliminary stage for the moment. External replication and independent validation are being undertaken, which aim to evaluate the adaptability and reusability of our approach, demonstrating its generalizability. Additionally, specific projects in the hospital have already benefited from using our approach to gather data on subjects such as biomarkers in the field of genomics, which was not possible before.

Furthermore, while this work relied on expert manual representation, future research will focus on automating the translation of free-text clinical notes into PCEs using natural language processing. Emerging methodologies leverage large language models (LLMs) equipped with retrieval-augmented generation to ground generated expressions in the extensive SNOMED CT hierarchy, a technique showing potential for high-fidelity clinical coding [56]. However, we acknowledge that the generation of structured sequences via LLMs introduces specific risks, such as exposure bias, which can affect the reliability of the output. Recent work highlights the importance of mitigating these biases in LLM distillation to ensure robust structured generation [57]. Addressing these challenges would dramatically scale implementation and unlock the potential for advanced semantic reasoners to infer new knowledge from grammatically rich, machine-readable clinical data.

Conclusions

This methodological study demonstrates how SNOMED CT's CG can be leveraged and extended to address recurrent semantic gaps encountered in a large-scale clinical data warehouse. Rather than constructing a new FDG from scratch, we have approached this theoretical goal by systematically extending the capabilities of an existing standard. Through specific modifications to the MRCM and syntax, we successfully addressed complex representational challenges such as negation, scalar values, and the integration of external terminologies, thereby reducing the tension between clinical expressivity and standardization.

Supported by a decade of implementation at HUG, this work illustrates that a grammatical framework, separating the rules of composition from the vocabulary itself, is essential for capturing meaning at scale. While standardized vocabularies provide the necessary lexical building blocks, it is the flexibility of the grammar that determines the fidelity of the representation. This study serves as a proof-of-concept that semantic interoperability can be advanced by methodically extending the expressive power of existing standards. However, the widespread adoption of such extensions requires robust governance frameworks to collaboratively manage and share grammatical rules across institutions.

Acknowledgments

The authors declare the use of generative artificial intelligence (GAI) in the research and writing process. According to the GAIDeT taxonomy (2025) [58], the following tasks were delegated to GAI tools under full human supervision: proofreading, editing, and reformatting. The GAI tools used were Gemini 2.5 Pro, Gemini 3, and ChatGPT 4.5. Responsibility for the final manuscript lies entirely with the authors. GAI tools are not listed as authors and do not bear responsibility for the final outcomes.

This declaration is submitted by CGB.

Funding

This work was funded with a grant from the Private Foundation of the Geneva University Hospitals. Funding by the Swiss Personalized Health Network initiative has partly contributed to enabling this work. The funding sources had no input or influence in the decision to publish this paper, and were not involved in the writing, editing, or submission procedures.

Abstract

Background: Gastroesophageal reflux disease (GERD) symptoms substantially impair patients' quality of life. The use of patient-reported outcome (PRO) instruments for symptom measurement has been advocated by regulatory authorities. However, current tools for GERD symptom evaluation are limited by recall bias. To improve the real-time characterization of GERD symptoms, we developed an electronic diary (e-diary) for daily symptom monitoring.

Objective: This study aimed to develop and optimize a PRO-based e-diary for GERD symptom evaluation and to examine the effect of symptom frequency on adherence.

Methods: The GERD e-diary evaluated 8 daytime (acid regurgitation, cough, heartburn, sour taste in the mouth, hiccups, hoarseness, dysphagia, and chest pain) and 2 nighttime symptoms (acid regurgitation and cough) for 8 consecutive weeks. Adherence, defined as the daily completion rate of e-diary, was analyzed and optimized across three stages: (1) no reminder, (2) sending reminder SMS text messaging upon the detection of missing data (no reminders during the first 3-5 days after enrollment), and (3) immediate installation of reminder system at enrollment. Weekly symptom frequency was calculated as the sum of symptomatic days per week. Multiple regression analyses were performed to examine the effects of system optimization and symptom frequency on adherence after controlling for confounders.

Results: A total of 138 patients with GERD (70 men, 68 women; mean [SD] age 52.9 [12.3] years) were recruited. At the first stage, the adherence was 47.2%, 40%, and 57.6% for nighttime, daytime, and overall symptoms. System optimization significantly improved the adherence of nighttime symptoms by 12.5% (95% CI 3.7-21.3) and 10.9% (95% CI 2.6-19.2), daytime symptoms by 21.7% (95% CI 14.2-29.2) and 20.8% (95% CI 13.7-27.9), and overall symptoms by 16.5% (95% CI 9.8-23.2) and 18.5% (95% CI 12.2-4.8) in the second and third stages, respectively. Symptom frequency was positively associated with adherence, increasing by 0.7% (95% CI 0.6-0.8) for overall symptoms and 0.9% (95% CI 0.7-1) for both daytime and nighttime symptoms per additional symptom frequency. Adherence gradually decreased along the study period. (first vs eighth week: nighttime 80.1% vs 61.5%, β=−18.6, 95% CI −26.9 to −10.3; daytime 85.1% vs 66.8%, β=−18.3, 95% CI −25.6 to −11; overall 95.1% vs 78%, β=−17.2, 95% CI −23.5 to −10.9).

Conclusions: The adherence of the GERD e-diary can be optimized by using SMS text messaging reminders. Higher symptom frequency was associated with increased adherence, although engagement declined over time. This innovative PRO-based e-diary with prolonged recording provides a real-time, prospective tool that overcomes the recall and ecological biases inherent in traditional short-term retrospective GERD symptom assessments. This advancement empowers patients through improved

self-awareness and provides physicians with precise, long-term data, facilitating tailored therapeutic interventions and supporting personalized GERD management.

KEYWORDS

adherence; e-diary; gastroesophageal reflux disease; GERD; symptom frequency; system optimization

Introduction

Gastroesophageal reflux disease (GERD) is a common disorder affecting approximately 20% of the general population [1]. GERD symptoms, including typical (heartburn and acid regurgitation) and atypical (cough, chest pain, sour taste in the mouth, hoarseness, dysphagia, and hiccups) symptoms, would bring significant burdens on patients' quality of life, reduce work productivity, and increase considerable medical resources worldwide [2-6]. As a symptom-driven disease, GERD should be evaluated for the presence, frequency, and severity of bothersome symptoms [1]. However, patient-reported clinical management outcomes often remain unsatisfactory, with more than 50% of patients continuing to experience bothersome symptoms despite proton pump inhibitor therapy [7]. This underscores the need for more nuanced approaches to symptom assessment and management.

Patient-reported outcomes (PROs) are the most direct and measured instrument for evaluation, an approach advocated by the Food and Drug Administration of the United States to assess treatment efficacy [8]. In GERD research, PROs have been used to evaluate the symptomatic improvements after acid-suppressant drugs, such as proton pump inhibitors or histamine-H2-receptor antagonists [9-11]. PROs have also been used in long-term studies to evaluate symptom resolution after surgery and endoscopic interventions and to assess improvements in quality of life [12-14]. However, most previous studies relied on questionnaires that required patients to recall symptoms over prolonged periods, possibly leading to recall bias. Furthermore, during outpatient evaluation and follow-up in patients with GERD, important information about the time course of symptom occurrence and relief is still limited because the caring physicians typically assess bothersome symptoms after weeks or even months of treatment. Notably, it has been reported that a 30-day recall of self-reported urinary incontinence is impaired and can be associated with demographic and psychosocial characteristics [15]. Patients with GERD are expected to face similar situations when using questionnaires to recall their symptoms [16-18]. Therefore, daily assessments of the GERD symptoms would provide a better understanding of the natural course of GERD symptoms and potentially alleviate the recall bias. Although patients with chronic gastroenterological diseases express strong interest in using mobile health apps for disease management, real-world adherence remains low, with high dropout rates [19]. Some studies report that up to 80% of participants engage only minimally or discontinue regular use, with retention rates dropping to as low as 3.9% after 15 days [20-22]. Existing GERD questionnaires also face limitations: their perceived impracticality for routine clinical use, along with challenges inherent to traditional paper-based symptom tracking—such as recall bias, inconsistent formatting, and poor adherence leading to incomplete or inaccurate data—collectively impede accurate and continuous symptom assessment for both patients and clinicians [23]. Given the high patient interest in digital health solutions, there is a critical need for novel mobile tools capable of overcoming these traditional limitations [24]. Although there are some smartphone apps for gastrointestinal disease, including GERD, available in the market, no app is compliant with the 2022 American College of Gastroenterology Guideline and not designed for physicians' management of GERD symptoms, and most of the apps are not evidence based [24-26].

To overcome recall bias and better address the progression and regression of GERD symptoms, in this study, we developed an e-diary for recording GERD symptoms. As low adherence in GERD diary recording would potentially limit the accountability of the e-diary, affecting clinical assessments and the associated outcomes, we tried to develop a strategy to enhance the 8-week adherence using the e-diary. Furthermore, our clinical observations and existing literature suggest a strong link between symptom severity and recording motivation: patients experiencing more frequent or intense symptoms typically demonstrate greater adherence and accuracy in documentation [27,28]. Therefore, we subsequently tested that higher symptom frequency would be associated with increased adherence to e-diary recording. The objective of the study was to examine the effects of symptom frequency and the degree of system optimization on weekly adherence, with the hypothesis that after adjusting for potential confounders, higher symptom frequency and greater system optimization would be associated with better weekly adherence. This will serve as a basis for developing strategies to improve patient adherence in completing the e-diary, thereby enhancing the clinical validity of the e-diary for GERD symptoms.

Methods

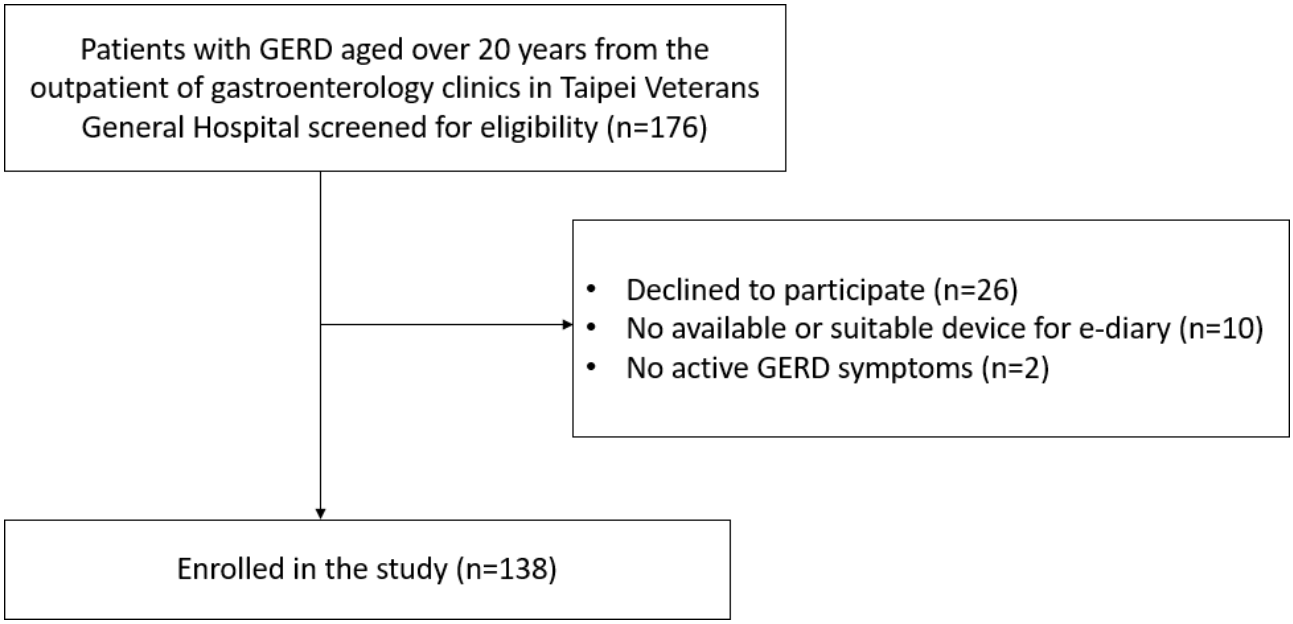
In this study, we followed the EQUATOR (Enhancing the Quality and Transparency of Health Research) guidelines using the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist [29].

Study Design and Participants

The study was a prospective observational cohort study. From October 2021 to January 2023, consecutive adults (aged ≥20 y) with GERD were recruited from the outpatient clinics of gastroenterology in Taipei Veterans General Hospital, a tertiary medical center in northern Taiwan. Eligible participants presented with either typical (acid reflux or heartburn) or atypical symptoms (hoarseness, throat discomfort, cough, or chest pain) for at least 3 months. Heartburn or regurgitation

should be noted for 4 days or more during the 7 days before the first visit. Patients who expressed interest and consented to daily symptom recording using the GERD e-diary were enrolled. A trained research assistant installed the GERD e-diary on the mobile phones of participants and provided instructions for use. These patients were asked to complete the GERD e-diary on a daily basis for 8 weeks. One or two follow-up visits in gastroenterology clinics would be arranged. To minimize potential selection and information bias, consecutive eligible patients attending the outpatient gastroenterology clinics were approached, and all data were prospectively recorded using standardized digital forms. As symptom data were collected directly from patients through an electronic diary (e-diary), recall bias was substantially reduced compared with paper questionnaires. The study size (n=138) was determined pragmatically according to the expected recruitment capacity within the 15-month study period and the pilot nature of this observational study. No formal sample size calculation was performed, consistent with the exploratory objectives. Patient flow from screening to analysis is summarized in Figure 1, which illustrates the number of patients invited (n=176), enrolled (n=138), and completing the 8-week follow-up, together with the reasons for exclusion.

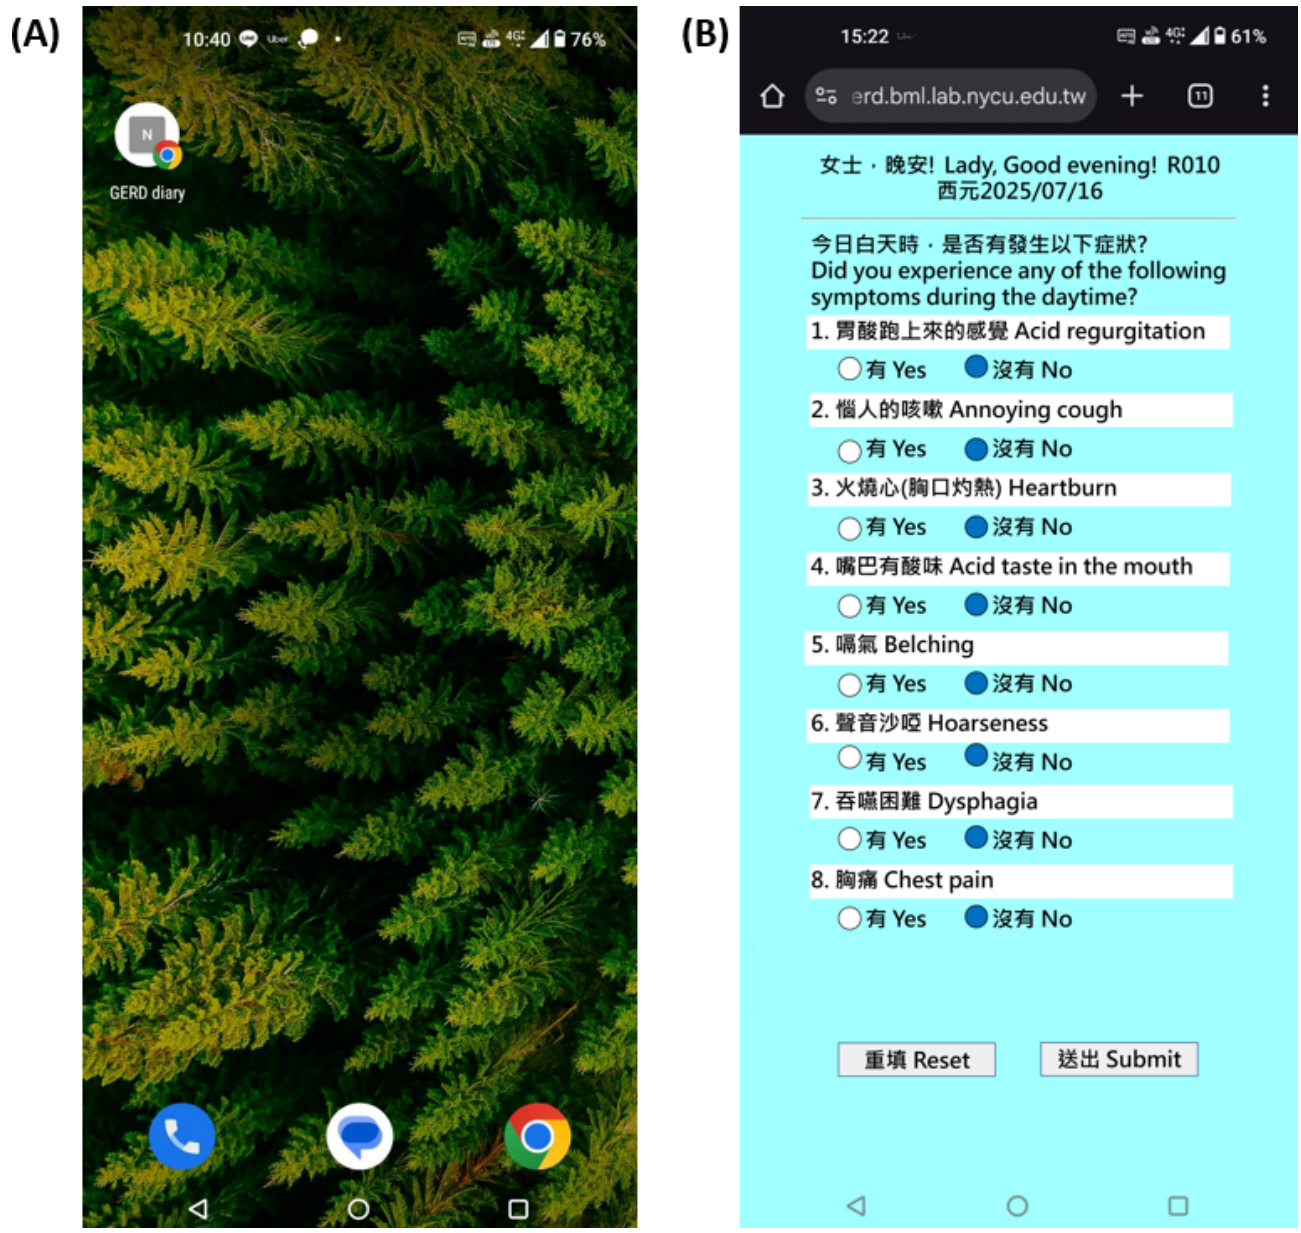
Figure 1. Patients flowchart. GERD: gastroesophageal reflux disease.



The GERD E-Diary

The web-based GERD e-diary was designed to record both nighttime and daytime GERD symptoms. Patients were asked to fill out the e-diary twice a day. In the morning, they were asked to fill in nighttime symptoms during the previous night, while in the evening, they were asked to record daytime symptoms that occurred during the concurrent day. The GERD e-diary was designed to assess 8 daytime symptoms (acid reflux, cough, heartburn, sour taste in the mouth, burping, hoarseness, dysphagia, and chest pain) and 2 nighttime symptoms (acid reflux and cough). The choice of these GERD symptom records was based on the Modified Reflux Symptom Questionnaire–Electronic Diary, which proved to be a reliable and valid PRO instrument [30]. After completing the e-diary, educational or inspiring messages would be randomly displayed to encourage continued participation. Although it was a web-based e-diary, we installed it as a smartphone shortcut icon that functioned like a mobile app, as Figure 2 showed.

Figure 2. Interface of the web-based gastroesophageal reflux disease (GERD) e-diary used in this cohort study conducted at Taipei Veterans General Hospital, Taiwan (October 2021 to January 2023). The shortcut icon was added to patients' smartphones, providing an app-like interface for direct daily input of GERD symptoms. (A) Home screen appearance; (B) symptom entry interface.



Optimization of the GERD E-Diary

Optimization of the e-diary system was developed with 3 stages. The first stage was initiated without reminders to the patients with GERD to complete the twice-daily questionnaire on mobile phones (October 7, 2021, to January 17, 2022; n=9). As most of these patients (n=5) failed to fill in the questionnaire (defined as completing <60% [range: 46.4% - 57.1%] of the overall symptom diary) in the first stage, we designed an SMS text messaging reminder in the second stage (January 18, 2022, to June 30, 2022; n=51). In this stage, the system would automatically check at noon and 10 PM each day to determine whether the patients had filled out the diary. Once an unfilled e-dairy was detected, an SMS text message was sent to the patients' mobile phones. If no entries were submitted for 3 consecutive days, an additional notification was sent to the research team to contact the patients. During the second stage, the reminder function was activated manually, resulting in no reminder function during the 3 to 5 days after enrollment. In the third stage of system optimization (July 1, 2022, to January 19, 2023; n=78), the reminder system was fully automated and activated immediately upon enrollment, eliminating the need for manual setup.

Adherence of the GERD E-Diary and Variables Affecting the Completeness of the E-Diary

The GERD e-diary adherence was evaluated by measuring the overall weekly symptom adherence rate, which was the number of days or nights symptoms filled out per week divided by 7. The overall symptom adherence rate was further categorized into nighttime (weekly nighttime adherence rate: number of nights filled out per week/7) and daytime (weekly daytime adherence rate: number of days filled out per week/7). The potential independent variables affecting the adherence rate, including the frequency of GERD symptoms (weekly total symptom days: 10 symptoms per day×7 days=70 symptom days,

ranging from 0 to 70) and the system optimization stage (3 stages, with higher stage indicating greater optimization), as well as the other confounders (such as age, gender, smoking, alcohol consumption, and comorbidities [sleep disorders, mental illnesses, sleep apnea, chronic obstructive pulmonary disease, asthma, liver or kidney diseases, cardiovascular diseases, diabetes mellitus, inflammatory bowel disease, central nervous system disorders, functional gastrointestinal disorders, and malignant diseases]) were measured.

Statistical Analysis

Descriptive statistics were performed for categorical variables as case numbers and percentages and means and SDs (including range) for continuous variables. The sampling method was clarified as convenience sampling of eligible outpatients. Any diary entry that was not completed on a given day was classified as nonadherence for that specific time point. As adherence was one of the key outcomes of interest, incomplete entries were interpreted as reflecting nonadherent behavior rather than ignorable missingness. Generalized estimating equations or multiple linear regression models were constructed to examine the effects of system optimization stage and weekly symptom frequency on adherence rates (nighttime, daytime, and overall). Independent variables included system optimization stage (categorical, 3 levels), symptom frequency (continuous), and potential confounders, such as age, gender, smoking, alcohol consumption, and major comorbidities. For repeated weekly adherence values across the 8-week observation period, a repeated-measures analysis with week as the within-subject variable was performed to assess temporal trends. All results are reported as β coefficients with corresponding 95% CIs and *P* values. Two-tailed significance was defined as $P<.05$.

Ethical Considerations

The study was reviewed and approved by the Medical Ethics Committee of Taipei Veterans General Hospital (2021-05-012CC) and conducted in accordance with the Declaration of Helsinki. Written informed consent was obtained from all eligible participants before data collection, covering both the collection of primary data and its secondary analysis. Participants were informed that they could withdraw from the study at any time without any impact on their future medical care. To ensure privacy protection, all data were deidentified using participant codes, and no identifiable information was disclosed. Participants received a reimbursement of TWD $500 (approximately US $16) for their participation in the study.

Results

Clinical Characteristics of Patients With GERD

A total of 138 patients with GERD (mean [SD] age 52.9 [12.3] y; range 24.4 - 78.4 y; 68 female patients) were enrolled. Approximately one-third (46/138, 33.3%) of patients displayed coexisting functional gastrointestinal disorders. The baseline characteristics and comorbidities are summarized in Table 1.

Table . Baseline demographic and clinical characteristics of 138 patients with gastroesophageal reflux disease enrolled from the outpatient gastroenterology clinics at Taipei Veterans General Hospital, Taiwan (October 2021 to January 2023).

Clinical characteristics	Values
Age (y), mean (SD); range	52.9 (12.3); 24.4 - 78.4
Female, n (%)	68 (49.3)
Smoking, n (%)	14 (10.1)
Alcohol, n (%)	30 (21.7)
Sleep disorders, n (%)	72 (52.2)
Mental illnesses, n (%)	7 (5.1)
Sleep apnea, n (%)	17 (12.3)
Chronic obstructive pulmonary disease, n (%)	2 (1.4)
Asthma, n (%)	14 (10.1)
Liver or kidney diseases, n (%)	15 (10.9)
Cardiovascular diseases, n (%)	38 (27.5)
Diabetes mellitus, n (%)	11 (8.0)
Inflammatory bowel disease, n (%)	5 (3.6)
Central nervous system disorders, n (%)	2 (1.4)
Functional gastrointestinal disorders, n (%)	46 (33.3)
Malignant diseases, n (%)	16 (11.6)

System Optimization and Effects of Symptom Frequency on Adherence

As presented in Table 2, during the first stage of system optimization, the nighttime symptom adherence rate was 47.2%. Implementation of the reminder system significantly increased adherence by 12.5% in the second ($P=.005$) and 10.9% in the third stages ($P=.01$). For daytime symptom reporting, the adherence rate in the first stage was 40.0%, which improved by 21.7% in the second ($P<.001$) and 20.8% in the third stages

(*P*<.001). The overall adherence reporting in the first stage was 57.6%, with further increases of 16.5% in the second (*P*<.001) and 18.5% in the third stages (*P*<.001). For every additional symptom frequency, there was a significant increase of 0.9% in adherence for both daytime and nighttime symptom reporting and an increase of 0.7% for overall symptom reporting (*P*<.001). These findings indicate that higher symptom frequency was positively correlated with participants' motivation to complete the GERD e-diary, suggesting that patients experiencing more frequent symptoms were more engaged in self-monitoring.

Table . Effects of system optimization and symptom frequency on adherence to the gastroesophageal reflux disease e-diary.[a]

Adherence (%)	β[b,c] (95% CI)	*P* value
Nighttime symptom		
System optimization (first stage)	47.2	
System optimization (second vs first stage)	+12.5 (3.7 to 21.3)	0.005
System optimization (third vs first stage)	+10.9 (2.6 to 19.2)	0.01
Symptom frequency	+0.9 (0.7 to 1)	<.001
Daytime symptom		
System optimization (first stage)	40	
System optimization (second vs first stage)	+21.7 (14.2 to 29.2)	<.001
System optimization (third vs first stage)	+20.8 (13.7 to 27.9)	<.001
Symptom frequency	+0.9 (0.7 to 1)	<.001
Overall symptom		
System optimization (first stage)	57.6	
System optimization (second vs first stage)	+16.5 (9.8 to 23.2)	<.001
System optimization (third vs first stage)	+18.5 (12.2 to 4.8)	<.001
Symptom frequency	+0.7 (0.6 to 0.8)	<.001

[a]Results derived from multiple linear regression models adjusted for potential confounders, including age, gender, smoking, alcohol consumption, and comorbidities.

[b]β=change in adherence in the second and third stages of system optimization compared with the first stage.

[c]β=change in adherence per additional symptom frequency.

Adherence Trends in GERD E-Diary Recording

Table 3 presents the weekly change in adherence rate among all enrolled patients with GERD. The nighttime symptom adherence rate was 80.1% during the first week and began to decrease significantly from the third week (71.5%; *P*=.04), reaching 61.5% by the eighth week (*P*<.001). For daytime symptom reporting, adherence was 85.1% in the first week and showed a significant decline beginning at the fourth week (76.0%; *P*=.01) and further to 66.8% by the eighth week (*P*<.001). Overall adherence followed a similar trend, starting at 95.1% in the first week, decreasing to 86.7% in the fourth week (*P*=.009), and dropping to 78.0% in the eighth week (*P*<.001). These results demonstrate a gradual decline in participant engagement with the e-diary over time, despite the implemented reminder optimization strategies.

Table . Weekly adherence trends of gastroesophageal reflux disease e-diary completion during the 8-week study period.

Symptoms and week	Adherence (%)	β[a] (95% CI)	*P* value
Nighttime symptoms			
1	80.1	N/A[b]	N/A
2	72	−8.1 (−16.4 to 0.2)	0.06
3	71.5	−8.6 (−16.9 to −0.3)	0.04
4	67.9	−12.2 (−20.5 to −3.9)	0.004
5	68.4	−11.7 (−20 to −3.4)	0.006
6	61.6	−18.5 (−26.8 to −10.2)	<.001
7	64.3	−15.8 (−24.1 to −7.5)	<.001

Comparison of GERD E-Diary With Previous GERD Evaluation Tools

The characteristics and differences between our current GERD e-diary study and previous GERD questionnaire studies are summarized in Table 4. This e-diary, using separate day and night assessments, can record 10 relevant GERD symptoms daily and also provide educational information.

Table . Comparison of patient-reported outcome (PRO) instruments for gastroesophageal reflux disease (GERD). The summary includes data entry frequency, number of symptoms recorded, and whether daytime and nighttime symptoms were separately assessed.

PRO instrument[a]	GRACI[b] [31]	Puhan et al [32]	GerdQ[c] [16]	RESQ-7[d] [33]	GERD e-diary

Discussion

Principal Findings

In this study, we demonstrated that a GERD e-diary was successfully developed to record GERD symptoms twice daily (day and night) with relatively high adherence. Patients' adherence was significantly improved with the application of SMS text messaging reminders in the e-diary system. In addition, patients who experienced more frequent symptoms tended to demonstrate higher levels of adherence. While the overall adherence rate reached approximately 80% over the 8-week period, a gradual decline was observed over time. This PRO-based e-diary, which enables prolonged and continuous symptom recording, provides a real-time and prospective assessment framework that substantially reduces the recall and ecological biases associated with conventional short-term, retrospective GERD symptom evaluations. By facilitating structured, longitudinal monitoring, the system not only enhances symptom awareness for patients but also offers clinicians high-resolution, long-term data that support more customized therapeutic decisions and advance personalized GERD management.

Comparison With Prior Work

PRO measures are essential for evaluating both disease burden and treatment efficacy in GERD [6]. Several instruments have been developed to capture these outcomes. For example, the GRACI (Gastroesophageal Reflux Disease Activity Index) integrates patient diaries with structured nurse-led interviews, thereby reducing physician workload and minimizing assessor bias [31]. Puhan et al [32] introduced a symptom diary that tracked heartburn frequency, severity, and antacid use over 4 to 6 weeks, achieving high adherence, with only 7.9% of patients completing fewer than 80% of entries. The GerdQ (Gastroesophageal Reflux Disease Questionnaire), a 6-item tool, facilitates diagnosis and management in primary care without the need for specialist referral [16]. Similarly, RESQ-7 (Reflux Symptom Questionnaire, 7-day recall) evaluates 13 GERD-related symptoms based on a 7-day recall period [33]. Despite their clinical value, most PRO tools have important limitations. They typically capture symptoms over short intervals (often 1 wk), which makes it difficult to assess temporal fluctuations in patients with intermittent symptoms. Relying on weekly recall instead of daily reporting also introduces bias, as patients tend to overestimate symptom intensity and underestimate frequency [34]. Daily PROs are generally more accurate, especially for variable symptoms [35], but even these prior studies fail to differentiate between daytime and nocturnal symptoms. This is a critical gap, as nighttime symptoms are common in GERD and strongly impact quality of life [36]. Additionally, many existing PROs record only a narrow range of symptoms, limiting their clinical comprehensiveness. Another concern lies in data collection methods. Traditional paper-based questionnaires are vulnerable to retrospective completion, which compromises accuracy. In contrast, electronic data entry systems can restrict both prospective and retrospective inputs, thereby reducing recall bias and improving data integrity [35]. To overcome these challenges, we developed a web-based GERD e-diary that records symptoms twice daily over an 8-week period. This approach provides a more reliable picture of symptom patterns, minimizes recall bias, and generates richer data for clinicians. Importantly, the e-diary also enhances patient awareness of their condition. Together, our GERD e-diary features improve the accuracy and comprehensiveness of GERD assessment, ultimately fostering greater confidence in management for both clinicians and patients.

In the first phase of building up the e-diary, the overall adherence rate was as low as approximately 40%. Therefore, we incorporated a reminder system into the e-diary and activated it upon the detection of missed entries. In the second stage, the reminder system became available only 3 days after enrollment, whereas in the third stage, it was activated immediately upon

enrollment. Both optimization measurements would significantly improve overall symptom adherence to approximately 80%. Previous research supported the effectiveness of reminders in enhancing health-related behaviors. For example, a review of 11 randomized controlled trials (1999 - 2009) confirmed that reminder interventions significantly improved daily medication adherence compared to no-reminder controls [37]. Another study demonstrated that daily SMS text messaging reminders enhanced adherence to antiasthmatic treatment [38]. Similarly, email and letter reminders significantly improved colorectal cancer screening rates compared to usual care, with no difference between the 2 reminder types (email and letter) [39]. Furthermore, reminding patients and clinicians, especially those directed at patients, is an effective strategy to improve colorectal cancer screening rates among individuals who are not up to date with screening [40]. In line with these findings, our study demonstrated that incorporating SMS text messaging reminders substantially improved adherence to GERD e-diary recordings. Despite the favorable results, there seemed to be little difference between the second and third stages of system optimization, which might be due to the short time delay (3 - 5 d) of the incorporation of the reminding systems.

We also found that higher symptom frequency was associated with increased adherence. Similar observations had been reported in other diseases. For instance, patients with urinary incontinence who experienced greater voiding frequency exhibited higher adherence to voiding diaries [27]. Furthermore, in patients with seasonal allergic rhinitis, symptom recording adherence to an e-diary was significantly higher during the peak grass pollen season, which coincided with more intense allergic symptoms [28]. All observations suggested that more frequent and severe symptoms may be associated with enhanced awareness and stronger motivation to report their disease status to health care providers.

Despite relatively high adherence at the beginning phase, our study showed a gradual decline in adherence over the 8-week period. This trend was consistent with previous findings in other diseases. For example, patients with allergic rhinitis demonstrated a slow decline in e-diary completion from 90% in the first week, 80% to 90% in the second to sixth weeks, and 70% to 80% after the seventh week [28]. A separate study assessing voiding diaries among patients with urinary incontinence similarly reported that a 7-day diary posed a higher burden than shorter 2- or 3-day formats [41]. In addition, 3 respiratory clinical trials also demonstrated that adherence decreased over time after randomization [42]. All results suggested that adherence to long-term daily symptom recording might be challenging for the patients to complete the daily diary study.

To improve long-term adherence, several strategies might be considered. Providing additional information and education could be applied to promote better adherence in e-diary recording [28]. Reducing diary duration may also enhance patient compliance and minimize burden [41]. Additional methods to increase patient engagement, such as customizing diary content and reminders based on patient needs, using user-friendly interfaces, and incorporating social and gamification features [21], or integration with wearable devices, might also help improve adherence. Using personalized adaptive reinforcement learning as a core behavioral strategy, it may be possible to optimize intervention timing and minimize alert fatigue, ensuring more stable long-term user participation in the future [43]. In this study, patients expressed a desire to see immediate visual representations of daily symptom changes. Understanding the psychological factors (eg, motivation) and socioeconomic status behind patient adherence could be invaluable for designing more effective interventions.

Study Strengths

Our study introduces a significant innovation in GERD management through the development of a web-based e-diary designed for daily symptom assessment. The primary strength of this approach lies in its ability to provide real-time, prospective data collection, thereby fundamentally overcoming the limitations of traditional paper-based questionnaires and retrospective recall, which are prone to significant recall and ecological biases for patients with GERD [44]. Unlike conventional studies that often rely on symptom scores primarily as a measure of drug response, our e-diary integrates symptom monitoring directly into daily clinical practice. This shift allows for the capture of fine-grained, fluctuating symptom patterns over an extended period, providing a more accurate and comprehensive understanding of the patient's condition. Second, by minimizing recall bias, our e-diary ensures higher data entry quality and more efficient data handling compared to traditional methods. Third, it empowers patients to actively participate in their self-management by collecting health data autonomously, fostering self-reliance and improved awareness of their condition [45]. Fourth, with the application of an SMS reminder system and educational feedback provided, the adherence rate of patients could be maintained up to 8 weeks, especially for those symptomatic patients. Fifth, our study benefits from the e-diary's ability to separately capture daytime and nighttime GERD symptoms. This distinction is clinically important, as nocturnal reflux is characterized by impaired esophageal clearance and is associated with more aggressive disease, including a higher risk of severe complications such as esophagitis [46]. Moreover, nighttime symptoms substantially impair patients' health-related quality of life [36]. These granular, time-specific symptom data provide essential insights for developing personalized management strategies. Finally, the detailed, real-time symptom data facilitate enhanced patient-physician collaboration. Physicians can readily visualize symptom changes, understand the variability in symptoms, and work more effectively with patients to tailor treatment strategies [47]. This paves the way for truly personalized treatment plans in the future that can adapt to individual patient needs and daily life events, potentially incorporating dietary or other therapeutic adjustments. Ultimately, this approach moves beyond simple response assessment, enabling a proactive feedback loop that can lead to more informed and timely clinical decisions, fostering greater confidence in management for both clinicians and patients.

Study Limitations

Limitations do exist in the study. First, patients with GERD were enrolled from a single center and included only patients capable of operating an e-diary, potentially limiting the

generalizability and overestimating adherence. Validation in multicenter or community-based cohorts should be conducted in the further studies. Second, days on which patients did not complete entries were recorded as symptom-free when calculating symptom frequency, which may lead to underestimation of the reported symptoms. Third, objective physiological parameters (eg, 24 h pH-impedance monitoring, reflux-symptom association probability, or treatment response) were not detected in this study, which would enhance the e-diary's clinical utility. Fourth, although SMS reminders improved the adherence, they might inadvertently increase psychological stress, symptom vigilance, or anxiety, which also may lead to worsening of GERD symptoms. This may account for part of the nonadherence observed in this study. Assessment of the Esophageal Hypervigilance and Anxiety Scale and other psychological measurements is warranted in subsequent studies to help balance engagement benefits against potential harm. Finally, we did not evaluate the satisfaction scores of patients with GERD and caring physicians. Further adjustments to this GERD e-diary by correcting the aforementioned limitations should be considered in future studies.

Conclusions

Our results demonstrate that system optimization can significantly enhance adherence in the newly developed GERD e-diary recording. Increased GERD symptom frequency was associated with adherence, although overall engagement declined gradually over 8 weeks. The development of this PRO-based GERD e-diary system can be a convenient tool for future application in clinical and research settings.

Abstract

Background: To meet the needs of individuals diagnosed with autism, internet-based interventions have been developed with a variety of objectives. A deeper understanding of the mechanisms of change may help tailor interventions to individual needs. The communicative behaviors of individuals with autism participating in text-based internet-based interventions remain largely unexplored, as do their potential relations to clinical outcomes. An improved understanding of participants' behaviors may help therapists better tailor support, promote engagement, and enhance treatment outcomes.

Objective: This study aimed to explore the communicative behaviors of individuals with autism participating in an internet-based intervention and to examine whether different behavioral patterns were associated with treatment outcomes or treatment adherence.

Methods: Messages from 34 participants enrolled in an 18-week internet-based cognitive behavioral therapy program were analyzed using abductive qualitative content analysis. Correlational analyses were used to examine the relationships between qualitative categories and change scores on outcome measures and rates of module completion.

Results: Fourteen behavioral categories were identified and grouped into three overarching domains: (1) "This is me," which encompasses the participants' narratives on identity, personality, autistic functioning, current and past circumstances, and worldview; (2) "Working with the treatment," which included statements related to engagement with the treatment process; and (3) "I struggle," which comprised of past and present negative experiences and challenges. Correlational analyses revealed associations between several behavioral categories and improvements in quality of life and treatment adherence.

Conclusions: The findings highlight the importance of self-narrative formulation among individuals with autism and suggest that certain communicative behaviors—particularly those involving identity reflection and recognition of treatment-related gains—were positively associated with therapeutic outcomes. The findings enhance our understanding of how individuals with autism engage in internet-based cognitive behavioral therapy and may serve as a valuable source of information for therapists when guiding expectations regarding client outcomes and identifying participants who may benefit from additional support.

autism; communicative behaviors; internet-based treatment; narrative identity

Introduction

Background

Autism is a neurodevelopmental condition characterized by difficulties in social communication and a stereotypical behavioral pattern [1]. These difficulties imply functional impairment in social situations and may affect psychological well-being [2,3] and low quality of life (QOL) [4]. Furthermore, individuals with autism face several challenges in accessing health care [5], and internet-based interventions offer a convenient and flexible format that may increase accessibility for this population.

The evidence base for internet-based interventions is growing, and an increasing number of diagnostic groups are being offered internet-based cognitive behavioral therapy (ICBT) [6]. Given the efficacy of ICBT, there is a need for an improved understanding of the mechanisms of change, as this knowledge would allow more targeted adaptations of treatment content to the specific needs of each service user [7].

Interventions that include therapist support tend to be more effective than those delivered without guidance [8]. In addition, factors such as participant adherence, treatment credibility, working alliance, and baseline symptom scores have all been identified as important predictors of treatment outcome in ICBT [9]. In particular, therapeutic alliance and treatment adherence are related to favorable outcomes [10,11].

Therapeutic feedback in ICBT is typically provided at regular intervals [7], in response to participant progress, and the participant may have the possibility to write to the therapist at their convenience, both in response to therapist feedback and to initiate a new conversation. Though the core ingredients in ICBT are expected to be embedded within the predetermined text-based modules or sessions, the established importance of therapeutic support [8] and alliance [10] implies that some change mechanisms are influenced by the one-to-one written communication.

The functional components of therapist feedback in ICBT, conceptualized as "therapist behaviors," are important for both adherence and outcome [12-14]. The client-related equivalent—patient behaviors in ICBT—remains less thoroughly explored. However, previous research indicates that different communicative patterns among participants in ICBT may also be associated with both outcome and adherence [15-17]. Increased insight into what is communicated by clients in ICBT is an important piece of the puzzle in forming an understanding of who is likely to benefit from the program—and who may not—as well as identifying individuals at risk of dropping out. This information can also serve as a valuable indicator to practitioners that a participant is struggling and may require additional support [15].

Svartvatten et al [11] explored behaviors reflected through client messages in ICBT for depression, and their relation to outcome and adherence. They identified 10 behavioral categories and found that "Alliance and Observes positive consequences" correlated positively with changes in outcome, and the behaviors "Alliance," "Identifies patterns and problem behaviors," "Maladaptive repetitive thinking," "Observes positive consequences," "Tries alternative behavior," "Chooses alternative behavior," and "Avoidance of treatment" were positively related to the number of modules completed.

In 2 comparative studies, Soucy et al [18] and Kraepelien et al [19] adopted the behavioral categories from Svartvatten's study to examine whether these could be generalized to their own data, including participants with depression, anxiety [18], and alcohol use disorder [19]. Although both studies found the predefined categories applicable, notable differences in both frequency and relation to adherence and outcome were observed. Based on inconsistent correlation results, both studies refrained from concluding the predictive value of client behaviors but suggested that the categories may still offer insight into the therapeutic process in ICBT. Soucy et al [18] noted that their directed (also referred to as deductive) content analysis approach—following the categories generated by Svartvatten—may have hindered the detection of other relevant themes. Therefore, they call for future research to analyze client messages inductively, without referring to pre-existing frameworks.

An inductive analytical approach may be especially justified when analyzing communicative patterns among individuals with autism, a population known to exhibit a qualitatively different communicative style compared to the norm, both generally [20] and in text-based online communication [21]. These communication differences may be manifested, for example, by an impaired narrative ability—a communicational skill important for sharing experiences and connecting with others [22]. Furthermore, research has shown that computer-mediated communication often is preferred over verbal communication among individuals with autism [21,23] and that they use internet-based communication in qualitatively different ways than individuals without autism [21,24,25]. These findings open up the possibility that the communicative behaviors in ICBT for autism may differ from those of other patient groups, which justifies approaching this question with an inductive approach, unrestricted by the deductive categories used in previous studies.

To manage the increasing number of individuals diagnosed with autism and to meet their needs, internet-based interventions have been developed with a variety of objectives, including increasing QOL [26], providing psychoeducation [27], and treating psychiatric comorbidities [28-30]. Although the research base on ICBT for autism is relatively scarce, the available studies suggest that internet-based interventions may be both particularly suitable for the needs of individuals with autism [27,31], as well as effective [27,29,30].

Within the current project, an 18-week internet-based intervention adapted for individuals with autism was evaluated for feasibility and effect compared to an active control group [26]. The results were complex and ambiguous; while no group-level effects were found on quantitative outcomes, participant satisfaction was high, and dropout rates were low, indicating good feasibility. A qualitative study on participant experiences of the intervention [31] showed that the participants

generally appreciated the internet-based format, and especially the opportunity to communicate with the therapist in writing.

However, the participants had varying experiences regarding therapist support and the messaging function. Some participants used the messaging function to enable a deeper conversation with the therapist, whereas others only occasionally responded to the therapeutic feedback, resulting in great variability in the amount of therapeutic contact [31]. Accordingly, the level of support was, to a great degree, dependent on the behavior of the participants. Whether this diverse use of the therapeutic support may be related to the treatment effect or adherence is, however, unclear and warrants further investigation. As the active ingredients in ICBT for individuals with autism are yet unexplored, we should remain open to the possibility that the varying communicative behaviors of participants may play a role, even in interventions where no group-level effect was found.

Little is known about the behavior reflected through participant messages in internet-based interventions for individuals with autism, or how variations in these behaviors may relate to treatment outcomes and adherence. Analyzing participant messages in ICBT may offer valuable insights into how individuals with autism engage in the treatment. Furthermore, early identification of specific participant behaviors may inform professionals about what to expect when treating individuals with autism, and thereby guide therapeutic decision-making. Improved understanding of client behaviors could thus be helpful both in identifying individuals at risk of dropping out and in guiding the development of future programs.

Objectives

This study aimed to gain knowledge about participants' communicative behaviors in an internet-based intervention for individuals with autism by investigating the content of participant messages. An additional aim was to explore whether the use of different behaviors (including word count and message frequency) was related to clinical outcome or adherence.

Methods

Design

This study used a mixed method design, using data collected as part of a larger randomized controlled trial (RCT) aimed at evaluating an internet-based cognitive behavioral intervention to improve QOL in autistic adults (ClinicalTrials.gov NCT03570372). A qualitative analysis of participant text messages and the calculation of change scores were first conducted independently, after which the qualitative and quantitative data were integrated through correlation analyses. The integration allowed the exploration of how the qualitative categories were related to quantitative changes.

Participants and Recruitment

All messages from participants in the intervention group (n=42) of an RCT on ICBT for individuals with autism [26] were included in the current qualitative analysis. The RCT was announced through posters in waiting rooms of health care facilities in Örebro county, Sweden, and as advertisements in the local press and on a social media platform (Facebook, Meta Platforms, Inc). Participants for the RCT were recruited by completing a digital self-application form administered through 1177, a Swedish national platform for online health care. The application form included questions on age, gender, living arrangement, occupation, and age at diagnosis. The inclusion process involved a structured interview based on the Mini International Neuropsychiatric Interview, along with a screening questionnaire covering autistic symptoms. Diagnoses were confirmed by collecting assessment records or by verbal confirmation from clinicians. A detailed description of the recruitment process and inclusion criteria of the RCT is provided in Westerberg et al [26].

Intervention

The intervention was based on an evidence-based cognitive behavioral therapy group treatment for adults with autism [32,33], which had been further developed, condensed, and adapted to an internet-based format by the first author, BW.

The intervention lasted 18 weeks. The intervention aimed to enhance QOL and sense of coherence (SOC) and to decrease psychiatric symptoms through the completion of 18 text-based modules focusing on themes relevant to these objectives (refer to Table S1 in Multimedia Appendix 1 for an overview of the themes). Each module included psychoeducation, exercises, and strategies based on cognitive behavioral therapy to enhance coping with everyday life challenges, but adapted to the needs of individuals with autism. In line with recommendations for such adaptations [34], a significant portion of the program was dedicated to psychoeducational content about autism, individual variations, and common comorbidities. The intervention also introduced tools and concepts to support self-understanding and provided terminology to describe participants' functioning. Every 2 weeks, the participants were invited to take part in a live chat session together with other participants, focused on discussing the theme of the most recent module.

In most modules, home exercises were designed to be completed either using text-based worksheets or as "field work" to be reported on the online platform. All modules also included reflective questions to be answered directly in conjunction with the text. The documentation and reports from the exercises, along with responses to the reflective questions, formed the basis for the therapeutic feedback.

Therapeutic feedback was delivered asynchronously via a messaging function available on the same platform as the treatment. The messaging function resembled an email page, allowing participants to respond to therapeutic feedback and initiate new conversations. Therapists were expected to reply within 1 working day. However, participants were not required to send any messages via this function.

Material

All messages written by participants using the messaging function were included. Aside from the removal of information that may reveal participant identities (such as names, telephone numbers, or web addresses), the messages were not modified in any way.

Change scores (from baseline to posttreatment) on outcomes from the RCT were included for a quantitative correlation analysis. The Brunnsviken Brief Quality of Life Scale (BBQ) [35], consisting of 12 items (responses ranging from 0=do not agree to 4=totally agree), was used to assess QOL. Each item related to satisfaction in a specific life area was weighted against a rating of the importance of that area. The multiplied products of each item-pair (satisfaction × importance across 6 life areas) were summed to obtain a total QOL score (range: 0-96), with higher scores representing a higher QOL.

The 13-item Sense of Coherence (SOC-13) scale was used to assess the concept of SOC [36]. SOC reflects the extent to which an individual perceives life events as coherent and comprehensible and life demands as manageable and meaningful. Items are rated on a 7-point scale, with a higher total score (range: 13-91) indicating a stronger SOC.

To assess symptoms of depression and anxiety during the past week, the Hospital Anxiety and Depression Scale (HADS) for depression (HADS-D; 7 items) and anxiety (HADS-A; 7 items) subscales were used [37]. Items are rated on a 4-point scale, with higher scores (range: 0-21) indicating greater symptom severity.

Word count and the frequency of participant and therapist messages were analyzed in relation to the outcome. Generic messages sent to all participants (such as reminders of the peer participant chat sessions) were removed from the data at an early stage. Similarly, messages whose sole purpose was to inform the participant that they had received a new module or to remind them to complete self-assessments were excluded from the analyses.

Qualitative Analysis

The material was analyzed using both a directed and conventional approach to content analysis [38], adopting a combination of inductive and deductive perspectives, resulting in an abductive analytical process [39]. All coding and sorting were conducted using NVivo qualitative data analysis software (Lumivero, LLC) [40] by 2 licensed psychologists (BW and KJ). BW was also 1 of 4 therapists during the trial and was therefore familiar with both the foundational elements and components of the program, as well as the specific setting and design of the trial. As personal identifiers were removed from the texts before analysis, the participants' identities were not revealed through the texts. However, the coding process was not fully blinded, as—due to her previous role as a therapist—BW could recognize certain utterances as stemming from individual participants.

Initially, all messages were read to gain an overall sense of the material and its character. Thereafter, BW segmented and condensed the texts into meaning units, after which BW and KJ jointly and inductively coded the meaning units from 5 participants and discussed the codes to develop a preliminary coding framework. All utterances that could be considered reflective of a behavior were given a descriptive code to capture the manifest content of the participant's messages.

In this analysis, a behavior was defined as statements in the participant messages that appeared to serve a function or convey an intention, either in relation to internal processes or to the treatment work or the therapist. These included both utterances with semantic and meta-linguistic content. Statements that—although functional—were considered not to be of importance for the research questions, such as using polite phrases ("have a good day") or clarifying the structure of the messages ("firstly I will answer your questions"), were excluded.

When a preliminary coding framework was established, the 2 researchers independently coded the texts of 1 participant and compared their interpretations and the wording of codes to refine the codes and to reach consensus regarding the final framework to be used thereafter. Once agreement regarding the wording of codes was achieved, BW coded the communication from the remaining 28 participants in the same manner.

When the texts of approximately 10 individuals had been coded, BW began inductively sorting the codes into clusters illustrating similar behaviors. During this process, a pattern emerged in which several of the clusters resembled categories identified in earlier research [11,18,19]. A decision was made to allow the use of previously identified categories [11] when a category was identified that clearly aligned with one of these. This resulted in an abductive approach, meaning that we moved iteratively between the data and the categories identified in earlier research, which were refined and adjusted to better fit our data during this process. Given the large amount of data and codes, coding and sorting were conducted alternately until all relevant meaning units had been coded and sorted. No third-party validation was conducted during the analysis process.

Quantitative Analysis

The frequencies of each participant's contribution of codes to the categories derived from the qualitative analysis were used in correlation analyses to explore relationships with the quantitative change scores. Change scores on BBQ, SOC-13, HADS-D, and HADS-A were calculated by subtracting preintervention scores from postintervention scores. Normality of the variables was assessed using the Shapiro-Wilk test.

To assess behavior categories in relation to module completion independently of the amount of text written, the individual frequency of codes in each category was divided by the total number of words written by each participant. Accordingly, the frequency of each behavior category was calculated as a proportion of the total number of words, which minimized the influence of overall text length (which would be strongly dependent on the number of modules completed), as the aim was to examine the relative prevalence of behaviors rather than general writing activity.

BBQ, HADS-D, and HADS-A were all normally distributed. However, as the distribution of SOC-13, all behavior category variables, word and message frequency, and module completion rates deviated from normality, Spearman rank-order correlation (ρ) was used to assess the associations between behavior categories and change scores, module completion, and word and message frequency. No adjustment for multiple testing was made, as the study was exploratory and did not involve predefined statistical hypotheses. All quantitative analyses were performed using SPSS Statistics (version 29) [41].

Ethical Considerations

The original trial received ethical approval from the Regional Ethics Committee in Uppsala, Sweden (ref no 2017/392), and the Swedish Ethical Review Authority later approved an amendment (ref no 2022-05792-02) with clarifications regarding this mixed methods study. At inclusion, all participants provided consent for their personal and medical data to be used for research purposes. All data were deidentified before analysis. Personal identifiers were removed from the analyzed text material, participants were assigned unique IDs, and the code key was accessible only to the research team. Participants did not receive any financial compensation for participation in this study. However, a gift card of 300 SEK (≈ US $32) was provided to participants on completion of the postintervention and follow-up assessments of the original RCT.

Results

Overview

As 8 participants did not provide any written material, the qualitative analysis included messages from 34 participants. Table 1 provides the baseline characteristics of the participants and the number of completed modules.

Table 1. Baseline characteristics and adherence of the participants included in the qualitative analysis (N=34).

Characteristic	Value
Age (years), mean (SD)	33.8 (10)
Gender, n (%)	
Men	14 (41.2)
Women	18 (52.9)
Other (nonbinary or transgender)	2 (5.9)
Habitation, n (%)	
With partner and/or children	12 (35.2)
With parents	9 (26.5)
Alone	11 (32.4)
Group or serviced housing	1 (2.9)
Other	1 (2.9)
Age when diagnosed (years), n (%)	
<19	11 (32.4)
20-35	14 (41.2)
>36	9 (26.5)
Occupation, n (%)	
Employed	4 (11.8)
Daily activities	2 (5.9)
Student	4 (11.8)
Job seeker	9 (26.5)
Sick leave	7 (20.6)
Other	8 (23.5)
Completed modules, mean (SD) and median (IQR)	15.6 (4.2) and 18 (14.8-18)

Categories From the Qualitative Content Analysis

In total, 2569 codes were identified, of which 2476 were considered relevant to the aim. These were sorted into 14 categories, which were further grouped into 3 overarching domains: “This is me” (1092 codes and 4 categories), “Working with the treatment” (861 codes and 6 categories), and “I struggle” (523 codes and 4 categories). Table 2 provides an overview and the relative frequency of codes (%) across domains and categories, as well as definitions of each category. Refer to Table S2 in Multimedia Appendix 1 for example codes and quotes from each category.

Table 2. Overview of domains, categories, and the relative frequency of codes (%), and definitions of each category.

Domain and category, %	Definition
This is me, 44.1%	
This is who I am, 15.5%	Texts reflecting a personal narrative about what kind of person one is, what qualities, difficulties, and needs they have, their autistic functioning, and how they (think that they) are perceived by others.
My present and past circumstances, 8.2%	Information on current events, everyday life, positive experiences, and early formative events.
Change is possible, 14.2%	Strategies that work or have potential to work, that they have developed through life, and show motivation and insight that they have the agency to act to progress.
My point of view, 6.2%	Beliefs, opinions, and thoughts about society, autism, human psychology, and the perspective of others.
Working with the treatment, 34.8%	
Appreciation and treatment alliance, 8.4%	Expressions of appreciation, a positive attitude, and bonds of alliance toward the treatment or the therapist.
Putting the treatment aside, 3.2%	Information about not having completed parts of the treatment, and reasons for this, including both psychological issues, such as forgetting and lacking energy, but also external events that got in the way of the treatment work.
Plans to attempt a new task, 7.0%	Reflections regarding how to – or plans to implement a treatment task or exercise, or deciding on a treatment goal.
Have attempted a new task, 4.6%	Reports on completion of a treatment task or exercise, or reflections around the implementation of a task or exercise.
Observing positive consequences of treatment, 3.2%	Statements illustrating that the participant has observed a positive consequence on their personal development from the treatment or specific exercises.
Problems with the treatment, 8.3%	Texts in which the participant expresses difficulties, frustration, or other negative aspects of the treatment content or format, such as failure to understand a task or its purpose, considering certain parts of the treatment irrelevant, or technical problems.
I struggle, 21.1%	
Life is and has been demanding, 11.6%	Descriptions of current and past difficult events or circumstances, that they have been treated badly throughout life, experienced failure, and have been enduring from mental ill-health.
Identifies patterns and problem behaviors, 3.1%	Texts reflecting identification and insight into maladaptive and safety behaviors, and identification of the relation between these behaviors and negative consequences.
I am troubled by mental ill-health, 4.3%	Factual descriptions of current mental ill-health, loneliness, and struggles and their causes and consequences, without engaging in maladaptive thoughts or rumination.
Maladaptive thoughts, 2.2%	Expressions of hopelessness, meaninglessness, or distress, as well as other cognitive distortions, indicate a stagnation of cognitive flexibility.

The domain “This is me” consists of the categories “This is who I am,” “My present and past circumstances,” “Change is possible,” and “My point of view.” The domain covers participants’ descriptions of themselves in terms of personality, abilities, and difficulties, as well as current and past life situations that have influenced who they are. It further comprises their beliefs and opinions, their view of life and others, how they have used strategies to manage problems, and how they have developed, or are motivated to develop and function better. This domain illustrates that participants have insight into their agency, responsibility, and ability to influence their situation, but also reflects self-awareness regarding how their autistic difficulties pose challenges in this.

The domain “Working with the treatment” contains the categories “Appreciation and treatment alliance,” “Putting the treatment aside,” “Plans to attempt a new task,” “Have attempted a new task,” “Observing positive consequences of treatment,” and “Problems with the treatment.” These categories include statements that are in some way related to participants’ engagement in the treatment. It involves both positive and negative experiences and effects of the treatment, as well as reports on completed tasks and plans for future tasks. Reasons why certain parts of the treatment were not carried out are also included in this domain.

The domain “I struggle” contains the categories “Life is and has been demanding,” “Identifies patterns and problem behaviors,” “I am troubled by mental ill-health,” and “Maladaptive thinking.” This domain contains descriptions of past and current negative events, experiences of failure, descriptions of a difficult life situation, experiences of mistreatment, and how these have negatively affected mental health. It also covers how their mental ill-health manifests in symptoms and negative behavioral patterns.

Nine of the categories were found to correspond to categories identified in previous studies. Refer to Table S3 in Multimedia Appendix 1 for an overview of the categories from this study and—where applicable—the corresponding category from the studies by Svartvatten et al [11] and Kraepelien et al [19]. Five categories not previously described by the literature were identified in this study. These are: "This is who I am," "My present and past circumstances," "Change is possible," "My point of view, and "Life is and has been demanding." Two categories identified in previous research, "Confrontational alliance rupture" [11,18,19] and "Observes alcohol-related setback" [19], were not identified in our data.

Correlation Between Frequency of Behaviors and Outcome

Table 3 provides baseline, posttreatment, and change scores on outcomes, and Table 4 provides correlations between the frequency of participant behaviors and change scores of outcomes and the number of completed modules. As 5 participants—although included in the qualitative analysis—did not complete the postassessment, the correlational analyses include data from 29 participants.

The domains "This is me" and "Working with the treatment" and the categories "This is who I am," "Change is possible," "My point of view," "Appreciation and treatment alliance," "Plans to attempt a new task," "Have attempted a new task," and "Observing positive consequences of treatment" correlated significantly with a positive change in BBQ. The domain "This is me" and the categories "This is who I am," "Change is possible," and "Identifies patterns and problem behaviors" correlated significantly with a higher number of completed modules. No other significant correlations between the frequency of behaviors and outcomes were observed.

These findings show that when participants more frequently expressed aspects of self-understanding (as in the domain "This is me") and engaged in behaviors related to the treatment (as in the domain "Working with the treatment"), they tended to experience greater improvements in QOL (BBQ) and complete more treatment modules. This pattern indicates that behaviors reflecting active engagement and self-reflection may play an important role in facilitating positive treatment outcomes.

A total of 515 participant messages were sent. The median number of words per participant was 825 (IQR 530-2110; range 64-5562), and the median number of messages per participant was 11 (IQR 5-18; range 1-75). There was a significant moderate positive correlation between change in BBQ score and the number of participant words (ρ=0.52; *P*=<.001) and the number of participant messages (ρ=0.42; *P*=.02). There was no significant correlation between the number of words written by the therapist and any of the outcome variables.

Table 3. Means and distribution of pre- and posttreatment scores, change scores, and paired samples t test results on outcomes of the participants included in the quantitative analysis (N=29).

Outcome	Pre, mean (SD); range	Post, mean (SD); range	Change score[a], mean (SD)	*t* test (*df*)	*P* value
BBQ[b]	41.14 (21.82); 0-96	45.90 (24.19); 0-96	4.76 (14.46)	–1.77 (28)	.09
SOC-13[c]	48.17 (15.01); 22-90	49.07 (14.49); 21-85	0.90 (9.82)	–0.49 (28)	.63
HADS-D[d]	7.45 (4.03); 0-15	6.83 (5.34); 0-19	–0.62 (3.63)	0.92 (28)	.37
HADS-A[d]	12.31 (4.97); 2-20	11.45 (5.10); 1-21	–0.86 (3.0)	1.55 (28)	.13

Discussion

Principal Findings

The purpose of this study was to explore written communicative behaviors among individuals with autism participating in an internet-based intervention aimed at improving QOL and to examine whether any of these behaviors were associated with treatment outcomes.

The results show that statements related to participants' descriptions of themselves in terms of personality, abilities, beliefs, experiences, and personal development were highly prevalent, with nearly half of the codes (44.1%) categorized under the domain "This is me." The most common category was "This is who I am" (15.5%), which included reflections on personality and autistic functioning. The second most frequent category was "Change is possible" (14.2%), consisting of statements expressing awareness that personal development and growth are possible, such as narratives of past growth or coping strategies perceived as helpful. "Life is and has been demanding," also accounting for a substantial portion (11.6%) of the codes, captured descriptions of adversity, experiences of mistreatment, failure, and mental ill-health.

Correlation analyses revealed that the domains "This is me" and "Working with the treatment," as well as the categories "My point of view," "This is who I am," and "Observing positive consequences of treatment," were significantly moderately associated with improvements in BBQ scores. These findings suggest that the opportunity to reflect openly on identity, personal perspectives, and the perceived impact of treatment may be particularly important for improving QOL in individuals with autism. Notably, the finding regarding "Observing positive consequences of treatment" aligns with previous findings by Soucy et al [18] and Svartvatten et al [11], who also reported a positive correlation between this behavior and treatment outcomes.

The significant moderate positive relation between BBQ scores and the category "Appreciation and treatment alliance" further supports a well-established body of research highlighting the importance of therapeutic alliance for the therapeutic outcomes [9-11,42,43]. In addition, the category "Have attempted a new task" was moderately positively correlated with changes in

BBQ, whereas "Change is possible" and "Plans to attempt a new task" showed weak associations. These findings indicate that motivational expressions related to trying new strategies and behaviors—both within and beyond the treatment context—may reflect treatment engagement and efficacy.

Moreover, the number of words and messages written by participants was also positively associated with improvement in BBQ scores. While earlier studies examining text quantity have primarily focused on its relation to adherence—showing that more words are associated with increased program completion [17,44]—our results indicate that text quantity may also be related to changes in outcomes in ICBT for individuals with autism.

Interestingly, while several communicative behaviors were associated with improvements in QOL (as measured by BBQ), no associations were observed with changes in anxiety or depression (HADS) or sense of coherence (SOC-13). One possible explanation is that QOL, as a subjective and existential construct, may be more readily influenced by participants' self-reflective and narrative expressions. In contrast, clinical symptoms of anxiety and depression, and the more stable SOC, may be less susceptible to short-term fluctuations driven by communicative behaviors. Despite earlier findings suggesting that SOC may improve from interventions [45]—which motivated its use as an outcome in the original RCT—this effect was not found in our study [26]. Another potential explanation is that the relatively greater pre-post variability in BBQ, compared with the smaller mean changes observed in HADS and SOC-13 scores, may have increased the likelihood of detecting statistically significant correlations for QOL but not for the other measures.

Regarding adherence, the domain "This is me" and the category "This is who I am" were moderately associated with the number of completed modules, while the categories "Change is possible" and "Identifies patterns and problem behaviors" showed weak associations. This partly supports previous findings by both Soucy et al [18] and Svartvatten et al [11], who also reported a positive correlation between "Identifies patterns and problem behaviors" and the number of modules completed.

Although no causal inferences can be made, the observed associations in this study may shed light on potential behavioral indicators that are beneficial for individuals with autism to engage in during internet-based psychological interventions.

The relatively large number of identified categories (n=14) illustrates a broad range of content shared by participants with their therapists and likely reflects the wide diversity among individuals with autism. Unlike ICBT, which targets specific disorders, this intervention focused on the individual's whole life, and given the comprehensive scope of the treatment (refer to Table S1 in Multimedia Appendix 1), the extensive result is not surprising. Furthermore, an obvious reason for the relatively high prevalence of specific behaviors (ie, those reflected in the domain "This is me" and the categories "This is who I am" and "Change is possible") is related to the treatment content itself, in which reflections on the self in relation to past, present, and future experiences were repeatedly encouraged.

Consequently, the content of this treatment may partly explain why the behavior categories in the current analysis were only partially similar to those identified in earlier studies [11,18,19]. The 4 categories constituting the domain "This is me," and the category "Life is and has been demanding," including meaning units not covered by earlier frameworks (Table S2 in Multimedia Appendix 1). In agreement with Soucy et al [18], our study supports the notion that a fully deductive process—that is, following the existing coding framework—would have hindered the detection of relevant themes.

Beyond treatment content, these divergent findings (compared with previous studies) must be considered in light of the unique characteristics of the study population—individuals with autism. A considerable proportion of the participant messages centered around identity, functioning, and experiences in relation to autism or psychiatric comorbidity, which were manifested in several ways. Some statements offered nonvaluing descriptions of how their autism contributed to shaping their identity, and others accounted for experiences and traits as contributing to personality formation independent of autistic traits. Regardless of etiology, it appeared fundamental for the participants to construct a narrative around who they are and how their functioning affects their lives. This internalized self-narrative—defining who they are, how they came to be, and where their life may be heading—can be described as their narrative identity [46,47].

Through the construction of a narrative identity, people define and communicate who they are to themselves and others [47,48]. This process fosters self-insight and understanding, allowing negative experiences to be reframed as opportunities for growth, which in turn has been linked to greater well-being [49,50]. Given the precondition of atypical functioning, the process of constructing a coherent self-narrative thus appears particularly relevant for individuals with autism. While research suggests that narrative skills [22,51] and identity formation [52] may be impaired in autism, Samra [53] highlights the importance of engaging with one's narrative identity. In their thesis on identity formation in individuals with autism, they argue that this engagement enhances self-awareness, supports meaning-making, and helps to envision one's future.

Our findings demonstrated a strong engagement in this narrative process, and in line with the suggestion of Samra [53], a positive association was observed between "This is me" statements and improvement in QOL. However, categories within the "I struggle" domain also reflected engagement in a narrative process, but without any positive correlation with QOL. This indicates that different narrative processes may serve different functions, consistent with research arguing that different modes of self-focus have distinct functional properties [54,55]. For example, Watkins et al [54-56] differentiate between maladaptive analytical self-focus—described as abstract, evaluative, and often ruminative—and adaptive experiential self-focus, which is concrete, process-oriented, and linked to positive self-evaluation.

Although we did not deductively categorize statements based on this distinction—maladaptive vs adaptive self-focus—our findings align with the theory and may still be interpreted within

this framework, offering potential guidance for clinicians in identifying and supporting beneficial communicative behaviors.

Limitations

This study design has several limitations. First, only text written via the messaging function of the intervention was included in the analysis; text written directly in response to exercises was excluded, as it was typically constrained by predefined questions and exercises, making it less relevant for the aim of identifying spontaneous communicative behaviors.

It should be noted that the participants included in this study are not fully representative of the entire autistic population, as a natural selection of individuals already familiar with technology applies for inclusion in a trial such as this. Moreover, participants who did not write anything were excluded from the current analyses, which may imply a certain selection bias, as these individuals might have refrained from messaging due to communication difficulties. Those failing to complete the postassessment were also excluded from the correlation analysis, which means that we are unable to conclude the relationship between behavior and outcome for these individuals. However, post hoc analyses with imputed zeros modeling noncorrespondence, as well as imputed zeros for change scores on quantitative outcomes, were conducted, showing that these procedures did not affect the correlational outcomes (data not shown).

Another limitation concerns the role of the primary analyst (BW), who also served as a therapist and was involved in developing the intervention. This dual role introduces a risk of bias, potentially influencing data interpretation, coding, and categorization. To minimize this bias, the initial phase of the analysis was conducted jointly with KJ, who had no previous involvement in treatment development or delivery. Furthermore, the coding approach was deliberately inductive and aimed to be as close to the text as possible. Nevertheless, future studies would benefit from involving fully independent third-party analysts to further strengthen the trustworthiness of the findings.

Another methodological limitation in this study is that the intercoder reliability was not statistically calculated. Typically, around 10%-25% of data units are coded by more than 1 researcher to facilitate a trustworthy estimate of intercoder reliability [57]. By collaborative coding of 5 (14.71%) of the data units in this study, the analysts could compare and discuss codes to develop a preliminary coding framework. By subsequently coding 1 of the participants' texts independently, the coding framework was further refined and agreed upon. We considered this to be sufficient to establish the final coding framework, but acknowledge that the reliability would be strengthened with additional collaborative coding. Furthermore, in future studies, interrater reliability should be assessed using a statistical test, for example, Cohen κ.

As our analysis did not account for the timing of the statements, it is uncertain whether any detection of potentially beneficial behaviors can be made at an early stage in the therapy. Early detection (or absence) of these behaviors could enable more individualized therapeutic support, such as encouraging these behaviors. Given the novelty of this research area and the fact that similar data have not previously been studied, we chose in this study to focus on broader behavioral patterns rather than their temporal distribution. Future research could consider focusing on early-stage behaviors as potential indicators of treatment response.

When interpreting the results from the correlation analyses, it should be noted that no correction for multiple comparisons was applied. Given the relatively large number of behavioral categories and correlations tested, there is an increased risk of inflated false positives, and the results should be interpreted with caution.

Finally, in the correlational analyses between behaviors and outcome, we did not control for therapist word count or therapist behaviors. Given previous research emphasizing the importance of therapist support and the varying number of therapist messages, therapist behavior may have influenced the relationships. However, since the therapist's word count was not directly correlated with outcomes in this study, it was not included as a covariate. Future studies should nevertheless consider therapist variables when exploring outcome predictors in ICBT for individuals with autism.

Conclusions

The findings of this study increase our understanding of how individuals with autism engage in ICBT and may serve as a valuable source of information for therapists in guiding both their expectations of client outcomes and identifying client behaviors to support. The results emphasize the importance of self-narrative formulation in individuals with autism and suggest that certain communicative behaviors—especially those involving identity reflection and recognition of treatment benefits—are positively related to improvements in QOL. Future research should explore ways to identify such behaviors early in treatment as potential indicators of individuals at risk of poorer outcomes, enabling clinicians to provide additional support or tailor interventions to better suit individual needs.

Acknowledgments

We thank all participants who contributed their text-based data for this study. We also thank associate professor Yang Cao, Örebro University, for guidance regarding the statistical analyses. The generative artificial intelligence (GAI) tool ChatGPT (OpenAI) was used for language editing by suggesting alternative phrasings of long and/or complex sentences or terms to improve clarity and readability. According to the GAIDeT taxonomy, the following tasks were delegated to GAI tools under full human supervision: proofreading and editing.

Funding

This work was financially supported by the Region Örebro Län, Sweden (grant nos OLL-935396, OLL-879651, OLL-887401, OLL-833131, OLL-785501, OLL-736321, OLL-878311, OLL-785311, OLL-985129, and OLL-1004448) and Stiftelsen Bror Gadelius Minnesfond (grant no 23003). The funding sources had no role in the study design, data collection, analysis, interpretation, writing of the report, or the decision to submit the article for publication.

Data Availability

The data supporting this study originates from a longitudinal intervention study conducted at the University Health Care Research Center, Örebro Region, Sweden. Data are available upon reasonable request from the corresponding author.

Authors' Contributions

BW led the conceptualization of the study, with FH providing supporting input. BW was responsible for data curation. Formal analysis was conducted by BW as the lead analyst, with KJ providing support. Funding acquisition was led by BW, with SB and FH providing supporting contributions. BW carried out the investigation. Methodology was led by BW, with FH supporting. Project administration was managed by BW. Supervision was led by FH, with SB providing support. BW drafted the original manuscript. Review and editing of the manuscript were led by BW, with FH, SB, KJ, and MUH providing supporting contributions.

Conflicts of Interest

None declared.

Abstract

Background: Metabolic dysfunction–associated steatohepatitis (MASH) cirrhosis is a leading indication for liver transplantation (LT). Patients with MASH cirrhosis are complex and often have extensive comorbidities. The current model for end-stage liver disease (MELD)–based liver allocation system has suboptimal concordance in predicting waitlist mortality for patients with MASH cirrhosis. Furthermore, it does not capture the competing outcomes of death and LT on the liver transplant waitlist.

Objective: A competing risk analysis using deep learning was conducted to forecast waitlist trajectories of patients with MASH cirrhosis using data available at the time of waitlisting.

Methods: A deep learning competing risk model was constructed using data from 17,551 waitlisted patients with MASH cirrhosis in the Scientific Registry of Transplant Recipients (SRTR) based on the DeepHit model framework with five-fold cross-validation. Model performance was evaluated and compared to single-risk Cox proportional hazards and random survival forests (RSF) models in predicting death or transplant using the concordance index and Brier score. Additionally, a novel performance metric, the competing event coherence (CEC) score, was developed to evaluate model performance in the setting of competing risks. Features associated with death and transplant in the DeepHit model were identified using permutation importance. Models were externally validated on data from the University Health Network.

Results: A total of 17,551 patients were included. The mean MELD at listing was 19.4 (SD 8.1). At 120 months of follow-up on the waitlist, 54.6% (9599/17551) of patients underwent LT, 25.6% (4510/17551) of patients died or were removed due to deterioration, and 19.8% (3442/17551) of patients were removed for improvement or were censored. In a competing risk scenario, DeepHit achieved the best CEC scores at 1 (0.813), 3 (0.811), 6 (0.794), and 12 months (0.772) on the waitlist. The cause-specific RSF model had the highest concordance indices for death or transplant at all time points (death: 0.874 at 1 month, 0.840 at 6 months, and 0.814 at 12 months) except for death at 3 months, where DeepHit (0.883) outperformed RSF. RSF also had lower Brier scores overall, except for transplant at 12 months, where DeepHit outperformed RSF (0.206 vs 0.228). These results were similar on external validation. On feature importance assessment, MELD at listing and its components, as well as functional status, age, and blood type, were associated with death and transplant on the waitlist.

Conclusions: A deep learning competing risk analysis can forecast the risks of both death and transplant in patients with MASH on the waitlist, helping to inform clinical decisions by identifying the most impactful covariates for each outcome.

Introduction

Metabolic dysfunction-associated steatohepatitis (MASH) cirrhosis is a leading cause of liver transplantation (LT) globally and the fastest growing indication for LT in the United States, with the prevalence of waitlisted candidates increasing from 2.5% to 20.4% between 2004 and 2019. The prevalence of MASH cirrhosis is projected to continue to rise significantly in the coming years [1,2]. Candidates waitlisted for LT are prioritized based on their model for end-stage liver disease (MELD) score, which has been periodically reviewed and updated, most recently to the MELD 3.0 score [3]. The MELD-based scoring system predicts waitlist mortality and does not account for type of liver disease, as previous studies have demonstrated minimal effects on the predictive performance [4]. Despite changes to MELD-based scoring systems in recent years and the increasing prevalence of MASH, MELD-based scoring systems have lower concordance in candidates with MASH cirrhosis compared to those listed with other liver diseases, highlighting the need to develop waitlist prediction models that capture the complexity of MASH cirrhosis [3-6]. There are several possible explanations for the lower concordance of MELD models in this population. Patients with MASH, particularly those in the low- to mid-MELD score range, tend to have faster disease progression than is captured by their MELD score progression, higher pre-LT mortality risk, and lower likelihood of recovery than other patients on the waitlist. Additionally, patients with MASH cirrhosis tend to develop clinically significant portal hypertension at lower MELD-sodium (MELD-Na) scores, contributing to higher waitlist mortality [5-8]. Despite having more severe comorbidities, such as portal hypertension, advanced age, higher BMI, diabetes, hypertension, and hyperlipidemia, patients with MASH cirrhosis are less likely to receive a transplant on the waitlist and more likely to face higher waitlist mortality and removal due to becoming too ill to undergo transplant compared to patients listed with other liver diseases [8-12]. Improving waitlist prediction in patients with MASH through developing MASH-specific models can aid clinicians in optimizing their waitlist outcomes and pretransplant status, thus potentially improving overall waitlist outcomes.

Another limitation of MELD-based models is that they provide information on the risk of death on the waitlist without accounting for the risk of transplantation, censoring patients who do not experience the event of interest and leading to biased estimation of risk [7]. These single-risk Cox proportional hazards (CoxPH)–based models cannot predict risk while accounting for the possibility that a patient can experience multiple events at a given time point on the waitlist, while a censored patient can experience a competing event that would make the primary event of interest clinically impossible (ie, a patient who undergoes LT cannot also die on the waitlist). The risks of each event cannot be compared between multiple cause–specific models. In contrast, competing risk models account for multiple mutually exclusive events [13]. Compared to traditional regression methods, machine learning (ML) can handle large, heterogeneous datasets and avoid several fundamental assumptions of linearity and proportionality that CoxPH models make [14-16]. For example, DeepHit is a deep learning competing risk neural network model that captures intricate, nonlinear interactions between several factors and outcomes (such as mortality and transplant) in one model [9,11,17,18]. By using a DeepHit-based model to predict waitlist outcomes, clinicians will better understand the trajectory of patients with MASH cirrhosis with numerous comorbidities who are at high risk of both mortality and transplantation. Patients with MASH at lower risk of death and transplant may be better candidates for living donor liver transplantation (LDLT) and can be redirected accordingly [19]. Due to the fundamental differences between competing risk and single-risk settings, current model evaluation metrics, such as the concordance index (C-index) and Brier score, may be inadequate for use in competing risk settings [12,20]. We design and propose the competing event coherence (CEC) score, a novel performance metric to assess models in a competing events scenario at the patient level. It is an interevent metric that evaluates the match between the event predicted by the model and the actual event that occurred at a given time point for each patient and takes into account multiple competing events.

In this study, we aimed to develop a MASH cirrhosis–specific deep learning model based on DeepHit using data at the time of waitlisting that accounts for the competing risks of death and transplant on the LT waitlist to forecast waitlist trajectory and inform clinical decision-making. We compared the performance of the DeepHit model to MASH-specific single-risk CoxPH and random survival forest (RSF) models. We externally validated the DeepHit model on single-center data. Finally, we developed a DeepHit dashboard to enter and visualize patient trajectory on the waitlist [21].

Methods

Study Design and Participants

We conducted our retrospective study using two study populations. Of 227,647 patients waitlisted in the Scientific Registry of Transplant Recipients (SRTR) from March 1, 2002, to March 2, 2021, we used data from 17,551 patients with MASH cirrhosis for model development (Figure S1). For external validation, we used data from 167 patients with MASH cirrhosis who were waitlisted at University Health Network (UHN), Toronto, Ontario, between 2012 and 2018. Inclusion and exclusion criteria were identical for both cohorts, ensuring consistency in the selection process. We included all adults aged 18 years or older with a primary diagnosis of MASH or cryptogenic cirrhosis (CC) and a BMI of 30 kg/m^2 or more based on previous studies that demonstrate the histological overlap between MASH cirrhosis and CC [22-24]. We excluded patients with a secondary diagnosis other than MASH cirrhosis or CC with a BMI of 30 kg/m^2 or more [22,25]. We excluded LT recipients who were never waitlisted, retransplants, multiorgan transplants, acute liver failure (including status 1 and status 1a candidates), concomitant liver etiologies (viral hepatitis B and C and alcoholic liver disease), hepatocellular carcinoma–related primary or secondary diagnosis or listed with exception points, and those with pre-existing liver malignancies; supplementary information 1). Patients were followed for up

to 120 months, or until death or deterioration, removal, or transplant, whichever occurred first. Events in both cohorts were classified as (1) death (died on the waitlist or removed due to deterioration), (2) received LT, or (3) censored, and event times were determined accordingly. Candidates removed due to deterioration were included in the death group, while those removed from the waitlist for other reasons were classified as censored (Figure S2). Waitlist outcome categorization is consistent with previous literature [26].

Models

We developed all models using SRTR data based on shared features between the SRTR and UHN datasets. The DeepHit model includes a shared network with fully connected layers to capture intrinsic patterns of the input features, which are then connected to two cause-specific subnetworks that learn the relationship between the input features, event type, and time of the event [11,27]. DeepHit outputs discrete monthly risk predictions of the competing events. The sum of the monthly prediction over the entire time horizon T for all the competing events is $1/K$, where K is the total number of competing events. In our case, the maximum event time is 120 months. The cumulative risk for 1 event over this time period is 0.5, as there are two competing events. The DeepHit model includes a shared network with fully connected layers and 2 cause-specific subnetworks that correspond to death and transplant. The joint distribution of the event and first hitting time is learned and outputted through a final layer to output r_i (k, $t|x_i$) defined as

rik,txi=fxi

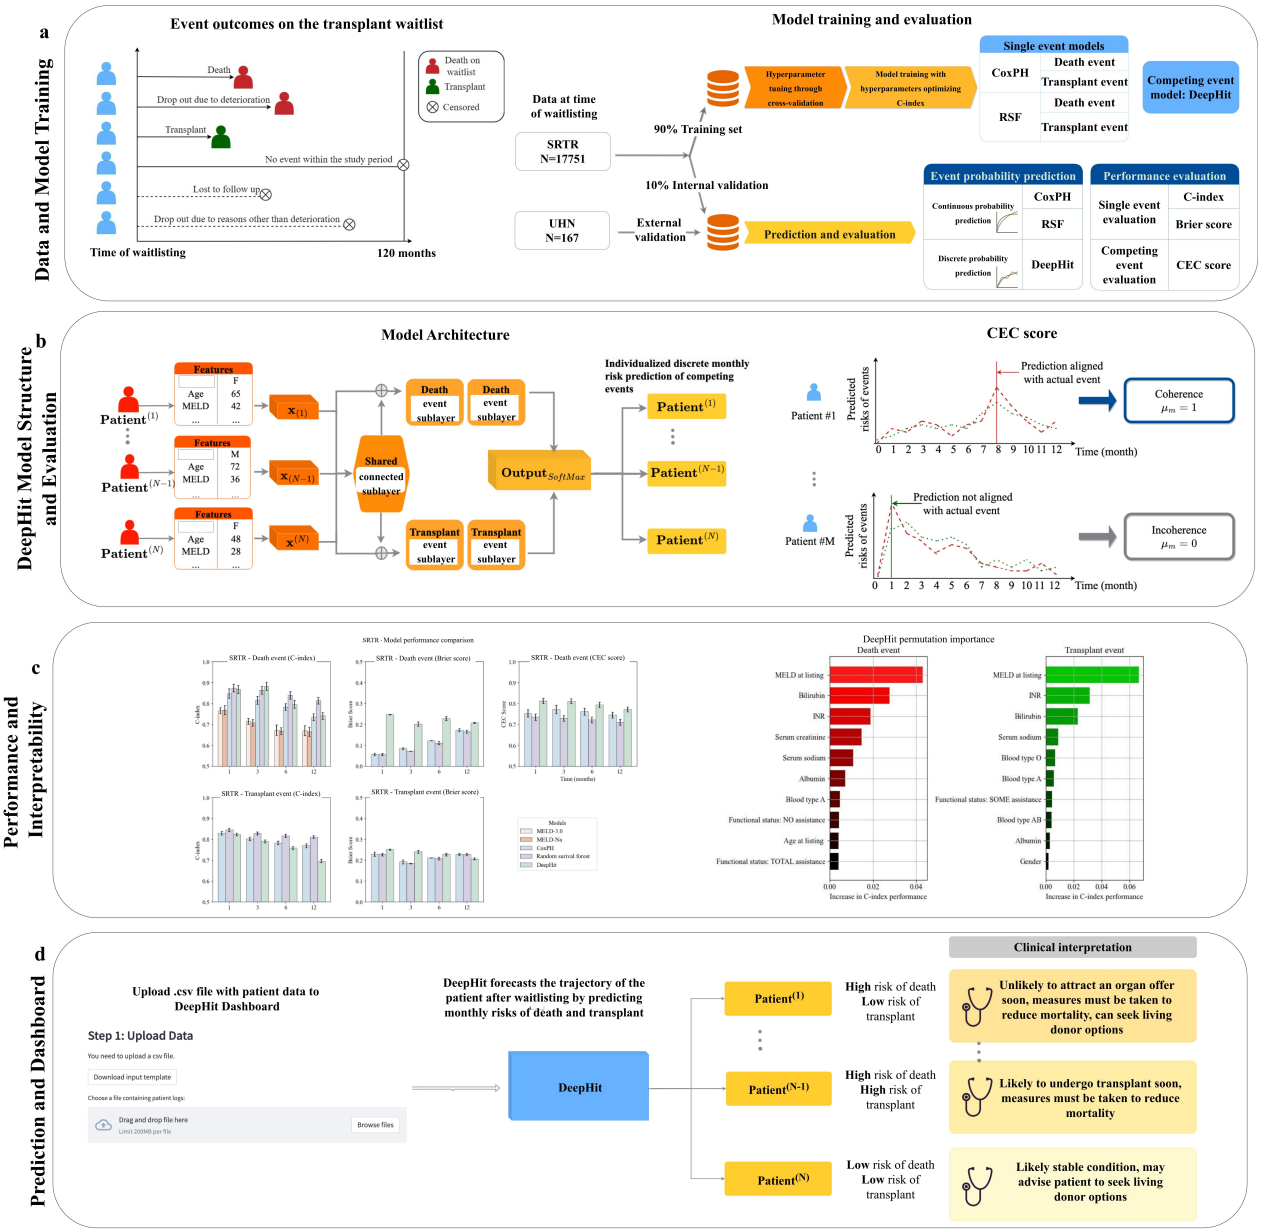
which is the predicted probability of the k event happening at a specific prediction time t, satisfying

∑k=1, t=1K, Tri(k,t|xi)=1

where f represents the DeepHit structure [11].

We compared DeepHit to single-risk CoxPH and RSF models predicting death or transplant. CoxPH is a linear model that predicts the hazard function with an assumption of proportionality where the individual hazard is proportional to the population baseline hazard that changes over time [14]. (Figure 1) For each cause-specific CoxPH or RSF model predicting death or transplant, the competing event (death or transplant) was censored. Model hyperparameters are available in Table S1 in Multimedia Appendix 1. For comparison, MELD-Na and MELD 3.0 scores were calculated to predict mortality (supplementary information 1)

Figure 1. DeepHit model. (A) The model training process, event prediction, and evaluation process are displayed. (B) The DeepHit model architecture is described. (C) The competing event coherence score evaluates model performance based on the prediction of an event compared to the actual event that occurred at the patient level. (D) DeepHit can be used to predict death and transplant and inform clinical decisions. C-index: concordance index; CEC: competing event coherence; CoxPH: Cox proportional hazards; INR: international normalized ratio; MASH: metabolic dysfunction–associated steatohepatitis; MELD: Model for End-Stage Liver Disease; RSF: random survival forest; SRTR: Scientific Registry of Transplant Recipients; and UHN: University Health Network.



Model Evaluation

Models were evaluated using the C-index and Brier scores. Furthermore, we propose a new metric to evaluate the percentage of prediction that is coherent to the actual event type and time at which it occurred in competing risk scenarios, known as the CEC score (or the μ-score). This overcomes the limitations of the C-index and the Brier score, which examine model performance under a single-risk scenario but cannot be used to compare all the predicted risks for the competing events at the same time. Ideally, at the time of the actual event that occurred, the predicted risk for that event should be higher than the predicted risk of other competing events. For the patients who had an event (death or transplant) within the time frame of interest, the percentage of coherence within the population was calculated. The CEC score measures the alignment between the model risk predictions and the actual patient event that occurred. For the M patients who had the event within the time frame t, the percentage of coherence within the population was calculated. The CEC score measures the alignment between the risk predictions and the actual patient event. Let's μ_m indicate the coherence status of the mth patient being evaluated. Further, let l^* and k^*_m denote the actual event time and event type of the mth patient, respectively; then the proposed μ-score is defined as

$$\mu\text{-score} = \frac{1}{M}\Sigma_{m=1}^{M}\mu_m$$

where coherence for the m patient μ_m is defined as

μm={1,if arg maxk∈ Krm(k,ℓ∗|xm)=km∗0,otherwise,

and r_m (k, $l^*|x_m$) denotes the predicted risks of the 2 events at the event time. Because CoxPH and RSF are single-risk models, we say that the prediction is in coherence (or alignment) if the probability of experiencing an event Pr_{event} is higher for the event corresponding to the actual event (at time l^* as compared to the competing one.

C-index, Brier scores, and CEC scores were computed for all models at four time points after waitlisting: 1, 3, 6, and 12 months. One month corresponds to the 25th percentile of event time in the population [17]. Mortality predictions were also generated using MELD-Na and MELD-3.0 scores for performance comparison. Transplant predictions were not developed for the MELD models since they are only intended to predict death on the waitlist. Since DeepHit is a competing risk model, when the performance was evaluated using single event metrics (C-index and Brier score), the competing event was treated as censored [11].

Statistical Analysis

To ensure the robustness of our model, we used rigorous cross-validation, including k-fold cross-validation and hyperparameter tuning to optimize model performance and ensure generalizability (supplementary information 2). SRTR data were split using stratified random split to preserve the event rate of the population in the training and test sets, which represented 90% and 10% of the entire population, respectively. Within the 90% training set, outer five-fold cross-validation was used to obtain an average performance across all validation folds.

Hyperparameter tuning was used to optimize the C-index. To evaluate the performance of our trained models, we first used single-risk metrics, including the time-dependent C-index and the time-dependent Brier score. The model with the highest performance on the outer validation set was used to test performance on the 10% test set as well as the UHN external validation set. Test performance was evaluated at 1, 3, 6, and 12 months using bootstrapping to obtain consistent results where each bootstrapped sample contains patients that were randomly sampled from the cohort with replacement. The Wilson Cox test was subsequently used to test statistical significance in the performance of DeepHit and the other models (CoxPH and RSF) based on the bootstrapped C-indices, Brier scores, and CEC score proposed as the following (Table S1).

Model Interpretability

Permutation importance was used to determine which covariates in the DeepHit model have the largest influence on the prediction of death and transplant by evaluating the contribution of each covariate to the C-index of the model via random permutation of each variable, which is then compared to the original data [28]. The permutation was done 20 times for each variable to obtain the average and SD of increase in C-index.

All analyses were done using Python version 3.8.8 (Python Software Foundation). CoxPH models were developed using the scikit-learn 1.1.1 library and the scikit-survival 0.16.0 library. The MASH-specific DeepHit model was developed using the TensorFlow 0.0.8 library. The data template can be downloaded as a .csv file. The codebase has been published on GitHub [29].

Ethical Considerations

Due to the use of publicly available deidentified United Network for Organ Sharing (UNOS) data, this study was exempt from Research Ethics Board (REB) review. For external validation, REB approval was obtained (REB number 21 - 5783).

Results

Characteristics of SRTR and UHN Cohorts

There were 17,551 patients with MASH in the SRTR cohort, of which 50.2% (8802/17551) were female. Mean MELD at listing was 19.4 (SD 8.1). By 120-month waitlist follow-up, 54.6% (9599/17551) of patients underwent LT, 25.6% (4510/17551) of patients died or were removed from the waitlist due to deterioration, and 19.8% (3442/17551) of patients were removed for improvement or were censored. Around 93.8% (9004/9599) of recipients underwent deceased donor liver transplantation (DDLT). There were 167 patients with MASH cirrhosis in the UHN dataset, and 46.1% (77/167) were female. The mean MELD at listing was 22.1 (SD 6.6). Overall, 62.9% (105/167) of patients underwent LT, of which 72.4% (76/105) of patients underwent DDLT, 23.4% (39/167) died, and 13.7% (23/167) were removed or censored (see supplementary information 1 and Table S2 in Multimedia Appendix 1). Additional features in the SRTR and UHN datasets are available in Table S3 in Multimedia Appendix 1.

Model Performance

In the competing risk scenario, DeepHit consistently achieved statistically significant higher CEC scores at each time point evaluated on the SRTR and UHN datasets (Figures 2 and 3). Numerical results are displayed in supplementary information 6. When comparing model performance using SRTR data (Figure 2), CoxPH, RFS, and DeepHit had higher C-indices than MELD-Na and MELD 3.0 for death events at 1, 3, 6, and 12 months, outperforming MELD-Na and MELD 3.0 at all time points. RSF achieved statistically significantly higher C-indices (P<.01) except in the RSF-DeepHit comparison at 3 months for death event and 1 month for transplant. RSF had statistically significantly lower Brier scores at each time point evaluated for death and transplant, except for at 12 months for the transplant event (DeepHit: 0.206 vs RSF: 0.228).

Figure 2. Model performance comparison with the Scientific Registry of Transplant Recipients data. Performance of models evaluated using C-index, Brier score, and CEC score on SRTR data. CEC: competing event coherence; C-index: concordance index; CoxPH: Cox proportional hazards; MELD: Model for end-stage liver disease; SRTR: Scientific Registry of Transplant Recipients.

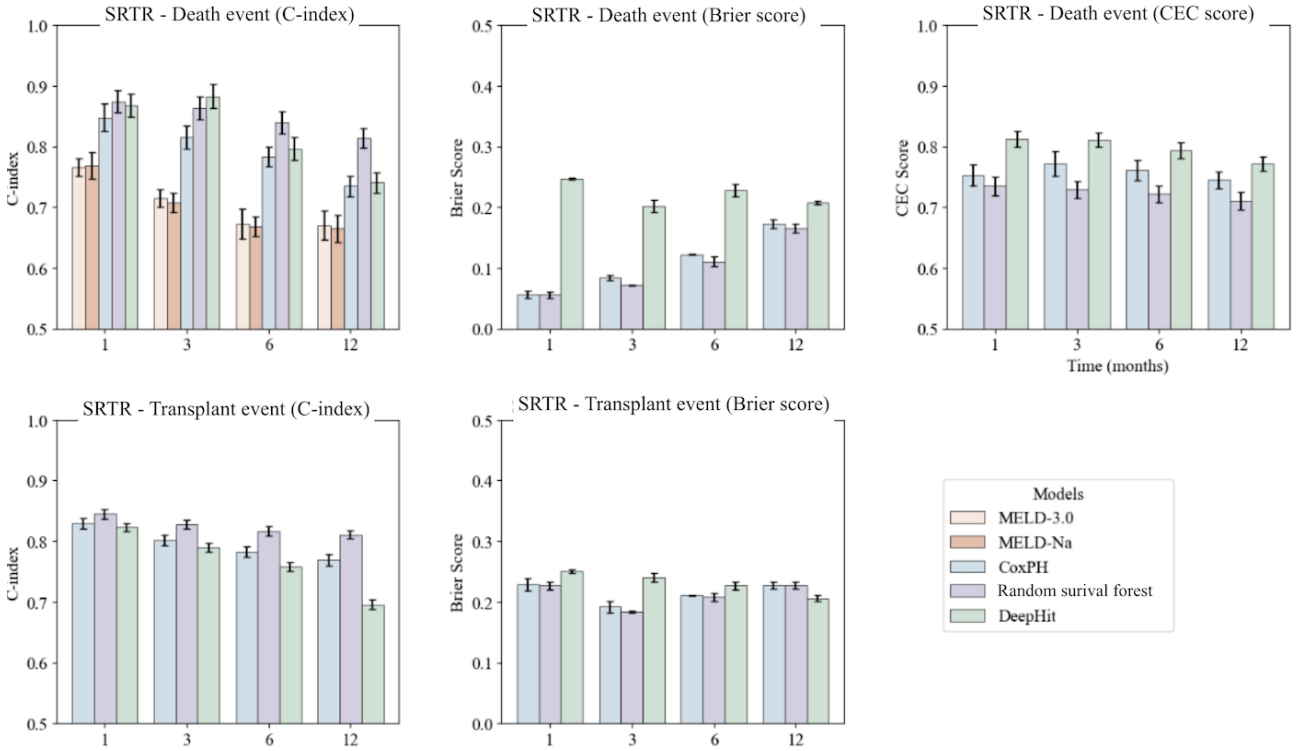


Figure 3. Model performance comparison and external validation of the model using University Health Network data. Performance of models evaluated using C-index, Brier score, and CEC score on UHN data. CEC: competing event coherence; C-index: concordance index; CoxPH: Cox proportional hazards; MELD: Model for end-stage liver disease; SRTR: Scientific Registry of Transplant Recipients.

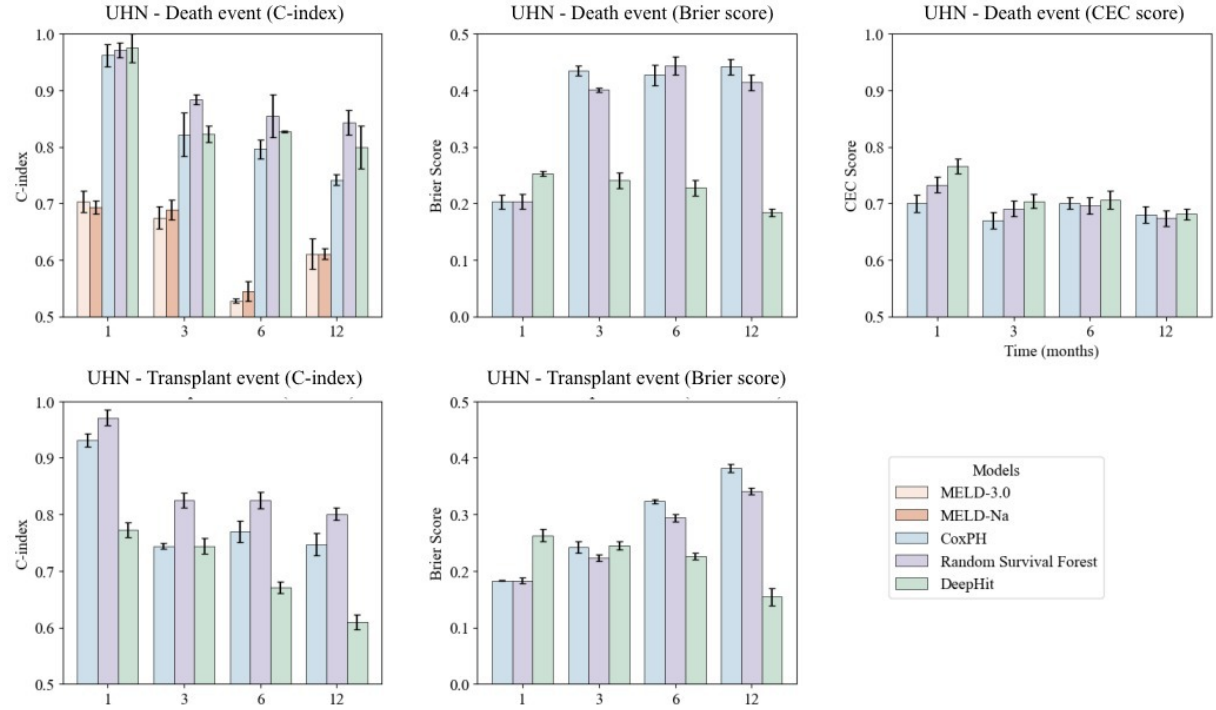

In external validation, DeepHit demonstrated a statistically significantly higher C-index at 1 month for death (0.975); however, RSF had the best performance at all other time points for the death and transplant events. DeepHit also exhibited lower Brier scores at 3, 6, and 12 months compared to RSF for death. For the transplant event, RSF had lower Brier scores at 1 and 3 months than DeepHit, while CoxPH and RSF performed better at 6 and 12 months (Figure 3). Full numerical results can be found in Table S4 in Multimedia Appendix 1.

Forecasting Waitlist Trajectory With DeepHit

Four patients from the SRTR were randomly selected, and their waitlist trajectories of death and transplant were predicted using RSF and DeepHit over a 120-month period based on data available at the time of waitlisting. Figure 4 displays two patients who died on the waitlist at month 33 and month 1, while Figure 5 displays two patients who were transplanted at month 1 and 12. The time at which the event (death or transplant) occurred and the corresponding prediction at that time is magnified. Patient characteristics for the sample patients used here are detailed in Table S5 in Multimedia Appendix 1. Cumulative risk predictions with RSF were generated using two separate models with death or transplant as the outcome of interest and displayed on one graph. Using DeepHit, we generated granular risk predictions from one competing risk model, allowing for visualization of the risk associated with each event over time compared.

Figure 4. Forecasting death on the waitlist using Random Survival Forest and DeepHit with patient examples using data at the time of waitlisting. The vertical line on each plot indicates the event (green=transplant; red=death) and the time at which it occurred. On the DeepHit plots, zoomed-in segments correspond to the time at which the actual event occurred. For a patient that experienced an event during month 1, they were categorized as experiencing the event at time 0. For a patient that experienced an event during months 1 and 2, they were categorized as experiencing the event at month 1 and so on.

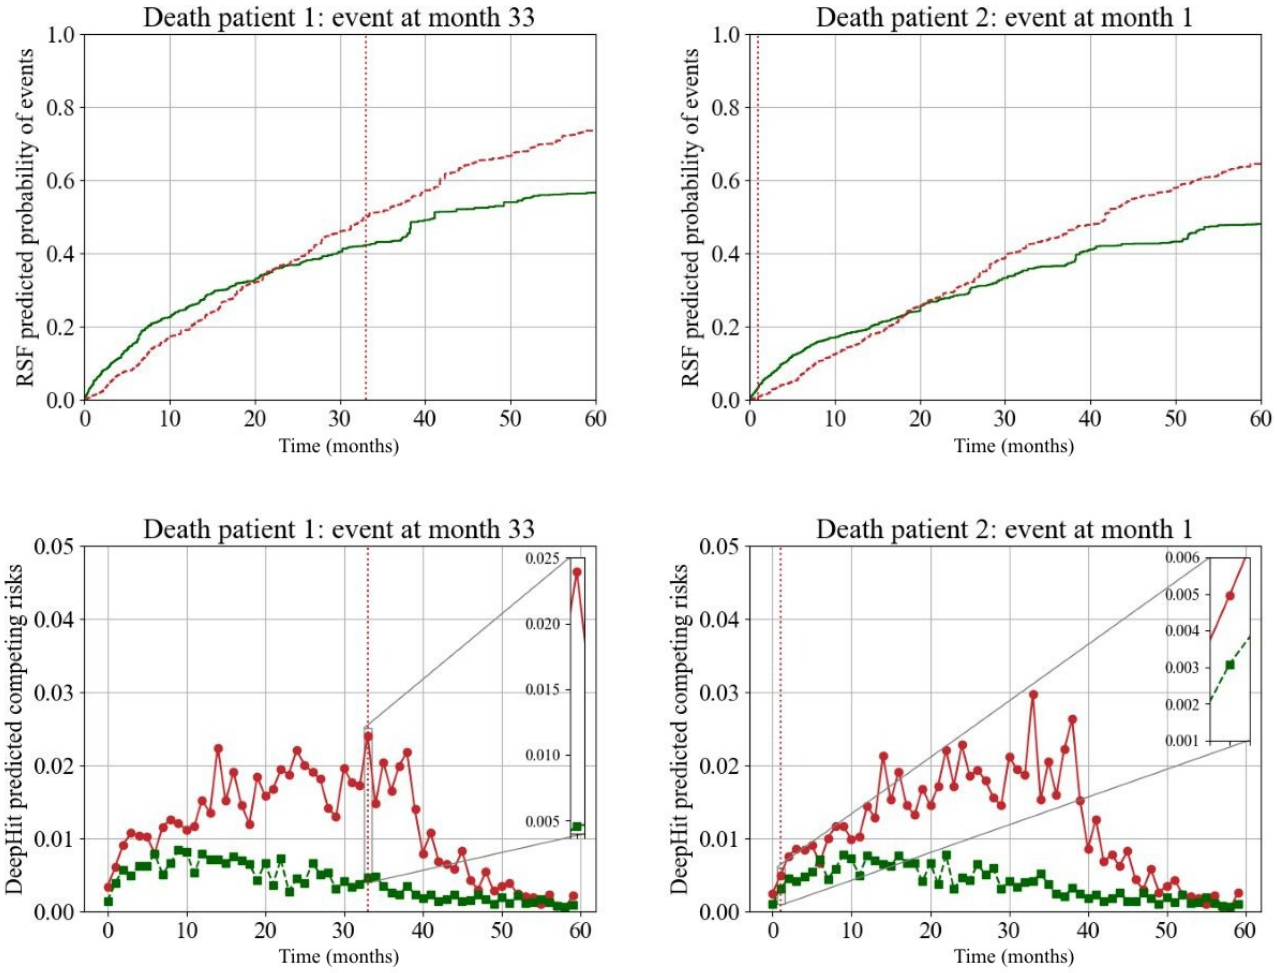

Figure 5. Forecasting transplant on the waitlist using random survival forest and DeepHit. Similar to Figure 4, transplant on the waitlist is predicted using RSF and DeepHit with each plot corresponding to a different patient.

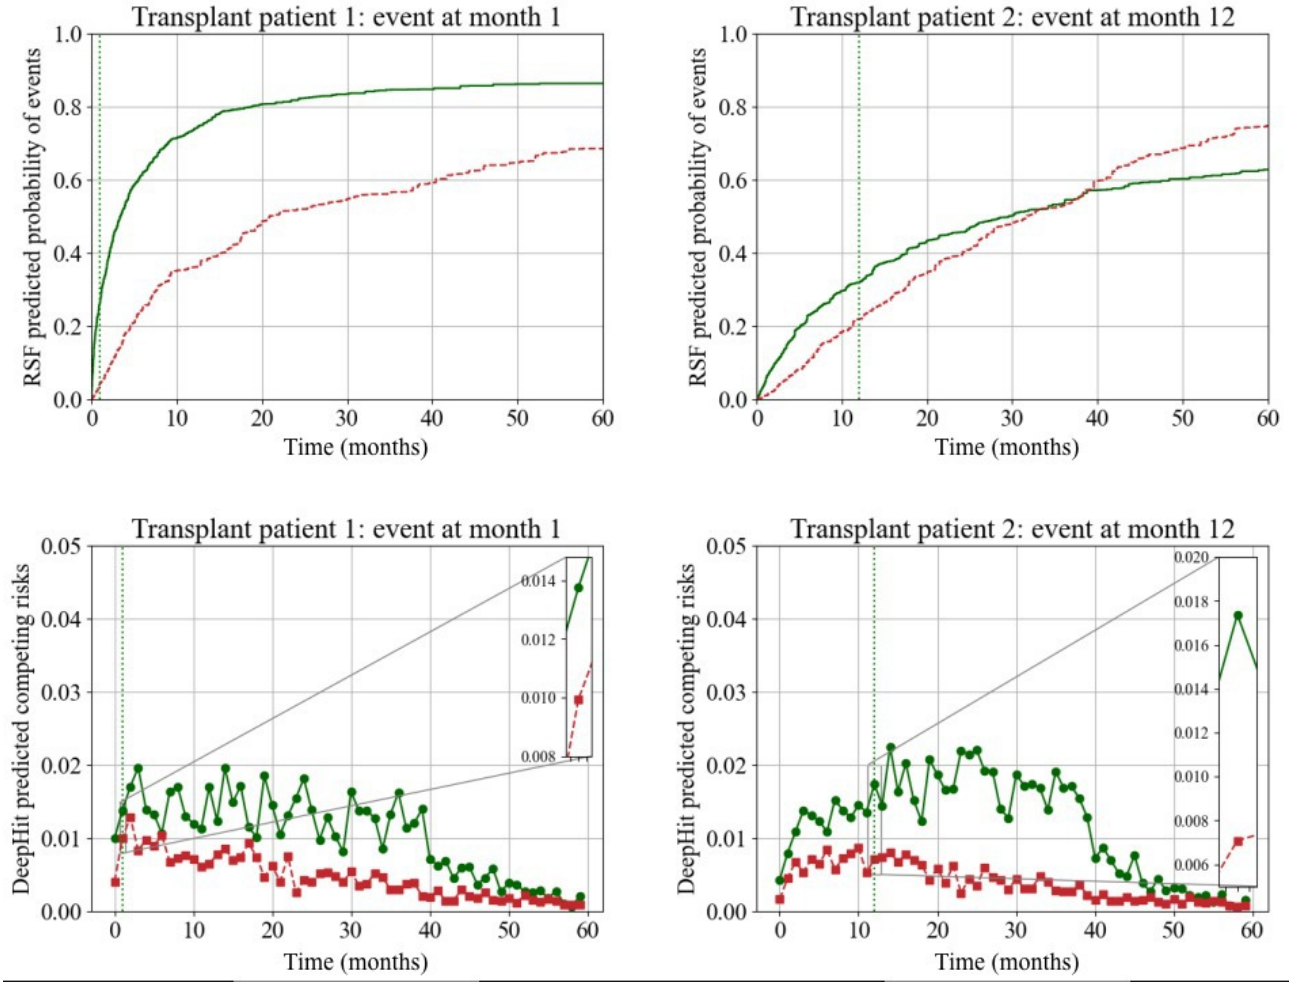
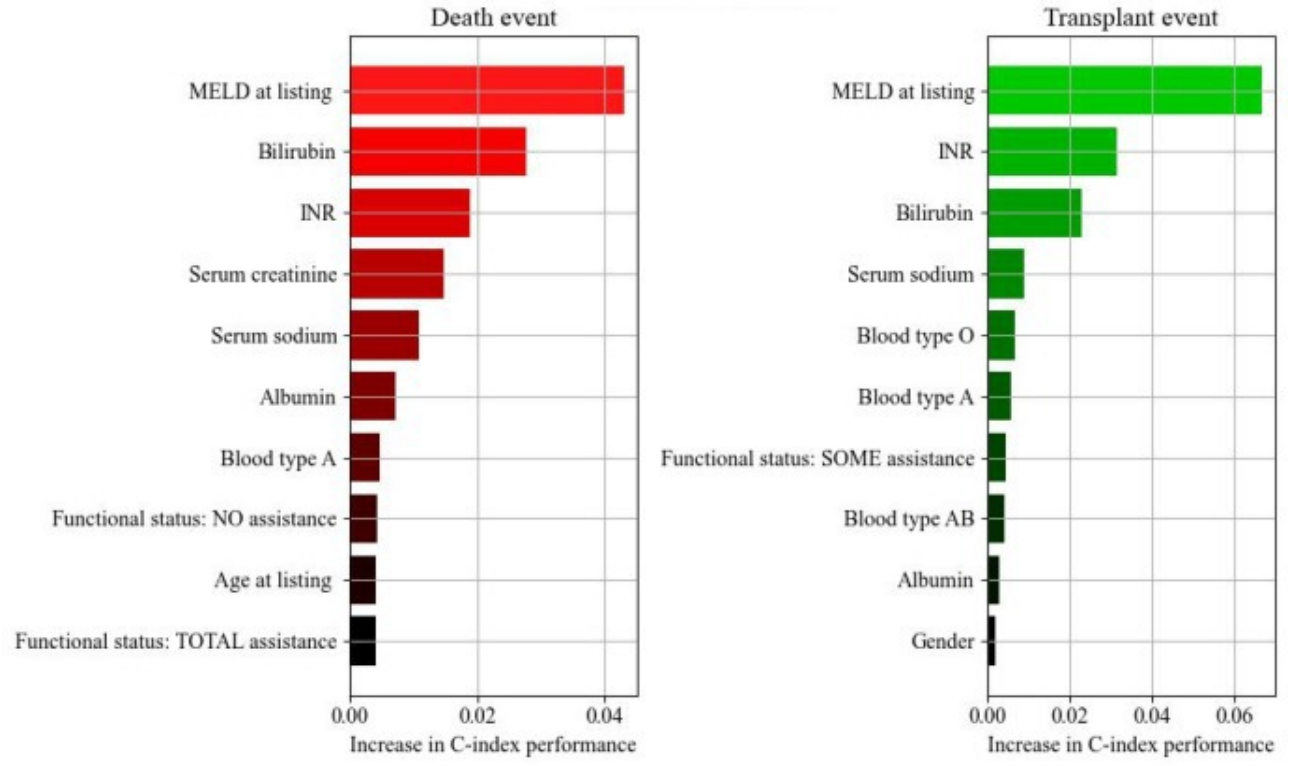


Permutation Importance Using DeepHit

In predicting the death event, MELD at listing emerged as the greatest contributor to the C-index, followed by bilirubin, INR, serum creatinine, and serum sodium. Additional non-MELD features identified were albumin, blood type A, functional status, and age at listing. For transplant events, MELD at listing took precedence, followed by INR and bilirubin. The non-MELD features that influenced transplantation comprised blood types O, A, and AB, as well as functional status, albumin, and gender (Figure 6).

Figure 6. Permutation importance of DeepHit model. Features with the greatest contribution to the prediction of death or transplant were determined using permutation importance. INR: international normalized ratio; MELD: Model for end-stage liver disease



Discussion

Principal Findings

This study aimed to forecast the LT waitlist trajectories of patients with MASH cirrhosis using a deep learning approach that leverages the changing relationships between covariates and risks over time while handling competing risks [11]. We compared a competing risk MASH cirrhosis–specific DeepHit model to single-risk CoxPH and RSF models in forecasting outcomes of death and transplant on the waitlist. We demonstrated that while RSF performed better at most evaluation time points using traditional model performance metrics, DeepHit outperforms RSF when evaluated in a competing risk scenario. Furthermore, we demonstrated that DeepHit can generate and visualize time-varying, discrete predictions of death and transplant. This allows for the identification of patients with a low probability of undergoing transplantation and those at an elevated risk of death while awaiting DDLT, enabling timely consideration of LDLT when available.

MELD-based models poorly predict death in patients with MASH compared to candidates listed for other etiologies and may underestimate the risk of death on the waitlist [5,6]. Additionally, MELD-based models do not provide information on the risk of transplantation. Patients with MASH have a lower 90-day and 1-year probability of transplant and a greater risk of waitlist mortality. Therefore, early identification of patients at low risk of transplant may expedite direction to LDLT and prevent MASH-related mortality on the waitlist [30]. Previous studies have indicated that LDLT results in comparable or improved postoperative outcomes for patients with and without MASH when compared to DDLT. Timely identification of patients enables them to undergo transplantation while in a less decompensated state, leading to more efficient resource usage [31-33]. While MASH-specific models, such as the DeepHit-based model, may not fully replace MELD-based models for waitlist prioritization and liver allocation of all candidates, they can be used to improve the management of waitlisted patients with MASH, particularly those with indolent disease who may spend months on the waitlist and deteriorate before receiving an LT offer. As the prevalence of MASH cirrhosis grows, careful management of waitlisted patients is critical for reducing overall waitlist morbidity and mortality [30]. The DeepHit MASH-specific model also highlights the potential to incorporate personalized prediction of waitlist outcomes at the patient level. This prediction can be updated as clinical status changes over time when modifiable factors associated with a higher risk of waitlist mortality are addressed, providing a more granular prediction of both death and transplant over time on the waitlist as opposed to risk of 90-day mortality alone.

We presented the CEC score as an alternative metric to evaluate competing risk models, emphasizing its role as an interevent measure that assesses a model's performance in predicting 2 competing events [34]. Unlike the C-index, which evaluates performance at the population level, the CEC score assesses performance at the patient level [12,20]. A major problem with the C-index in the setting of competing risks is that the discrimination of a model is reduced when covariates may be associated with both the primary and competing event [20]. Our analysis demonstrates that DeepHit more accurately predicts the actual event (death or transplant) that occurred at specific time points when evaluated using the CEC score compared to

RSF, although RSF performs better based on the C-index and Brier scores. Although the C-index and Brier scores are limited in the scenario of competing risks, DeepHit still exhibited robust performance when evaluated using these metrics, although it was statistically weaker than RSF.

While RSF performed well in a single-risk scenario when evaluated with the C-index and Brier scores, using a noncompeting risk model to predict risk in a clinical setting where patients are at risk of multiple competing events may lead to greater misclassification of risk for single events. We demonstrated this through the improved performance of DeepHit compared to RSF when evaluated with the CEC score. Competing risk analysis may improve predictions of outcomes at the patient level [35-40]. Furthermore, censoring of competing risks can lead to event overestimation in populations at highest risk of experiencing either of the competing events [41]. Competing risk models to evaluate the risks of death and transplant on the waitlist are limited in the field of LT but have been more extensively described and applied to kidney transplantation. Smits et al [42] found that Kaplan-Meier overestimates the chance of transplantation compared to competing risk analysis by over 30% [43]. This not only highlights the importance of competing risk models but also using metrics, such as the CEC score, in the analysis of models to accurately assess performance. We highlight the advantages of DeepHit, whose neural network architecture is particularly well-suited to capturing complex, nonlinear, and interdependent relationships among variables in medium-sized datasets. In contrast to traditional survival models, DeepHit does not rely on restrictive assumptions, such as proportional hazards, enabling greater flexibility in modeling intricate data patterns. Crucially, DeepHit is inherently designed to handle competing risks, estimating the joint probability distribution over multiple, mutually exclusive event types. This multitask learning framework allows the model to share information across outcomes while retaining event-specific distinctions, resulting in more accurate and clinically meaningful survival estimates. By applying a competing risk-specific metric—the CEC score—we demonstrated that DeepHit consistently outperforms traditional ML approaches in predicting time-to-event outcomes with competing risks. These capabilities make DeepHit especially valuable in clinical settings characterized by multiple potential outcomes, such as the organ transplant waitlist.

Previous studies have assessed features associated with death and transplant in LT candidates waitlisted for all indications [5,44-46]. Despite patients with MASH cirrhosis constituting a large and increasing portion of the LT waitlist, limited studies have assessed features associated with death and transplant exclusively in this population [47]. Studies have shown that factors, such as dialysis, sex, race, serum albumin and creatinine, low performance status, and high MELD are associated with increased or decreased risk of transplant among all candidates [5,44-46]. We evaluated the contribution of various covariates in predicting death and transplant events using DeepHit permutation importance, aiming to improve the C-index. In our DeepHit model, MELD at listing emerged as the highest-ranked feature for both death and transplant, followed by components of the MELD score, such as INR, bilirubin, and serum sodium, which have been previously demonstrated [10]. Our permutation analysis reinforced the critical role of MELD-based models in predicting outcomes, showing that biochemical features already included in MELD-based models are implicated in waitlist risk of death and transplant in patients with MASH cirrhosis, potentially reflecting part of the comorbidity burden in this population. Given that SRTR is a historical dataset where allocation is largely determined by MELD score, these findings are not unexpected. Functional status was a highly ranked feature for both events and has been associated with an increased likelihood of transplantation as well as increased waitlist mortality [48]. Poor functional status contributed to the death prediction, possibly because complications of cirrhosis (such as encephalopathy) are associated with poor functional status and increase the risk of death in all LT waitlist candidates [44]. While INR and bilirubin also ranked high, we did not identify creatinine or dialysis in the last week as significant features associated with the prediction of waitlist death or transplant. Age contributed to the death prediction, which has not been found previously in studies on all LT waitlist candidates. Patients with MASH are older, and older patients tend to have poorer waitlist outcomes; therefore, this finding is expected in a MASH cirrhosis cohort [45]. For the transplant event, we found that blood type AB ranked high. These candidates can accept donor livers from nearly all blood types. In other studies, dialysis, sex, race, serum albumin and creatinine, low performance status, and high MELD have been found to be associated with increased or decreased risk of transplant in all candidates [5].

Limitations

The SRTR is a retrospective dataset and limitations, such as high missingness and heterogeneity of data collection must be noted. Furthermore, there are limited longitudinal features in the SRTR dataset, which makes the development of a dynamic model challenging [49]. The permutation importance method is limited as it does not provide information on the directionality of risk such as provided by a hazard ratio, which makes it difficult to apply DeepHit to clinical scenarios where risk factors can be identified and modified to improve outcomes. Furthermore, none of the models developed consider individual organ availability, donor compatibility, and regional variation. Although the DeepHit model performed well when externally validated on the UHN dataset, the UHN sample size was relatively small at 167 patients. Further work should seek to validate this model on larger datasets. Finally, the use of historical waitlist candidate data to devise a ranking system may perpetuate existing inequities and biases in liver allocation; therefore, DeepHit should not be used for definitive decision-making on waitlisting or delisting but can be used in conjunction with other tools.

Conclusion

The DeepHit model can be used to forecast waitlist trajectories of both death and transplant in a competing risk scenario for patients with MASH, using data available at the time of listing. With DeepHit, discretized and dynamic changes of the risk of death and transplant can be visualized and compared across multiple time points and between events. This information can

enhance the current strategies for managing candidates with LT with MASH cirrhosis and act as a tool to advocate for LDLT in patients who are at high risk of waitlist dropout but underserved by MELD-based mortality predictions. A DeepHit MASH-specific model can be used as a clinical adjunct to inform and modify clinical interventions to optimize patient survival on the waitlist. Future studies should focus on improving the evaluation and interpretability of DeepHit models to expand their use in clinical settings, as well as developing larger scale ML models that consider all patients on the LT waitlist.

Data Availability

The data reported here have been supplied by the Hennepin Healthcare Research Institute (HHRI) as the contractor for the Scientific Registry of Transplant Recipients (SRTR). The interpretation and reporting of these data are the responsibility of the author(s) and in no way should be seen as an official policy of or interpretation by the SRTR or the U.S. Government. The data will not be made available to the public. The codebase has been published on GitHub [29].

Authors' Contributions

GP, YS, SR, and MB contributed to conceptualization. YS performed data curation and investigation. YS and SR were involved in formal analysis. MB was responsible for funding acquisition. YS, GP, SR, and MB performed the methodology. YS and GP managed project administration. MB and SR provided resources. YS, SR, and CL handled the software. MB and SR were responsible for supervision. YS and CL conducted visualization. GP and YS were responsible for writing the original draft. GP, YS, ET, NH, SA, SR, and MB participated in writing review and editing.

Conflicts of Interest

MB has received investigator-initiated grants from Novo Nordisk, Merck, Paladin, Roche, Eisai, Natera, and Astra Zeneca.

Abstract

Background: Electrocardiogram (ECG) data constitutes one of the most widely available biosignal data in clinical and research settings, providing critical insights into cardiovascular diseases as well as broader health conditions. Advancements in deep learning demonstrate high performance in diverse ECG classification tasks, ranging from arrhythmia detection to risk prediction for various diseases. However, the widespread adoption of deep learning for ECG analysis faces significant barriers, including the heterogeneity of file formats, restricted access to pretrained model weights, and complex technical workflows for out-of-domain users.

Objective: This study aims to address major bottlenecks in ECG-based deep learning by introducing ExChanGeAI, an open-source, web-based platform designed to offer an integrated, user-friendly platform for ECG data analysis. Our objective is to streamline the entire workflow—from initial data ingestion (regardless of device or format) and intuitive visualization to privacy-preserving model training and task-specific fine-tuning—making advanced ECG deep learning accessible for both clinical researchers and practitioners without machine learning (ML) expertise.

Methods: ExChanGeAI incorporates robust preprocessing modules for various ECG file types, a set of interactive visualization tools for exploratory data analysis, and multiple state-of-the-art deep learning architectures for ECGs. Users can choose to train models from scratch or fine-tune pretrained models using their own datasets, while all computations are performed locally to ensure data privacy. The platform is adaptable for deployment on personal computers as well as scalable to high-performance computing infrastructures. We demonstrate the platform's performance on several clinically relevant classification tasks across 3 external and heterogeneous validation datasets, including a newly curated test set from routine care, evaluating both model generalizability and resource efficiency.

Results: Our experiments show that de novo training with user-provided, task-specific data can outperform a leading foundation model, while requiring substantially fewer parameters and computational resources. The platform enables users to empirically determine the most suitable model for their specific tasks, based on systematic validations, while lowering technical barriers for out-of-domain experts and promoting open research.

Conclusions: ExChanGeAI provides a comprehensive, privacy-aware platform that democratizes access to ECG analysis and model training. By simplifying complex workflows, ExChanGeAI empowers out-of-domain researchers to use state-of-the-art ML on diverse datasets, democratizing the access to ML in the field of ECG data. The platform is available as open-source code under the Massachusetts Institute of Technology (MIT) license.

health informatics; electrocardiogram; machine Learning; deep learning; end-to-end platform

Introduction

Background

Deep learning methods applied to Electrocardiogram (ECG) analyses have demonstrated their potential as practice-changing diagnostic tools, providing critical insights into heart-related diseases [1-3]. While the push for newer technologies and improved performance metrics is essential, ensuring these advancements are accessible for general use is equally important. Tools like ChatGPT (OpenAI) have demonstrated the potential for a broad and easy application of artificial intelligence (AI), allowing users to leverage sophisticated technologies without

in-depth expertise. Clinician-researchers who seek to apply machine learning (ML) to assess its potential benefits should have access to solutions that facilitate exploration and application without requiring extensive technical knowledge from data handling to data analysis. To address these challenges, there is a need for a comprehensive, end-to-end platform that integrates currently fragmented technical steps like ECG-specific data handling, preprocessing, data visualization, and model training, including transfer learning that requires cumbersome manual scripting. This would enable a seamless workflow from data loading to model deployment and would not only empower researchers to apply and train or fine-tune deep learning models for ECG analysis without programming but also facilitate reproducibility. Moreover, existing pretrained models for ECG data may not disclose model weights, which presents significant challenges (refer to "Related Work" below). While open weights empower users to use and adapt the model, they also promote reproducibility and transparency [4,5].

Additionally, the broad use of medical data is crucial for the advancement of personalized and specialized medicine but inhibits some immediate risks, such as data breaches [6]. As datasets continue to grow and come from diverse sources, ensuring data security becomes increasingly complex. To address this challenge, specialized decentralized learning techniques, such as federated learning or swarm learning, allow valuable insights to be gained without directly sharing sensitive data [7]. Furthermore, establishing uniform data standards can simplify data handling, reduce technical barriers related to varying data formats, and eliminate the need for programming, thereby making advanced analytics accessible to a broader range of users.

In this work, we introduce a novel open-source end-to-end platform for 12-lead ECGs called ExChanGeAI that streamlines essential steps of ECG analysis: (1) data loading and preprocessing of multiple input formats, (2) manual and computer-aided analysis of ECG waveform data, (3) one-click fine-tuning of classification models, allowing users to train and customize ML models with no prior expertise, (4) the trained models use the cross-platform industry-standard Open Neural Network Exchange (ONNX), enabling deployment in every instance of ExChanGeAI and facilitating the exchange of custom models across different instances, and (5) prediction of diseases with and without using pretrained models. Model sharing is supported via an integrated and adaptable WebDav file server called Model ExChanGe. The platform is built upon the principle of open-source code and open-weights, offering full transparency and control, empowering users to contribute to the advancement of ECG analysis models.

Related Work

Multiple studies and reviews have addressed ECG classification and have shown that fine-tuning and transfer learning improve classification results [8-10]. A study has reported improved model accuracy by fine-tuning networks trained on diverse datasets, demonstrating enhanced performance transitioning to smaller datasets [11]. However, the used data and pretrained models were not shared. Another study used transfer learning with convolutional neural networks (CNNs) for atrial fibrillation classification, pretraining on large public datasets and fine-tuning on smaller sets, achieving performance gains [9]. While code was available, pretrained models were not shared, and usability remains a significant barrier. Multiple reviews have summarized ECG analysis pipelines and deep learning methods, such as detailed essential pipeline steps [12] and reviews of techniques like CNNs and recurrent neural networks for arrhythmia classification [13]. The SelfONN model [14] showed competitive performance in general ECG classification on PTB-XL (Physikalisch-Technischen Bundesanstalt-extra large [National Metrology Institute of Germany]) but lacked resource sharing. Various types of autoencoders, including low-rank attention [15], long short-term memory [16], adversarial [17], and denoising [18] approaches, have been explored for feature extraction, anomaly detection, and noise handling. The low-rank attention autoencoder reported high accuracy on 2 datasets by focusing on spatial features. ECG-NET, based on long short-term memory, proclaimed high accuracy for arrhythmia classification on a single database in beat-based validation. An adversarial autoencoder with a temporal CNN published superior scores of anomaly detection for 2 datasets. The attention-based denoising autoencoder improved noisy ECG signal reconstruction. However, limitations across these studies include dataset dependence, restricted generalizability, lack of publicly available pretrained models and code, and validation variability.

In a recent study leveraging the gold-standard PTB-XL [19,20] dataset, the performance characteristics of multiple deep learning models were evaluated across a spectrum of training-data sizes [21]. Notable findings indicated that the InceptionTime and XceptionTime architectures [22,23] exhibited particularly compelling performances. Specifically, InceptionTime demonstrated superior efficacy when trained with smaller datasets, whereas XceptionTime surpassed all other models in performance as training dataset size increased. This suggests a potential trade-off between model complexity and data requirements for optimal diagnostic accuracy in this domain. Due to the demonstrated strength in low- and high-data scenarios, these leading architectures for ECG analysis are highly relevant for evaluation and inclusion in the platform, particularly in contexts where training data availability may vary, such as in medical contexts.

There have also been several claimed foundation models in the field of ECG classification [24]. To the best of our knowledge, these, however, are trained on a singular database [25] and are yet undisclosed or have closed-source code and weights [26,27] in general. In one case, the published weights are different from the original model of the paper due to privacy concerns [28]. A request to publish another trained model has been declined due to intellectual property and legal concerns [29]. They are trained with techniques, such as contrastive and masked learning. This allows for unsupervised training, but restricts the learning to the latent space. For downstream tasks, such as classification, fine-tuning is required. The publications report high scores for classification; however, additional tasks are not available in the published model. While these models mark significant progress in the field, they often grapple with issues, such as overfitting to specific datasets, limited scalability, or insufficient handling

of the variability and quality complications intrinsic to diverse ECG datasets.

Despite advances in ECG analysis and deep learning, the current workflows remain complex, requiring manual data transformation, preprocessing, and the use of separate tools for the visualization and analysis of ECGs, as well as for training and fine-tuning deep learning models. This fragmentation multiplies technical burdens, hinders reproducibility, and acts as a major barrier for widespread clinical adoption. Some frameworks exist to reduce the boilerplate of ML, such as the graphical tool Orange (University of Ljubljana) [30]. It does not require code, yet the workflow has to be set up manually per drag-and-drop, and it does not include any of the ECG analysis tools, such as QRS detection. In the case of AutoML tools, such as GAMA (General Automated Machine learning Assistant; originally developed by Pieter Gijsbers and Joaquin Vanschoren at the Eindhoven University of Technology) [31], it still remains code-centric. Data ingestion, for both methods, is not available out-of-the-box, such as for Digital Imaging and Communication in Medicine (DICOM), even ignoring the sampling rate, lead order, and other inconsistencies across datasets. Both tools remain unsuitable for end-to-end ECG analysis and training of ML models without substantial ML or data scientist expertise. Our work directly addresses this gap with ExChanGeAI, an integrated, accessible, and containerized end-to-end platform. This platform facilitates the visualization, transformation, prediction, and fine-tuning of deep learning models specifically for ECG data. It can leverage pretrained models, and it supports a broad range of formats and preprocessing steps, ensuring usability across different clinical and research settings. ExChanGeAI serves as a valuable resource for researchers, enabling efficient training and fine-tuning of deep learning models while preserving data privacy. This enhances both the accessibility and utility of advanced ECG analysis.

Methods

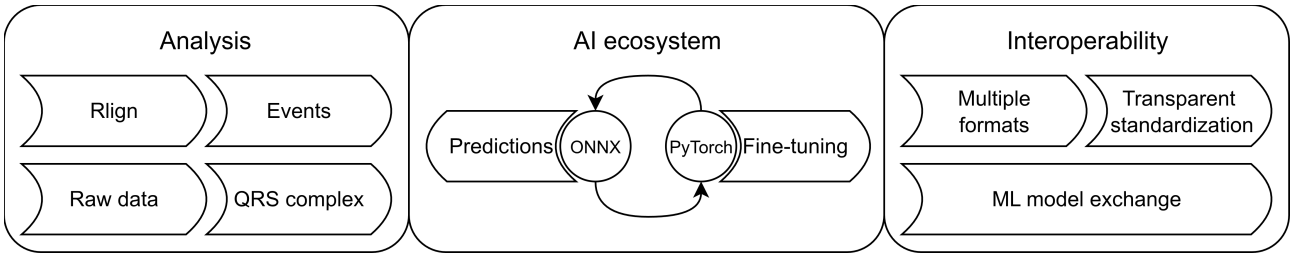
Overview

This section introduces the ExChanGeAI platform, a fully containerized, interoperable, and standardized end-to-end platform for ECG analysis, diagnosis prediction, and model fine-tuning. It is designed for nonexpert users, enabling advanced AI-enabled workflows in a unified interface without requiring specialized technical expertise. The open-source code is freely available under the MIT license [32].

ExChanGeAI Platform

ExChanGeAI is a containerized web application providing an integrated suite of AI-enabled ECG analysis tools for researchers and clinicians. The platform merges human expert analysis capabilities and AI predictions in a unified, interactive end-to-end platform (refer to Figure 1). The functionalities include (1) signal analysis, (2) model-based prediction, (3) model exchange and repository, and (4) semiautomated training and fine-tuning.

Figure 1. Overview of the capabilities of the end-to-end platform ExChanGeAI and its three main distinct parts: (1) Analysis, (2) The Artificial Intelligence Ecosystem, and (3) Interoperability. AI: artificial intelligence; ML: machine learning; ONNX: Open Neural Network Exchange.



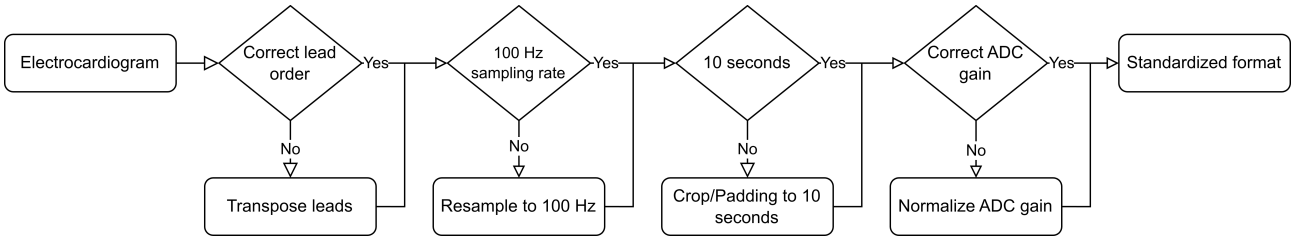
The platform is open-source, using the standardized ONNX model format and additionally supports and encourages the open-weights practice of ML models [4]. The platform consists of multiple views with different foci. The analysis view integrates the visualization of waveforms of raw signals, QRS complexes, and events (fiducial points), computed transparently by Neurokit2 [33]. Additionally, precise R-peak alignment and median beat transformations are supported through the integration of the recently published ECG-preprocessing package, Rlign [34]. These data transformations can be exported in different formats for further research. The platform focuses on resting 12-lead ECGs, displayed in a 2x6 grid in mV scale, and integrates general spatial transformations, including zooming with synchronized adaptation across all leads. This signal view has been designed in collaboration with cardiologists for their everyday use. For visualizing QRS complexes and events, lead II is conventionally applied. The prediction view uses selected models to predict diagnoses and other targets—such as QTc—based on raw signal data, offering a table with predicted diagnosis probabilities (or arbitrary keys), highlighted with a clear color-coding scheme. Dataset distributions, confusion matrices, and class-wise receiver operating characteristic curves can be computed on the platform itself, including suggested thresholds for class-specific Fmax scores. This enables researchers to optimize the threshold for each specific dataset and the health care providers' requested strategy. These differ gradually and can focus on either specificity or sensitivity, depending on the classification targets. Models are provided within the platform using an integrated and interchangeable file server, which enables the crucial aspect of model sharing (see section "Interoperability and Model Sharing"). Currently, we provide multiple models for four targets: (1) diagnostic superclasses, (2) anterior and inferior myocardial infarction (MI), (3) diverse bundle branch blocks, and (4) revascularization need (refer to section "Results"). Researchers can also train specialist models based on their own labeled data. The training and fine-tuning require no prior knowledge of ML. Currently, only 12-lead ECG data with corresponding labels are required. The backend is engineered for high performance and scalability using asynchronous views,

multithreading, and full compute unified device architecture GPU (graphics processing unit) support, including multi-GPU data-parallel training for large-scale fine-tuning.

Data Loading and Preprocessing

ExChanGeAI is designed to handle the variability of real-world ECG data. It supports various ECG input formats, across all possible sampling rates, CSV files (.csv), NumPy arrays (.npy, .npz), DICOM-stored WaveformSequences (.dcm), MATLAB (MathWorks) formatted data (.mat), general DAT files (.dat), and XML files (.xml). Major research and clinical ECG standards (PhysioNet - DAT, UK Biobank - XML) are supported. For ExChanGeAI, all data are normalized by resampling frequency signals to a configurable unified frequency target (defaulting to 100 Hz) using the Fast Fourier Transform, as previous work has shown that the sampling rate does not notably decrease the performance of ML models, but reduces computational overhead manifold [35-38]. This parameter is fully configurable, allowing users to adjust the sampling rate in a local deployment to match specific requirements. Signals not conforming to the standardized format (12-lead, 10-second waveform) are adjusted via expansion or cropping, and all scales are automatically standardized to millivolt (mV) with a 1000 analog-to-digital converter units gain, if necessary (refer to Figure 2).

Figure 2. Flowchart of the preprocessing applied to any electrocardiogram data while being loaded into the application, independent of the file format. ADC: analog-to-digital converter.



Interoperability and Model Sharing

The platform enables training of new models in a secure and privacy-preserving manner. Still, as seen with many publications in the medical domain, pretrained models are not made public [26,29] or depend on external libraries and require specific versions [28]. To promote the open and interoperable ML standard, this work adopts the ONNX as the primary used format. Therefore, our platform is compatible with all ONNX models, honoring the current operation set (Opset 20 and below), and PyTorch models, if the given model structure is provided alongside. The models are not specified with any special requirements, except for a dynamic batch size export. With the use of ONNX, this work aims to ensure that the trained model is widely accessible and interoperable. Therefore, a model sharing interface, called Model ExChanGe, is integrated into the platform, where curated pretrained models are automatically synced and made available for prediction as well as fine-tuning. Additional models can be published into the repository, or your own WebDav instance can be set up.

By default, ExChanGeAI provides 3 baseline model architectures—each as pretrained and untrained models. This includes the XceptionTime [23], InceptionTime [22], and the PhysioNet/CinC Challenge 2021 12-lead second-best model, DSAIL SNU (Data Science & Artificial Intelligence Laboratory Seoul National University [19,39,40])—the best model did not provide weights. Additional models can be incorporated by uploading them into the platform or using the default model exchange file server. We incorporate all evaluated models to extend the research community with open-source and pretrained model weights.

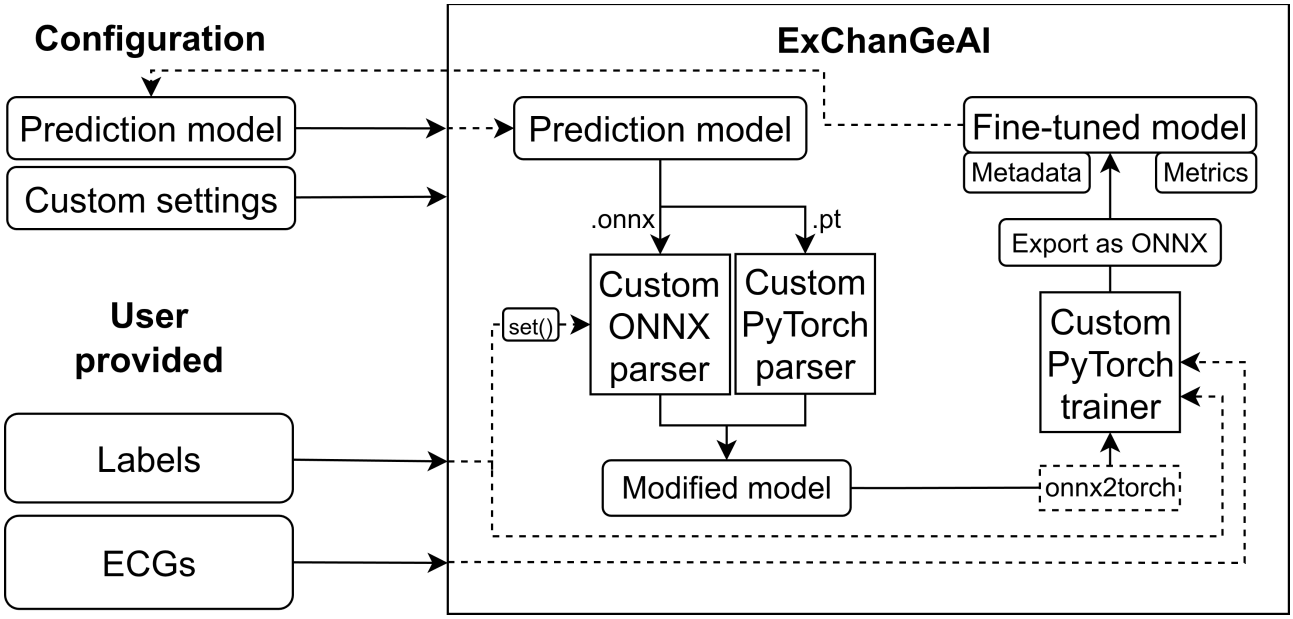
The adoption of the ONNX industry-standard model format ensures that ExChanGeAI is not limited to a proprietary ecosystem. Models trained or fine-tuned with ExChanGeAI can be seamlessly imported, shared, or deployed across different institutions and environments, whether in research settings or clinical contexts. This plug-and-play capability allows users to leverage pretrained models, contribute their own, or integrate compatible architectures developed externally, with zero code changes and minimal configuration. As a result, the platform not only accelerates collaboration but also supports sustainable, evolving workflows as new models and data become available.

Fine-Tuning Platform

ExChanGeAI provides an interactive user interface for fine-tuning with user-supplied data, abstracting all low-level ML steps, and facilitating the exchange of prediction models among researchers. To ensure broad compatibility with various models and platforms, we natively support PyTorch and developed a custom parser for ONNX models to adapt the computation graph where applicable. ExChanGeAI is built upon PyTorch [41], which facilitates on-device training and leverages the ONNX framework during inference. ONNX's custom training runtime does not support all PyTorch operators with corresponding gradient implementations, such as functions like ReduceMin and diverse Pooling Operators (Opset≤18). While defining custom operators may solve this, it requires detailed implementation knowledge for each unknown operator, creating a significant barrier for practical applications. To overcome these limitations, we use onnx2torch to convert our uniquely parsed ONNX models into PyTorch models. This conversion enhances compatibility, allowing training across different ONNX Opset versions and using the extensive feature set of PyTorch. Crucially, our parser automatically adapts the classification head to the new number of classification targets. These conversion steps are computed independently for each fine-tuning process and are entirely transparent to the user, without requiring any programming knowledge (refer to Figure 3). We provide two distinct training methods, including fine-tuning the classification heads, where the majority of the model weights are frozen, or training the entire model. Both

methods use pretrained weights if a pretrained model is selected. The freezing of weights is handled automatically in the background, only allowing modification of the unfrozen weights or those belonging to the classification head.

Figure 3. Overview of the semiautomatic fine-tuning process in the backend of ExChanGeAI. ECG: electrocardiogram; ONNX: Open Neural Network Exchange.



The training and fine-tuning process uses by default the AdamW optimizer [42], due to its better generalizability and convergence than the default Adam optimizer [43], and the ExponentialLR learning rate scheduler (γ=0.9). Adaptive optimization algorithms tend to be more robust, have faster convergence, and therefore improve resource usage [44]. Other optimizers, such as variants of Adam and stochastic gradient descent, are available as alternatives. Initially, a learning rate finder is executed to automatically determine the optimal initial learning rate based on the provided model and data. It has been shown that this method improves the convergence speed and reliability [45]. Furthermore, the loaded data is automatically split into stratified training/evaluation sets with an 80/20% distribution. We limit the training process to a default maximum of 50 epochs and incorporate checkpointing for models with the lowest weighted validation loss, alongside early stopping. Advanced settings, such as other optimizers, batch size, number of epochs, maximum initial learning rate, and gamma can be adapted via the user interface, if required. The best model, in addition to training and evaluation statistics, is exported and downloaded after completion. To ensure comprehensive reporting and documentation, the exported statements include (1) the number of samples, (2) distribution and corresponding labels, (3) the used base model, (4) the training and evaluation loss per epoch, and (5) the corresponding F_1-scores on the evaluation set.

Evaluation

To thoroughly assess the reliability and performance of ExChanGeAI's training process, we conduct a series of scenario-based tests. The training and prediction capabilities are one of the key features of this work and are therefore mainly evaluated via training and fine-tuning of classification models on various tasks and tests on internal and external datasets using the ExChanGeAI platform, where possible. This benchmarking is crucial for validating the platform's core value proposition (1) to empower users, even without ML expertise, and (2) to rapidly develop and deploy accurate prediction models for ECG analysis. Demonstrating robust performance across diverse datasets reinforces the platform's usability and reliability, ultimately building trust and accelerating adoption among clinicians and researchers.

Datasets

To train and fine-tune deep learning models, we use multiple targets and use the large open-access gold standard PTB-XL dataset [20]. In order to demonstrate model training under data-scarce conditions, the provided stratified fold 9 is used for training and fold 10 for intradataset testing. Age and sex, while technically predictable from ECG signals, are generally of limited clinical relevance in the context of model development, as these attributes are readily and reliably obtained through direct patient observation rather than requiring inferential prediction from ECG data.

The comparison includes a wide-ranging spectrum of ischemic heart diseases, structural heart diseases, and conduction abnormalities: (1) broad diagnostic categories, including MI, ST/T changes, conduction disturbances, and hypertrophy, (2) specific comparisons, such as anterior MI vs inferior MI, and diverse types of bundle branch blocks, including complete left (CLBBB), complete right (CRBBB), and incomplete left (ILBBB). The label distribution of PTB-XL is outlined in the Multimedia Appendix 1. A comparison baseline XceptionTime model is trained on the folds 1 - 8 of PTB-XL for all targets to outline the training performance under data-rich conditions. We also compare our baseline model against the benchmark scores of InceptionTime from the PTB-XL benchmark paper [46]. To facilitate a direct comparison of the platform's one-click training capabilities with the benchmark paper, we additionally trained

an InceptionTime model on folds 1 - 8 of PTB-XL, focusing on the superclasses.

To analyze the applicability of models across sites, we evaluate all models on interdatasets based on Yang et al [47,48], MIMIC-IV-ECG (Medical Information Mart for Intensive Care IV Electrocardiogram) [49], and Emergency Department Münster (EDMS) [38], which is an entirely new dataset from our hospital site. This helps to gauge the model's generalizability across different ECG recordings. The latter two datasets demonstrate a relatively balanced distribution with respect to age and sex, whereas the former dataset is predominantly male and represents the smallest sample size among the 3 test sets (Multimedia Appendix 2). We selected these datasets to ensure both clinical relevance and diversity in our evaluation. EDMS is a newly collected internal dataset derived from routine clinical care, providing contemporary, real-world ECG data. MIMIC-IV ECG represents one of the largest publicly available routine care datasets, enabling robust large-scale analyses. PTB-XL serves as the gold standard for annotated ECG data, offering high-quality expert labels, while the Yang et al dataset provides a similarly gold-standard resource from an entirely different geographical region, allowing us to assess model generalizability across populations. To prevent patient leakage, only one record per patient was kept in PTB-XL before the stratified split.

Some classes present slight variations, such as MIMIC and EDMS, which do not have descriptive ECG statements but general *ICD-10* (*International Classification of Diseases, 10th Revision*) codes, which are not necessarily based solely on the given ECG. We extract the signals with the corresponding fitting maps and merged superclasses. The corresponding *ICD-10* codes, or included statements, are given for each map (refer to Table 1). This includes changes such as that bundle branch blocks (BBBs) are only encoded and divided into left- and right-BBB. We evaluate the prediction performance accordingly, counting complete- and incomplete-RBBB as the superclass RBBB. Physionet classes, from the pretrained models, are mapped to the BBB and superclasses where applicable, as no MI classes are included. For MIMIC and EDMS, in instances of multiple ECGs of the same patient, only the first record was used to negate any multiple patient testing.

Table . Matched superclass and bundle branch block statements of PhysioNet 2021 and Emergency Department Münster to PTB-XL (Physikalisch-Technischen Bundesanstalt-extra large [National Metrology Institute of Germany]) classes.

Classes	Superclasses		Bundle branch blocks		
PTB-XL[a]	CD[b]	STTC[c]	CLBBB[d]	CRBBB[e]	IRBBB[f]
PhysioNet 2021	BBB[g], CLBBB|LBBB[h], CRBBB|RBBB[i], IRBBB, IAVB[j], LAnFB[k], NSIVCB[l]	TAb[m], TInv[n], LQT[o]	CLBBB|LBBB	CRBBB|RBBB	IRBBB
EDMS[p]	—[q]		LBBB	RBBB	

[a]Physikalisch-Technischen Bundesanstalt-extra large.

[b]CD: conduction disturbance.

[c]STTC: ST/T Changes.

[d]CLBBB: complete left bundle branch block.

[e]CRBBB: complete right bundle branch block.

[f]IRBBB: incomplete right bundle branch block.

[g]BBB: bundle branch block.

[h]LBBB: left bundle branch block.

[i]RBBB: right bundle branch block.

[j] IAVB: first-degree atrioventricular block.

[k]LAnFB: left anterior fascicular block.

[l]NSIVCB: nonspecific intraventricular conduction disorder.

[m]Tab: T wave abnormal.

[n]TInv: T wave inversion.

[o]LQT: prolonged QT interval.

[p]EDMS: Emergency Department Münster.

[q]Not available.

Table 2 shows a comprehensive overview of all extracted targets, the number of samples, and mapped *ICD-10* codes across the different external test datasets. Most datasets are uncurated and reflect real-world implications, in contrast to semicurated datasets, such as PTB-XL. There may be bad quality data, as well as discrepancies between *ICD-10* codes and mapped classes. The codes may be based on other electronic health data than the ECG, and differences may occur due to indifference between suspected and confirmed diagnoses. Label noise, which is only present in MIMIC and EDMS, may lead to underestimation of classification performance [50]. This, however, allows us to compare the models across real-world

data, showing possible impact on clinical care. An additional case study with a manually annotated gold standard is evaluated on the internal EDMS dataset. To demonstrate the advanced classification task of revascularization ("does the patient require revascularization?"), which is not available in PTB-XL, the models are trained and fine-tuned using the new EDMS dataset. The labels of revascularization are case-based if the patient has been treated with a revascularization. It consists of 240 positive and negative cases each, whereas negative cases are only a stratified subset of the complete annotated dataset. An additional stratified subset (20%) of these data points is kept as testing data.

Table . External test datasets and their class distribution across all categories, their mapping from diagnostic statements or *ICD-10* (*International Classification of Diseases, 10th Revision*) codes to PTB-XL (Physikalisch-Technischen Bundesanstalt-extra large [National Metrology Institute of Germany] classes, and the data format, including sampling rate, analog-to-digital converter gain, and additional annotations.

Publication, notes, and target	Classes

[s]RBBB: right bundle branch block.

[t]EDMS: Emergency Department Münster.

Model Selection

We use the best-performing models based on the aforementioned previous research [21]. The study has shown that the InceptionTime performs well with less data in comparison to XceptionTime, but its performance lags behind when larger datasets are used. Therefore, we train a baseline model on XceptionTime, as its capability exceeds InceptionTime due to the large amount of data available for the baseline model. In comparison to the InceptionTime and XceptionTime models, we evaluate the DSAIL SNU PhysioNet 2021 model [39,40,51], the PhysioNet 2021 competition leader with available weights, and the only available foundation model, ECG-FM (Electrocardiogram Foundation Model) [28]. We aim to assess the effectiveness and improvements gained using ExChanGeAI's training and fine-tuning capabilities and the possible use of pretrained models, especially in resource-constrained environments with very few data points.

Preprocessing and Training

We evaluated the various architectures using two training strategies: (1) fine-tuning only the classification head and (2) training all layers. Trainings were conducted using the default settings of ExChanGeAI (commit number 4d862c04) to maintain consistency and integrity.

Xception and InceptionTime models are trained de novo (from random initialization) using non-normalized ECG data, which has been internally validated to achieve higher performance. ECG-FM and DSAIL SNU are pretrained models on PhysioNet 2021 labels, which were then fine-tuned for each classification target on PTB-XL fold 9 to demonstrate fine-tuning capabilities. In a special case, to showcase the capability of cross-task transfer learning, a pretrained XceptionTime model (superclasses with PTB-XL folds 1 - 8) was separately fine-tuned on the revascularization task.

The ECG-FM foundation model's training data details are unknown, though it is based on PhysioNet 2021 (which includes PTB-XL), limiting the validity of intradataset evaluation. The "physionet_finetuned" model differs from published results due to inaccessible weights and requires 500 Hz, 5-second *z* score normalized inputs. The training of ECG-FM was implemented with custom training code due to dependency complexities. It requires a custom library, which is only compatible with the end-of-life version of Python 3.9 (Python Software Foundation). Additionally, an ONNX export is not possible with these custom functions, impeding the usage of interoperable standards and therefore the deployment into the platform. The PyTorch implementation, as an alternative, could not be used due to the outdated and unsupported versions of major libraries, resulting in dependency conflicts. The results of ECG-FM are therefore achieved outside the platform, yet are given for comparative purposes. DSAIL SNU was adapted for ONNX export and initialized with the unavailable coinput features (age and sex) using the default values and their required missing feature flags as specified in its corresponding publication, alongside the used minimum-maximum normalization in pretraining.

All ECG recordings were processed at the sampling rate required by each model. For ECG-FM, recordings that are natively 500 Hz (PTB-XL, Yang et al , MIMIC-IV-ECG) were used unchanged, while recordings available only at 100 Hz (EDMS) were up-sampled to 500 Hz via a Fast Fourier Transform to match the model's input requirement. DSAIL SNU, XceptionTime, and InceptionTime require a 10-second ECG sampled at 100 Hz. Consequently, any 500 Hz recordings (PTB-XL, Yang et al, MIMIC-IV-ECG) were down-sampled to 100 Hz using the platform's interoperable data-loading pipeline, and recordings only available at 100 Hz (EDMS) were left unchanged.

Performance Metrics

To evaluate model performance, we use the F_1-score for overall assessment and calculate the average and median for central tendency across datasets. Predictions are derived by selecting the class with the highest probability. We use the F_1-score rather than area under the curve because clinical relevance often requires accurate classification at a single operating threshold—outlining the critical balance between precision and recall—whereas area under the curve summarizes performance across all possible thresholds and may not reflect the real-world consequences of specific predictions. Additionally, we focus on the weighted F_1-score to account for the class imbalance commonly seen in medical datasets, ensuring that minority classes are appropriately represented in the evaluation. Macro F_1, accuracy, precision, recall, Brier score, and expected calibration error top-label, and classwise (macro and weighted), with bootstrapped 95% CIs, as well as per class metrics, confusion matrices, and 2-sided paired *t* tests for external datasets, are given in the Multimedia Appendix 3. For F_1-score evaluation, classes not present in the PhysioNet labels were removed. To reflect realistic out-of-distribution prediction, the comparison did not remove false positives. Robustness, indicated by lower IQR and coefficient of variation (CV) values, suggests consistency across datasets. Computational scaling is analyzed using the number of parameters, floating-point operations per second (FLOPs), training, and inference timings. For all architectures on the ExChanGeAI platform, estimated timings are reported as the mean with SD, evaluated using a run of 1500 ECGs from the MIMIC database, based on the superclass subset and the respective models.

These comprehensive evaluations enable us to determine how well models within ExChanGeAI perform under varied conditions, providing insights into their practical application in

diverse real-world scenarios. Through this extensive testing framework, we confirm ExChanGeAI's robustness, adaptability, and reliability for ECG analysis across multiple datasets, diagnostic statements, and applicability for different use cases.

Ethical Considerations

Collection and analysis of the EDMS dataset were approved by the responsible medical ethics committee (Ärztekammer Westfalen-Lippe, approval EDMS: no. 2022 - 494 f-S) under a waiver of informed consent in accordance with state law for health data privacy (§6 Abs. 2 Gesundheitsdatenschutzgesetz Nordrhein Westfalen (Health Data Protection Act of North Rhine-Westphalia)). The creation and analysis of the MIMIC-IV-ECG dataset were reviewed by the Institutional Review Boards of Beth Israel Deaconess Medical Center and the Massachusetts Institute of Technology, which waived the requirement for individual patient consent because the project did not impact clinical care and all protected health information was deidentified. The Yang et al dataset was approved by the Medical Ethics Committee of Chinese People's Liberation Army General Hospital (approval no S2019-318-03) under informed consent from the participants. The PTB-XL dataset is publicly available under a waiver of the Institutional Ethics Committee (approval no PTB-2020 - 1), complying with Health Insurance Portability and Accountability Act (HIPAA) standards. All waivers allow secondary analysis with given approvals under the respective data regulation and privacy protection standards.

Results

The central goal of ExChanGeAI is to make model selection and empirical comparison tractable, reproducible, and accessible within a single, seamless platform. Therefore, the interface is visually structured into different foci, such as data analysis (refer to Figure 4). The analysis view provides interactive visualization of individual ECG files. Users can select to view ECG data based on multiple views - raw time series, QRS complexes, fiducial point annotation, Rlign median beats, and Rlign time-aligned ECG. When visualizing QRS complexes, the interface displays overlaid waveforms, potentially highlighting morphological features. For raw time series visualization, the platform presents the standard 12-lead ECG signals as separate plots, allowing for detailed inspection of each lead's waveform. The fine-tuning view displays options for model selection, training method, and custom model naming. A bar chart visualization summarizes the distribution of labels within the loaded dataset, presenting counts for categories, such as "CLBBB," "IRBBB," and "CRBBB" as shown in Figure 5. Numerical dataset characteristics, including the total number of imported ECGs and labels, are presented as well.

Figure 4. Overview of the ExChanGeAI web interface, showing the "Analyse" page with a sample electrocardiogram in QRS-waveforms. ECG: electrocardiogram.

Figure 5. Overview of the ExChanGeAI web interface, showing the "Finetune" page, showing the default necessary parameters, and the data distribution across labels of an example bundle-branch-block dataset. ECG: electrocardiogram.

Table 3 shows the weighted F_1-scores of the Xception-, InceptionTime, DSAIL SNU, and ECG-FM architectures across the different classification targets on the test datasets. The tables are organized such that columns represent different models, while rows represent various classification tasks and datasets. Specifically, each row corresponds to a particular classification task evaluated across different test sets (PTB-XL, Yang et al, MIMIC-IV, and EDMS). The most comprehensively de novo–trained model XceptionTime serves as a reference (Training PTB-XL folds 1-8) for assessing performance scaling with increased data availability.

Table . Performance evaluation of various models on electrocardiogram classification tasks across the test datasets.

[f]Not applicable.

[g]Second best model in this category.

[h]These models were pre-trained on datasets including PTB-XL; results on this specific target should be interpreted as in-distribution evaluations.

[i]Best model in this category.

[j]MIMIC-IV: Medical Information Mart for Intensive Care IV.

[k]EDMS: Emergency Department Münster.

[l]Transfer learning based on reference XceptionTime (superclasses with folds 1 - 8).

[m]CV: coefficient of variation.

For illustration, the first row presents superclass classification scores on the PTB-XL test dataset, whereas the reference XceptionTime (trained on PTB-XL folds 1 - 8) achieves a weighted F_1-score of 0.792, and XceptionTime, trained on fold 9 only, reaches 0.686. As an example for MI, the InceptionTime model achieves the second-best F_1-score across both

inter-datasets (0.726 on MIMIC-IV and 0.584 on EDMS), while XceptionTime achieves a slightly higher score on the former (0.734), and ECG-FM on the latter (0.532). The last rows show the aggregated statistics, showing Xception and InceptionTime have the best average and median F_1-scores, outlining the top overall performing models, while DSAIL SNU shows the best IQR and CV values, exhibiting the most robust scores across external datasets. As anticipated, increasing the amount of training data leads to improved performance. Importantly, ExChanGeAI is able to handle this scalability, achieving better outcomes as more data are incorporated (see reference model "XceptionTime" in Table 3). For example, on the PTB-XL dataset, test performance on the superclasses and myocardial infarct targets improves substantially—by 15.4% and 9.96% respectively—when XceptionTime is trained on folds 1‐8 compared to training only on fold 9.

XceptionTime and InceptionTime, representing architectures trained de novo on PTB-XL, meaning with random initialization and without any prior training at all, often achieved the highest results across classification tasks. In contrast, the pretrained models, DSAIL SNU and ECG-FM, exhibited a more nuanced performance profile in our limited data setting. Initially, both models demonstrated suboptimal classification accuracy, especially on datasets outside of their pretraining domain (PhysioNet 2021). Fine-tuning them on a single PTB-XL fold for each classification target led to significant improvements for both DSAIL SNU and ECG-FM. However, they were outperformed by the de novo InceptionTime (8 out of 9 targets) and XceptionTime models (7 out of 9) within our evaluation. Still, fine-tuned DSAIL SNU exhibited the best robustness (lowest IQR and CV), suggesting stable results across disparate external cohorts despite lower mean and median F_1-scores. This increase in intradataset performance does not always translate to interdataset performance, as expected, due to overfitting to the dataset distribution. Overall, XceptionTime and InceptionTime trained from scratch showed the highest average and median F_1-scores across all evaluated classification tasks.

The InceptionTime model trained on folds 1‐8, as reported in the PTB-XL benchmark paper [46], achieves a macro F_1-score of 0.7495. In comparison, our reference XceptionTime model attains a macro F_1-score of 0.768, while a comparable training (not in Table 3) of InceptionTime achieves 0.7707. These results demonstrate that ExChanGeAI's training capabilities not only match but also surpass established benchmark baselines, all without reliance on additional resources. Additionally, the platform's flexible workflow enables rapid prototyping for novel tasks, such as revascularization prediction (absent in PTB-XL), trained and evaluated using the new EDMS dataset. Here, transfer learning, based upon the reference XceptionTime (0.750), increased the F_1-score by 9% relative to de novo XceptionTime (0.688).

Additionally, it has to be noted that the foundation model ECG-FM is the largest with over 90 million parameters, followed by DSAIL SNU (2M), Xception (401K), and InceptionTime (457K). In terms of computational complexity, ECG-FM is the most demanding (14 GFLOPS), followed in descending order by Inception-(460 MFLOPS), XceptionTime (256 MFLOPS), and DSAIL SNU (89 MFLOPS). The inference timings on a 6-core Zen4 CPU correspond to mean 27 (SD 33.78) ms (XceptionTime), mean 26 (SD 36.56) ms (InceptionTime), and mean 29.5 (SD 13.9) ms (DSAIL) using the ExChanGeAI platform. Training with 1500 training samples is estimated with mean 13180 (SD 44) ms per epoch and 8.79 ms per sample (XceptionTime), mean 19520 (SD 153) ms per epoch and 13.01 ms per sample (InceptionTime), and mean 10210 (SD 34) ms per epoch and 6.80 ms per sample (DSAIL). Comparing the classification performance against the computational complexity, XceptionTime and InceptionTime stand out as the top performers. All models trained on the PTB-XL dataset are available in Multimedia Appendix 4.

Discussion

Overview

Our evaluation of ExChanGeAI on established architectures reveals several key insights into model selection, particularly in data-constrained scenarios. The end-to-end platform streamlines both training and fine-tuning, yielding robust performance metrics across diverse ECG classification tasks.

Comparison With Prior Work

Our evaluation shows training on limited data and cross-dataset testing exposes inherent generalization gaps and variability in performance—a major difference compared to the often overoptimistic intradataset results seen in the literature. Consequently, the near-perfect accuracy metrics—in intratest set and simple tasks, such as tachy- and bradycardia prediction [28]—are not reproducible when models are evaluated on external, independent datasets. However, when models are evaluated using intradataset testing and ample training data are available, achieving high scores becomes more feasible and reproducible on external datasets (see the baseline XceptionTime model in the Multimedia Appendix 3). As expected and in line with previous findings [52,53], all models exhibited performance drops on external datasets. Yet, as an important factor, the end-to-end platform training surpasses the established benchmark InceptionTime model, outlining the competitive training performance of the platform without requiring expert knowledge.

Principal Findings

XceptionTime models were particularly notable for their parameter efficiency and competitive accuracy, reaffirming their architectural strength. Notably, learning from scratch proved to be a strong alternative to transfer learning, as de novo XceptionTime and InceptionTime models often outperformed fine-tuned pretrained models despite having fewer parameters. However, performance variability was observed across different classification tasks and datasets, as expected, indicating a sensitivity to dataset-specific scaling and parameter optimization within specific model architectures. Pretrained models, while anticipated to leverage their extensive prior knowledge, presented a mixed picture in our data-limited scenarios: while fine-tuning improved their performance, they generally did not consistently surpass the de novo trained XceptionTime and InceptionTime models. However, the pretrained model did

exhibit enhanced robustness against performance degradation across external datasets in most cases, compared to de novo trained models. Among all, DSAIL SNU demonstrated the lowest performance variance, underscoring its robustness.

Limitations

First, while pretrained models offer potential advantages, their benefits are not guaranteed in data-constrained scenarios. Training from scratch within ExChanGeAI frequently yielded top results. This underscores the critical importance of empirical validation and careful model selection tailored to each dataset and use case. Second, the inherent influence of model architecture on performance, coupled with the relative consistency of the subsequent training process across architectures, underscores the value of an end-to-end platform that simplifies exploration and deployment of diverse, yet effective, models. Third, while the evaluation was conducted using data-constrained scenarios, rigorous validation across diverse external datasets and the baseline comparison model also outlines the advantage of more training samples; however, these may be difficult to obtain in a clinical setting. Fourth, while the given models can be trained outside the platform, with even more customization, the usage of ExChanGeAI reduces many technical burdens, facilitating faster deployment as it eliminates the need for code for data ingestion, preprocessing, training, and evaluation for new models. Fifth, all evaluations have been conducted with a 100 Hz sampling rate by default, which, according to multiple research papers, does not notably decrease the classification performance. However, downsampling may lead to a loss of high-frequency clinical details, such as fragmentation and notches. Researchers should be aware that this loss of fidelity may be critical for specific pathologies not covered in the current classification tasks, though the platform allows for higher sampling rates if required. Sixth, defining “revascularization” by treatment status serves as a proxy for actionable clinical need. While this implies that the label incorporates medical decision-making alongside pathology, predicting this outcome remains a clinically vital advancement for identifying patients requiring urgent intervention. Seventh, while the platform supports seamless deployment of ONNX-compatible architectures, we acknowledge that integrating foundation models with external dependencies or specific libraries (eg, ECG-FM) currently requires execution via external scripts rather than the native end-to-end platform. Eighth, the DSAIL SNU model replaces missing age/sex with default values and missing flag indicators, exactly as it was pretrained. If demographic data were available, its performance may improve beyond the results reported here. Finally, we contributed to the evaluation of the novel revascularization task using a stratified 20% hold-out subset of our EDMS cohort. Consequently, these new results can serve as an internal validation only, and the generalizability to external cohorts cannot be guaranteed.

Future Work

While acknowledging potential limitations for expert users seeking highly specialized customizations, the platform’s modular design allows for the future integration of additional compatible architectures, expanding its versatility. The main focus of possible future work could be the integration of explainable or interpretable ML, including its visualization for each prediction.

Conclusions

A major strength of ExChanGeAI is its ability to democratize advanced deep learning for ECG analysis. By integrating pretrained, fine-tuned, and untrained models within a unified interface, ExChanGeAI overcomes significant barriers associated with data loading, model-specific installation, environment setup, and code dependencies, particularly benefiting nonexperts and general-purpose applications. This not only enables rapid prototyping and empirical validation by both experts and nonexperts but also encourages open science and sharing of ready-to-use models for collaborative research. Ultimately, ExChanGeAI aims to enhance the accessibility of deep learning models and reduce operational overhead, facilitating broader adoption and accelerating progress. This approach not only minimizes human error and technical debt but also supports best practices for reproducible research and clinical validation. Limitations are mainly posed by the available data and infrastructure, even though the training, on modern machines, becomes significantly easier due to the large increase in computational power in recent years and wider adoption of specialized hardware, such as GPUs and neural processing units.

In conclusion, this work introduced ExChanGeAI, a novel open-source platform designed to streamline and democratize the application of deep learning for ECG analysis. Our results demonstrate the effectiveness of ExChanGeAI across both conventional and state-of-the-art deep learning models—even with limited data—and highlight that pretrained models are not always superior in data-constrained scenarios. Regular empirical benchmarking and model selection remain crucial. By promoting accessibility, reproducibility, and systematic model comparison, ExChanGeAI broadens participation in deep learning research and clinical adoption in ECG analysis.

Acknowledgments

This work was partially supported by the Interdisciplinary Centre for Clinical Research (IZKF) Münster, Germany (grant SEED/020/23 to AB). We acknowledge support by the Open-Access Publication Fund of the Medical Faculty of the Otto-von-Guericke University Magdeburg. Abstract

Background: The rise of generative artificial intelligence (AI) tools such as ChatGPT is rapidly transforming how people access information online. In the health context, generative AI is seen as a potentially disruptive information source due to its low entry barriers, conversational style, and ability to tailor content to users' needs. However, little is known about whether and how individuals use generative AI for health purposes, and which groups may benefit or be left behind, raising important questions of digital health equity.

Objective: This study aimed to assess the current relevance of generative AI as a health information source and to identify key factors predicting individuals' intention to use it. We applied the Unified Theory of Acceptance and Use of Technology 2, focusing on 6 core predictors: performance expectancy, effort expectancy, facilitating conditions, social influence, habit, and hedonic motivation. In addition, we extended the model by including health literacy and health status. A cross-national design enabled comparison across 4 European countries.

Methods: A representative online survey was conducted in September 2024 with 1990 participants aged 16 to 74 years from Austria (n=502), Denmark (n=507), France (n=498), and Serbia (n=483). Structural equation modeling with metric measurement invariance was used to test associations across countries.

Results: Usage of generative AI for health information was still limited: only 39.5% of respondents reported having used it at least rarely. Generative AI ranked last among all measured health information sources (mean 2.08, SD 1.66); instead, medical experts (mean 4.77, SD 1.70) and online search engines (mean 4.57, SD 1.88) are still the most frequently used health information sources. Despite this, performance expectancy (b range=0.44-0.53; all P<.001), habit (b range=0.28-0.32; all P<.001), and hedonic motivation (b range=0.22-0.45; all P<.001) consistently predicted behavioral intention in all countries. Facilitating conditions also showed small but significant effects (b range=0.12-0.24; all P<.01). In contrast, effort expectancy, social influence, health literacy, and health status were unrelated to intention in all countries, with one marginal exception (France: health status, b=−0.09; P=.007). Model fit was good (comparative fit index=0.95; root mean square error of approximation=0.03), and metric invariance was confirmed.

Conclusions: Generative AI use for health information is currently driven by early adopters—those who find it useful, easy to integrate, enjoyable, and have the necessary skills and infrastructure to do so. Cross-national consistency suggests a shared adoption pattern across Europe. To promote equitable adoption, communication efforts should focus on usefulness, convenience, and enjoyment, while ensuring digital access and safeguards for vulnerable users.

KEYWORDS

generative AI; artificial intelligence; health information–seeking; UTAUT2; Unified Theory of Acceptance and Use of Technology 2; AI adoption

Introduction

Background

When people look for health information today, they no longer only consult physicians, pharmacists, or search engines. Increasingly, they also encounter generative artificial intelligence (AI) tools such as ChatGPT or the World Health Organization (WHO)'s chatbot Sarah, which simulate human-like conversations and provide instant responses. These tools promise a new way of accessing medical knowledge: fast, convenient, and interactive. At first glance, this accessibility seems to hold great potential for reducing barriers to health information, therefore directly impacting digital health equity—defined as equitable access to and use of digital health information technology that supports informed decision-making and enhances health [1].

However, the picture is more complex. On the one hand, generative AI can offer cost-free entry points (eg, basic versions of ChatGPT or automatically displayed answers in Google search via Google's Gemini), deliver content in multiple languages, and rephrase complex medical concepts into more understandable terms. In doing so, it could strengthen patient education, address health inequalities, and help bridge communication gaps between citizens and health care providers [2,3]. On the other hand, effective use still depends on internet-enabled devices and adequate digital skills, which are not equally distributed. As a result, the very technology that appears open and inclusive may also risk exacerbating existing digital divides [4].

Moreover, unlike other types of information, health-related questions are often sensitive and personal. At the same time, the inner workings of generative AI remain opaque, and the accuracy of its outputs is not guaranteed [5]. All these tensions raise important questions about adoption: Who is most likely to turn to generative AI for health information, and what factors shape this intention? Moreover, since health communication practices and digital infrastructures differ across countries, cross-national research is urgently needed.

To address these questions, this study draws on the Unified Theory of Acceptance and Use of Technology 2 (UTAUT2) [6]. The model proposes that performance expectancy, effort expectancy, facilitating conditions, social influence, habit, and hedonic motivation shape technology use. We extend this framework by also examining the roles of health literacy and health status in predicting intention to use generative AI for health information. Using cross-national survey data from Austria, Denmark, France, and Serbia, we investigate the drivers of adoption to shed light on both individual and contextual factors that may guide the diffusion of generative AI in health contexts.

Generative AI as Novel Health Information Source

Generative AI constitutes a potentially disruptive force in the health information ecosystem [7]. However, despite its rapid advancement and widespread availability, empirical research on its role in health information–seeking remains limited [2]. At the same time, broader trends highlight the ongoing digitalization of health-related knowledge acquisition. A representative survey conducted in Germany in 2019 revealed that only 48% of respondents consulted a medical professional for their most recent health issue, while 1 in 3 turned first to the internet [8]. Similar findings show that online sources—particularly search engines—are the primary means of accessing health information, both for caregivers and the general population [9,10]. Family and friends and traditional mass media (eg, print media and health-related TV programming) rank behind medical professionals and online sources [8].

The introduction of generative AI tools like ChatGPT may shift these established hierarchies. Unlike static web content or conventional search engines, generative AI enables dialogic, personalized interactions that simulate human conversation. These features may position generative AI as a compelling alternative to established online and offline health information sources. However, current evidence suggests that trust in generative AI—especially regarding complex health-related issues—is still limited [11], which might restrict its present adoption potential to early adopters [2]. This raises questions about how generative AI integrates into the broader ecosystem of health information sources.

To address this gap, we first explore: How does the use of generative AI for health information–seeking compare to that of more established health information sources?

Explaining Predictors of Technology Adoption: UTAUT2

The UTAUT2 [6] is one of the most popular models to explain technology adoption. It builds on the technology acceptance model [12], emphasizing perceived usefulness and ease of use, and the initial UTAUT model [13], which added performance expectancy, effort expectancy, facilitating conditions, and social influence as predictors of adoption behavior. UTAUT2 extends these frameworks to consumer contexts by incorporating hedonic motivation and habit [6,14] . The UTAUT2 model has demonstrated its versatility in explaining the adoption of diverse eHealth technologies, such as wearable devices [15], health websites [16], and health apps [17]. Additionally, recent studies have highlighted its relevance in understanding the uptake of generative AI technologies [18-21], showcasing its capacity to extend beyond traditional eHealth domains. However, so far, studies on predictors of usage intentions in the context of AI health information–seeking are lacking.

Performance expectancy, a central construct in the UTAUT2 framework, reflects the belief that using technology will lead to performance benefits [22]. In the context of health information–seeking using generative AI, performance expectancy is shaped by users' perceptions of how effectively these tools can enhance their own life, including aspects such as health–decision-making and task efficiency [23]. Consequently, as users anticipate greater usefulness from adopting generative AI as a health information source, their intention to use such technologies strengthens [18-20,24]. Based on this, we propose the following hypothesis: "the higher the performance expectancy, the stronger the intention to use generative AI for health information–seeking" (H1). Effort

expectancy, closely tied to ease of use, emphasizes simplicity in technology adoption [13]. Generative AI tools like ChatGPT benefit from high effort expectancy when users find them intuitive and easy to integrate into their workflows, particularly during the early adoption phase [18,19,23,24]. Addressing usability concerns early can reduce resistance and build user confidence, strengthening behavioral intention [23,25]. Therefore, we propose that "the higher the effort expectancy, the stronger the intention to use generative AI for health information–seeking" (H2). Facilitating conditions refer to the resources, skills, and support necessary for using technology [22]. These include training, knowledge, technical assistance, and system compatibility, which significantly enhance behavioral intention and usage [6,25]. In technologically mature settings, facilitating conditions are critical for sustained adoption and user satisfaction [26]. In line with the UTAUT2, we hypothesize that "the better the facilitating conditions, the stronger the intention to use generative AI for health information–seeking" (H3). Social influence indicates the perception that peers, such as family, friends, or colleagues, believe one should adopt a technology [22]. It plays a crucial role in early adoption, where external validation often outweighs personal experience [6]. Positive reinforcement within social or professional networks can normalize usage [18,24,25,27]: If people perceive that their peers already use generative AI for health information–seeking, their own intention to do so might increase as well. We, therefore, propose that "the greater the perceived social influence, the stronger the intention to use generative AI for health information–seeking" (H4). Habit specifies the extent to which behavior becomes automatic through repetition and prior use [26]. It strongly influences behavioral intention and long-term adoption, emphasizing the importance of regular engagement with technology [6,28]. For generative AI as a health information source, fostering habitual use can solidify its integration into daily routines and enhance sustained adoption [25]. This leads us to state, "the more it is a habit to use generative AI, the stronger the intention to use generative AI for health information–seeking" (H5). Hedonic motivation refers to the enjoyment or pleasure derived from using technology, particularly relevant in consumer contexts [26]. It directly impacts behavioral intention, especially for technologies involving entertainment or leisure [29]. For generative AI like ChatGPT, it can be expected that the interaction is perceived as fun or entertaining, which can boost user engagement and drive adoption [30]. Accordingly, we suggest the following hypothesis: "the higher the hedonic motivation, the stronger the intention to use generative AI for health information–seeking" (H6).

Influence of Health Literacy and Health Status

With the growing integration of digital tools into everyday lives, the role of health literacy in online health information–seeking has garnered increasing attention. Health literacy has been conceptualized as an individual's capacity to search, access, comprehend, and critically evaluate health information, as well as to use the acquired knowledge to effectively address health-related issues [31,32]. Digital health literacy refers to these abilities in the context of digital environments [33-35]. Generally, low health literacy scores have been associated with undesirable health outcomes [36].

Research suggests that low levels of health literacy are associated with decreased trust in online health resources [37], including the outputs of AI tools [38], and lower overall adoption of online health technologies [39]. Furthermore, initial studies indicate a positive association between health literacy levels and attitudes toward the use of AI tools for medical consultations [40].

On the other hand, individuals with higher levels of health literacy are generally better equipped to critically evaluate online health information and scrutinize it in greater detail [37,41]. This heightened evaluative capacity could make them more aware of the limitations and potential risks of generative AI outputs, such as inaccurate information, bias, data privacy concerns, or oversimplified medical advice [42]. Moreover, individuals with higher health literacy are more likely to trust and use high-quality medical online resources, whereas those with limited health literacy prefer accessible but potentially less reliable sources [43]. In this context, outputs from generative AI might be perceived as lower-quality sources by highly digital health–literate individuals. As a result, while higher health literacy could foster openness to using generative AI for health purposes, it might also lead to greater skepticism or hesitancy in relying on these tools. Nonetheless, there is not enough research in the context of generative AI specifically to make conclusive predictions.

Another well-established factor in online health information–seeking, yet underexplored in the context of AI, is individuals' health status: Studies suggest that people with poor health are significantly more likely to consult the internet for health information compared to those with good health [44,45]. Being chronically ill has also been associated with increased reliance on internet-based technologies for health-related purposes [46]. This relationship can be explained by the fact that individuals in poor health often experience greater health-related concerns, which in turn heightens their motivation to seek information online.

Given these complex relationships, we propose the second research question: How does health literacy and health status influence the intention to seek health information using generative AI?

Cross-National Comparison

In this study, we investigate the predictors of generative AI adoption for health information–seeking across 4 European countries: Austria, Denmark, France, and Serbia. While these countries share certain similarities, they also display notable differences that could shape the strength of the UTAUT2 predictors on the intention to use generative AI for health purposes. Thus, this cross-national approach ensures that the observed effects are generalizable and not confined to specific national contexts or unique country conditions.

The selected countries share two key characteristics. First, all 4 countries provide universal health coverage, ensuring broad access to health care services for their populations. Second, a

significant portion of health care expenditure in these countries is publicly funded [47-50].

Despite these commonalities, there are also critical factors that differ among the countries and may shape the predictors of generative AI adoption. On the one hand, variations in digital infrastructure could significantly impact facilitating conditions, effort expectancy, and social influence as predictors of generative AI use. Denmark consistently ranks among Europe's most digitally advanced nations, boasting high internet penetration and widespread adoption of e-health solutions [51]. This strong digital ecosystem likely enhances the perceived ease of use and social endorsement of generative AI. In contrast, Austria, France, and Serbia exhibit more moderate levels of digital adoption in the context of health information, which may limit the perceived use and social norms regarding such technologies [51].

On the other hand, access to and trust in health care providers vary significantly across these countries, potentially influencing performance expectancy and social influence. In nations with robust health care systems—characterized by a high availability of medical professionals and easy access to care—individuals are more likely to rely on doctors for health advice, as they are often viewed as the most trusted source of health information [8]. Denmark exemplifies this with its high levels of public trust in the health care system [52], which may reduce the perceived benefits and social norms around using generative AI for health purposes. Conversely, in western Balkan countries like Serbia, studies report generally low levels of trust in the health care system [53]. In such contexts, individuals may be more inclined to seek alternative information sources, potentially amplifying the perceived benefits of generative AI use.

By examining these diverse national contexts, this study not only tests the universality of the UTAUT2 model but also deepens our understanding of the contextual factors that shape generative AI adoption for health purposes. We ask: How do the predictors of generative AI use for health information–seeking differ across Austria, Denmark, France, and Serbia?

Methods

Ethical Considerations

Before data collection, the study received ethical approval from the institutional review board of the Department of Communication at the University of Vienna (approval ID: 1205). All participants provided written informed consent prior to participating in the study. The data were collected in anonymized form and no personal identifiers were recorded or stored. Participants received a compensation of €1.50 (US $1.74) for completing the study through the panel provider.

Recruitment

Recruitment of participants occurred during September 2024 via *Bilendi*, an international panel provider. *Bilendi* recruited the participants via email. The panel is checked for quality and attendance on a regular basis. The study was conducted in Austria, France, Denmark, and Serbia, with participants randomly selected to achieve samples representative of age, gender, and educational background. The provider's panel sizes in the respective countries were as follows: Austria: n=60,000; Denmark: n=90,000; France: n=815,000; and Serbia: n=15,100. Per country, the study aimed to reach 500 participants.

Inclusion criteria required participants to be aged between 16 and 74 years. Additionally, respondents who completed the survey in less than one-third of the median completion time (speeders) were excluded. Completion rates (excluding screened-out participants) were high across all 4 countries, ranging from 84.3% to 89.8%. Further details on survey design, administration, and response rates are provided in the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) checklist (Checklist 1).

Procedure and Measures

Overview

The study consisted of two components. The first component, a survey, investigated predictors of the intention to use generative AI for health information–seeking. The second component, an experimental study, explored the influence of disease-related factors on these intentions [54]. To ensure respondents shared a common understanding of the concept, the survey began with a short definition of "generative AI," describing it as technologies that engage in natural language conversations with users and generate responses in real-time. Examples such as ChatGPT, Google's Gemini, and Microsoft Copilot were provided.

The original questionnaire was developed in English and subsequently translated into German, French, Danish, and Serbian. Each translation was performed by a bilingual team member and back-translated into English by a different native speaker to ensure conceptual equivalence with the original items.

This study focused on the following constructs (a complete item list with descriptive analysis and construct reliability values can be found in Multimedia Appendix 1).

Dependent Variables

Sources of Health Information–Seeking

Participants rated the frequency with which they use 8 health information [55] sources on a 7-point Likert scale (1 = "never" to 7 = "very often"). The sources included conversations with medical professionals, pharmacists, and family or friends, as well as books, mass media, internet search engines (eg, Google and Ecosia), and generative AI.

AI Usage Intentions

Participants' willingness to use generative AI [25] for health information–seeking was assessed using 3 items (eg, "I intend to use generative AI for health information seeking"), rated on a 7-point Likert scale (1 = "strongly disagree" to 7 = "strongly agree").

UTAUT2 Predictor Variables

All UTAUT2 model [6,25,56,57] predictors were measured on a 7-point Likert scale (1 = "strongly disagree" to 7 = "strongly agree"). The predictors have been described below.

Performance Expectancy

Perceived benefits of using generative AI for health information–seeking were measured with 4 items (eg, "Using generative AI would save me time when researching health topics").

Effort Expectancy

The perceived ease of using generative AI as a health information source was assessed with 4 items (eg, "Learning to use generative AI for health information–seeking seems easy for me").

Social Influence

Three items measured the extent to which participants felt that important others encouraged their use of generative AI for health information–seeking (eg, "People who are important to me think that I should use generative AI for health-information seeking").

Hedonic Motivation

The enjoyment of using generative AI for health information–seeking was assessed with 3 items (eg, "I think using generative AI for health-information seeking could be fun").

Facilitating Conditions

Participants' perceptions of available resources and support for using generative AI to seek health information were measured with 4 items (eg, access to devices and reliable internet, and knowledge).

Habit

The extent to which turning to generative AI when seeking health information had become a habitual behavior was measured with 3 items (eg, "I automatically turn to generative AI whenever I have questions about my health").

Model Extension Variables

Health Literacy

Health literacy [58] was assessed with 10 items, asking participants to rate their confidence in tasks such as finding understandable health information. Responses were recorded on a 4-point Likert scale (1 = "not at all true" to 4 = "absolutely true").

Health Status

We measured participants' health status using 1 item ("How would you describe your current health status?"; 1 = "very poor" to 7 = "very good").

Control Variables: Sociodemographic Variables

We further measured participants' age, gender, and educational level.

Statistical Analysis

Power

An a priori power analysis was conducted to determine the required sample size for structural equation modeling. Assuming an anticipated effect size of 0.25, a desired statistical power of 0.95, and a significance level of .05, the analysis indicated that a minimum of 391 participants per country would be necessary to detect the hypothesized effects [59].

Analytical Plan

We used AMOS version 26 (IBM Corp) to run a latent variable, multigroup structural equation model using a maximum-likelihood estimator with full information. We computed the comparative fit index, the Tucker-Lewis Index, the chi-square to degrees of freedom ratio (χ^2/df), and the root mean square error of approximation. We also secured metric measurement invariance to be able to compare the paths across countries. We controlled for age, gender, and education (binary coded).

Results

User Statistics

In total, data were collected from 1990 respondents, comprising 502 from Austria, 507 from Denmark, 498 from France, and 483 from Serbia. The overall mean age of participants was 45.1 (SD 15.7) years, with 50.2% (n=998) identifying as female participants. In terms of educational attainment, 83.8% (n=1634) of the sample reported completing at least a medium or higher level of education (secondary level II or higher). Furthermore, 87.4% (n=787) of respondents indicated prior use of generative AI for health information–seeking (at least rarely). Detailed demographic and background characteristics of the sample are summarized in Table 1.

Table . Descriptive characteristics of survey respondents from Austria, Denmark, France, and Serbia (N=1990; September 2024).

Demographic characteristics	Overall, n (%)	Austria, n (%)	Denmark, n (%)	France, n (%)	Serbia, n (%)
Education[a]					
Secondary I or lower	356 (18.24)	93 (18.6)	136 (26.9)	109 (21.9)	18 (3.7)
Secondary II	1080 (55.36)	303 (60.3)	179 (35.3)	224 (45.0)	374 (77.4)
Tertiary	554 (28.39)	106 (21.1)	192 (37.9)	165 (33.1)	91 (18.8)
Gender					
Female	998 (50.15)	252 (49.8)	251 (49.5)	256 (51.4)	239 (49.5)
Male	992 (49.85)	250 (50.2)	256 (50.5)	242 (48.6)	244 (50.5)
Prior experience[b]					
No	1203 (60.45)	316 (62.9)	328 (64.7)	326 (65.5)	233 (48.2)
Yes	787 (39.54)	186 (37.1)	179 (35.3)	172 (34.5)	250 (51.8)

[a]Educational attainment was categorized as low (secondary level I or below) and medium or high (secondary level II or higher). In Serbia, however, representativeness was achieved by grouping educational levels into low or medium (secondary level II or below) and high (tertiary education) due to sampling limitations.

[b]Prior experience: no = "I have never used Generative AI for health information seeking" and yes = "I have used Generative AI for health information seeking at least rarely."

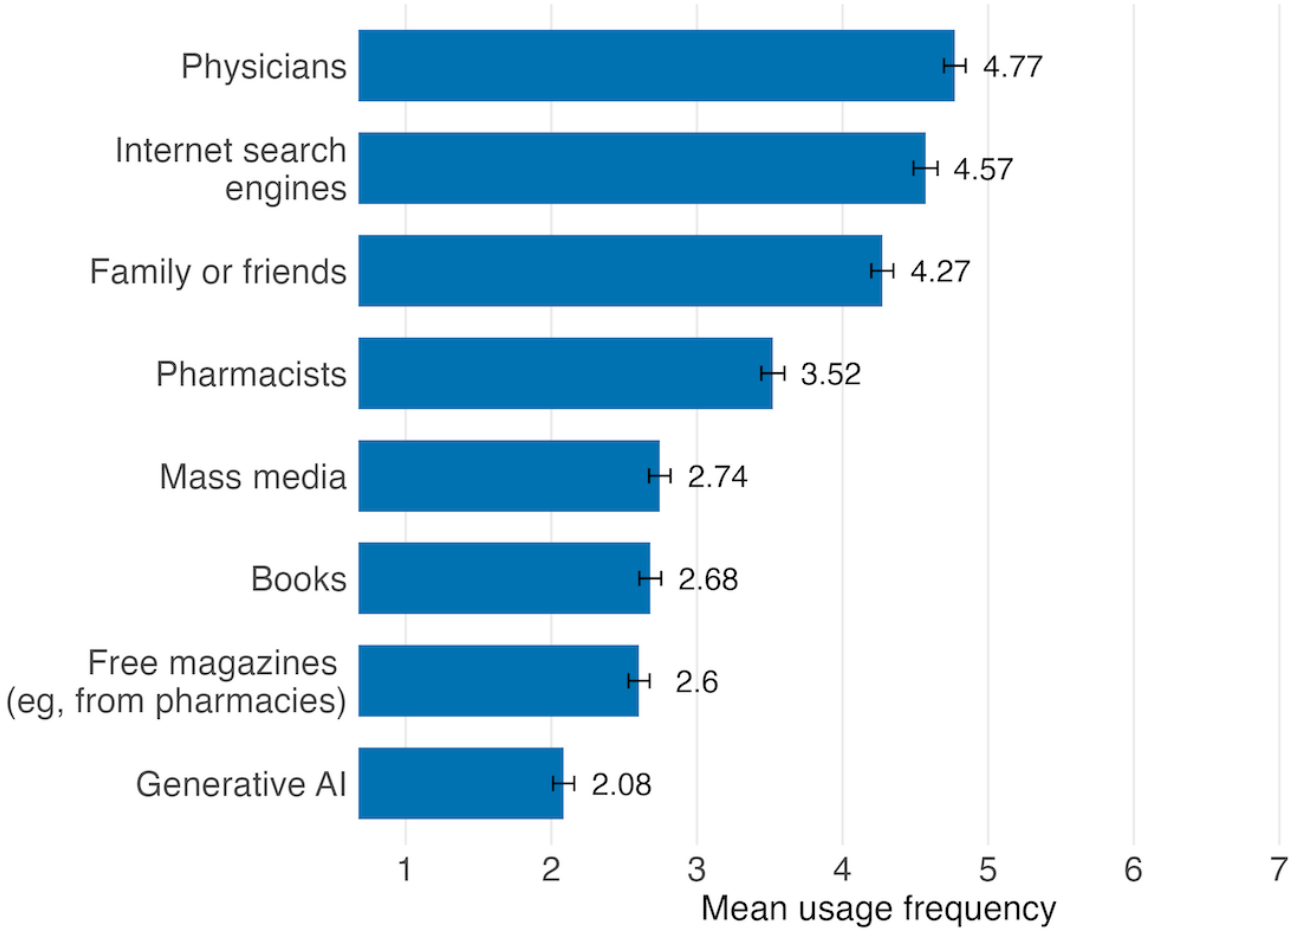
Statistical tests revealed no significant differences in gender distribution across countries (χ^2_3=0.48; *P*=.92) and no significant differences in age (Kruskal-Wallis χ^2_3=2.15; *P*=.54). In contrast, educational attainment varied significantly between countries (χ^2_3=550.76; *P*<.001), reflecting sampling-related imbalances in Serbia where low versus medium or high education was assessed differently than in the other countries. Finally, prior experience with health information–seeking showed significant country differences (Kruskal-Wallis χ^2_3=30.95; *P*<.001), with higher levels reported in Serbia.

Evaluation Outcomes

Descriptive Analysis

In our first research question, we explored how generative AI compares to more established health information sources in terms of usage frequency across countries. As illustrated in Figure 1, generative AI ranks last among all measured sources, indicating that, as of autumn 2024, it is rarely used for health information–seeking (mean 2.08, SD 1.66). In stark contrast, online search engines like Google are highly used, ranking second with a mean usage frequency of 4.57 (SD 1.88), following conversations with physicians, which hold the top position (4.77, SD 1.70). Family and friends also play a significant role, ranking third (4.27, SD 1.73), alongside pharmacists (3.52, SD 1.81). In comparison, traditional mass media such as TV, newspapers, and magazines are used less frequently (2.74, SD 1.68), as are books (2.68, SD 1.70) and free magazines provided by pharmacies or health insurance companies (2.60, SD 1.65). The relative ranking of information sources was consistent across all 4 countries, with physicians, internet search engines, and family or friends occupying the top positions and generative AI ranking last. However, some variation in mean usage frequencies was observed between countries; detailed country-level results are presented in Multimedia Appendix 2.

Figure 1. Mean usage frequency of different health information sources among survey respondents (N=1990) in Austria, Denmark, France, and Serbia (95% CI; September 2024). AI: artificial intelligence.



Model Evaluation

For the hypothesis tests, the results are shown in Table 2. Model fit was good (comparative fit index=0.95; Tucker-Lewis-Index=.93; χ^2/df =2.47, *P*<.001; root mean square error of approximation=0.03, 95% CI 0.03-0.03). We examined the metric measurement invariance of all latent variables by constraining all factor loadings as equal for all 4 countries. When comparing the constrained model to the unconstrained model, we found no significant difference in model fit (*P*=.16). Thus, metric invariance across countries was established.

Table . Structural equation model predicting the intention to use generative artificial intelligence (AI) for health information among survey respondents in Austria, Denmark, France, and Serbia (N=1990; September 2024).

[f]The different subscripts in each row indicate a significant difference between paths (*P*<.05)

In line with H1, we found a highly significant positive association between performance expectancy and the intention to use generative AI for health information–seeking across all 4 countries (Austria: b=0.47, *P*<.001; Denmark: b=0.52, *P*<.001; France: b=0.53, *P*<.001; Serbia: b=0.44, *P*<.001). In contrast, H2 was not supported: effort expectancy showed no significant association with behavioral intention in any of the countries. Turning to H3, results revealed a positive association between facilitating conditions and the intention to use generative AI as a health information source, consistently observed across all 4 contexts (Austria: b=0.12, *P*=.005; Denmark: b=0.17, *P*<.001; France: b=0.22, *P*<.001; Serbia: b=0.24, *P*<.001). By contrast, no support was found for H4: perceived social influence was unrelated to behavioral intention in any of the countries. As predicted in H5, habit was positively associated with behavioral intention to use generative AI for health information–seeking throughout the sample (Austria: *b*=0.29, *P*<.001; Denmark: b=0.32, *P*<.001; France: b=0.28, *P*<.001; Serbia: *b*=0.28, *P*<.001). A similar pattern emerged for H6: hedonic motivation was significantly positively related to behavioral intention in all countries (Austria: b=0.45, *P*<.001; Denmark: b=0.22, *P*<.001; France: b=0.33, *P*<.001; Serbia: b=0.23, *P*<.001).

Finally, with regard to our second research question—which examined whether health literacy and health status predict the intention to seek health information using generative AI—we found no substantial associations. Only in France did health status show a marginal negative effect (b=−0.09; *P*=.007).

Discussion

Principal Results

This study investigated the predictors of intention to use generative AI for health information–seeking, drawing on the UTAUT2 framework and expanding it with health literacy and health status. Using cross-national survey data from Austria, Denmark, France, and Serbia, our findings show that generative AI is still only rarely used for health information–seeking. At the same time, performance expectancy, facilitating conditions, habit, and hedonic motivation consistently emerged as significant predictors of behavioral intention, whereas effort expectancy, social influence, health literacy, and health status were not related to intention. These patterns were consistent across all 4 countries, suggesting a robust set of psychological drivers underlying the early adoption of generative AI in health contexts. A detailed examination of these findings is provided as follows.

First, with regard to overall usage patterns, the data shows that generative AI currently plays only a minor role in health information–seeking: 60% of the respondents reported never

having used a generative AI tool for health-related questions. This result lends itself to 2 contrasting interpretations.

On the one hand, it challenges the popular narrative that generative AI is rapidly transforming health information–seeking behavior. Instead, the findings align with previous studies, showing that generative AI is currently infrequently used in the context of health information [2]. Traditional sources—such as medical professionals and search engines—continue to dominate [8], underscoring that generative AI has yet to achieve mainstream adoption.

On the other hand, despite persistent concerns about data privacy, algorithmic bias, and accuracy, it is noteworthy that 40% of the respondents have already experimented with generative AI for health purposes. Given that this technology only became widely accessible relatively recently, such early uptake is remarkable. From the perspective of technology adoption models, such as the Rogers Diffusion of Innovations [60], this pattern is characteristic of early adopters. It is therefore plausible to assume that the use of generative AI for health information–seeking will increase further as the technology matures and moves toward mainstream adoption.

To better understand the drivers of future uptake, we applied an extended version of the UTAUT2 model. Our findings confirmed the predictive power of performance expectancy, facilitating conditions, habit, and hedonic motivation. This aligns with prior research on digital health tools, indicating that users value usefulness, access, familiarity, and enjoyment [18,20,24].

In detail, the results show that performance expectancy—the perceived usefulness of the technology—had a strong positive effect on behavioral intention in all four countries. This finding suggests that the more respondents believe generative AI is useful to manage health-related questions, the more they will use it. Thus, if public health stakeholders or developers aim to encourage responsible AI use, they should emphasize the tangible benefits of generative AI, such as 24/7 availability, rapid response times, and the potential for personalized information. Perceived usefulness may also be fostered when individuals try out generative AI for the first time, that is, they learn that they can benefit from the technology.

At the same time, our study challenges established UTAUT2 assumptions. Effort expectancy, often seen as central to technology adoption, was not a relevant factor—possibly due to the intuitive nature of generative AI tools and the ubiquity of basic digital skills [61]. Using generative AI does not require any specific background knowledge beyond opening a webpage. Since online search engines are already the most frequently used health source, the basic skills needed for generative AI are widely present, potentially rendering effort expectancy less decisive.

Taken together, this emerging pattern—the strong effect of performance expectancy and the null effect of effort expectancy—underscores the distinction between usefulness and usability, which are closely related but not identical [62]. Usability refers to the ease of interacting with a system (eg, ease of learning and error prevention), whereas usefulness (utility) captures whether the system provides the functions and information that users actually need. Our findings suggest that in health contexts, utility is the decisive factor: people intend to use generative AI if its outputs are perceived as useful, while usability-related aspects appear less influential.

Importantly, this does not mean that barriers to adoption are absent. Rather, our findings show that they lie not in usability but in facilitating conditions—the structural and contextual resources that enable technology use. Across all countries, the availability of digital infrastructure, devices, and basic knowledge significantly shaped behavioral intention. In other words, while generative AI may be easy to use once accessed, unequal access to the necessary resources continues to pose a substantial adoption barrier. Consequently, facilitating conditions emerge as a key digital health equity concern [4]. Without adequate access, disadvantaged populations may be excluded from benefiting from generative AI, meaning that the technology risks widening rather than narrowing the digital divide in health information–seeking.

We also found that social influence—an important predictor in other studies on AI uptake [18,24]—did not play a meaningful role in shaping behavioral intention. This suggests that health-related information search is a rather personal topic, and that individuals may not always be willing to disclose what kind of information they are looking for. As a result, the intention to use generative AI for health information–seeking is largely independent of peer opinions or social norms.

In contrast, habit consistently predicted behavioral intention across all countries. From this finding, we may conclude that generative AI use for health information is likely to occur automatically, similar to how people use search engines. When individuals feel familiar with a technology, they are more likely to rely on it without conscious deliberation. However, this finding should be interpreted with caution, as the majority of participants had never used generative AI for health purposes. Much of the variance in habit may therefore reflect mere use versus nonuse. Accordingly, variables capturing initial adoption should be clearly distinguished from those measuring habit.

By including health literacy and health status as additional predictors, our study adds a novel dimension to existing research. In contrast to studies showing direct paths between these constructs and online health information–seeking [37,40,46], we found no such association for AI health information–seeking. However, each of these findings carries different implications. First, the absence of a significant association between health literacy and intention indicates that individuals' ability to understand and evaluate health information was not related to whether they reported turning to generative AI. This finding may suggest that the use of such tools is driven less by informed decision-making and more by general curiosity or interest in new technologies. Importantly, this raises concerns: people with lower health literacy may be just as likely to consult generative AI as those with higher health literacy—despite being less equipped to critically assess its outputs. Given the known risk of AI hallucinations—fabricated or inaccurate information presented in a confident tone [63]—this could lead to misinformation and, in the worst case,

harmful health decisions, as users with limited health literacy might find it difficult to distinguish between reliable and misleading content.

Second, the lack of an association between self-reported health status and intention suggests that the current use of generative AI is not primarily driven by medical need or urgency. People do not seem more likely to consult generative AI when facing a health problem; rather, usage may occur proactively or even recreationally. This challenges assumptions that such tools are primarily used in response to a health issue, and it underscores the importance of understanding user motivations beyond immediate health concerns.

Importantly, these patterns were largely consistent across all 4 countries, as confirmed by the measurement-invariant structural model. This cross-national consistency suggests that the psychological drivers of generative AI adoption in health contexts may transcend national boundaries and cultural differences, pointing to a universal set of adoption mechanisms.

Limitations

Several limitations should be acknowledged. First, due to the cross-sectional nature of this study, no causal conclusions can be drawn. Future research should therefore aim to replicate these findings using experimental or longitudinal designs. Second, we relied on self-reported data, which may be subject to social desirability bias. The use of behavioral data is thus warranted to validate these findings. Third, including additional predictors—such as individual differences or specific concerns—could provide deeper insights into the use of generative AI. Fourth, our comparative findings are based on data from only 4 countries, which limits the ability to conduct multilevel analyses. Also, as in all cross-sectional research, there is a risk of unmeasured third variables. In particular, we did not include AI trust and perceived AI risk. However, these constructs are conceptually close to performance expectancy, as trust reduces uncertainty about the system's outputs and thereby enhances expected performance gains, whereas perceived risk erodes expected utility. In this sense, they are likely to be partially reflected in the performance expectancy construct already included in our model. That said, and highlighting that our model explains around 80% of the variance, trust and perceived risk could still suppress some of the predictors we have modeled. Thus, future research should include additional constructs outside the UTAUT2 framework [64]. Finally, health status was measured with a single self-rated item. While single-item measures of subjective health may not capture the full complexity of an individual's medical condition, this approach is widely used in demographic and population health research. Prior work has demonstrated that the self-rated health item is a valid and reliable indicator, predicting key outcomes such as mortality, use of health services, and health expenditures in large-scale surveys [65]. Nevertheless, we acknowledge that a more fine-grained measure (eg, including specific chronic conditions or severity indices) could have provided additional insights, and future studies may benefit from applying such extended health measures.

Conclusions

This study applied the UTAUT2 model to investigate the factors that drive the use of generative AI for health information–seeking. Although overall usage remains limited, our findings show that performance expectancy, facilitating conditions, habit, and hedonic motivation are positively associated with behavioral intentions. These patterns, observed across all 4 countries—Austria, Denmark, France, and Serbia—suggest that current users of generative AI are likely to be early adopters: individuals who are tech-savvy, curious, and open to innovation. This aligns with the Rogers Diffusion of Innovations theory, which conceptualizes adoption as a gradual process beginning with a small, innovation-oriented segment of the population.

The lack of significant effects for effort expectancy and social influence across all countries reinforces this interpretation: early adopters tend to base their decisions on personal evaluations rather than external opinions and are rarely deterred by usability concerns. Furthermore, the fact that behavioral intention was unrelated to health status or health literacy underscores that current usage is not driven by acute medical need or advanced health literacy, but rather by interest, convenience, and technological exploration.

The cross-national consistency of these findings is particularly striking. Despite differences in health care systems, digital infrastructures, and culture, the same psychological and contextual factors influenced generative AI use in all countries surveyed. This suggests a shared adoption logic that transcends national boundaries—at least in the early stages of diffusion.

Looking ahead, these insights help illuminate how generative AI might transition from a niche tool to a widely used resource. As the technology becomes more embedded in everyday life, broader segments of the population—the so-called early and late majority—will likely demand stronger assurances of trustworthiness, safety, and added value. To enable responsible and inclusive adoption, it is therefore crucial to reduce digital access barriers, enhance transparency, and implement safeguards against health misinformation, especially for users with limited health literacy.

From a practical perspective, our findings suggest that communication strategies aiming to promote generative AI for health purposes should emphasize concrete benefits, ease of access, and even enjoyment. Rather than exclusively targeting individuals with chronic or urgent health needs, positioning generative AI as an engaging, low-barrier tool may broaden its appeal—reaching users who might otherwise be disengaged from traditional health information sources.

In sum, generative AI holds significant potential as a future health information resource—but its trajectory will depend on how well we understand and support the evolving needs of its users across different adoption phases and contexts.

Abstract

Background: Artificial intelligence (AI)–enabled devices are increasingly used in health care. However, there has been limited research on patients' informational preferences, including which elements of AI device labeling enhance patient understanding, trust, and acceptance. Clear and effective patient-facing communication is essential to address patient concerns and support informed decision-making regarding AI-enabled care.

Objective: We evaluated 3 aims using simulated AI device labels in a cardiovascular context. First, we identified key information elements that influence patient trust and acceptance of an AI device. Second, we examined how these effects varied based on patient characteristics. Third, we explored how patients evaluated informational content of AI labels and their perceived effectiveness of the AI labels in informing decision-making about the use of AI device, building trust in the device, and shaping their intention to use it in their health care.

Methods: We recruited 340 US patients from ResearchMatch.org to participate in a web-based survey that contained 2 experiments. In the discrete choice experiment, participants indicated preferences in terms of trust and acceptance regarding 16 pairs of simulated AI device labels that varied across 8 types of information needs identified in our previous qualitative work. In the single profile factorial experiment, participants evaluated 4 randomly assigned label prototypes regarding the label's legibility, comprehensibility, information overload, credibility, and perceived effectiveness in informing about the AI device, as well as participants' trust in the AI device and intention to use the device in their health care. Data were analyzed using mixed effects binary or ordinal logistic regression.

Results: The discrete choice experiment showed that information about regulatory approval, high device performance, provider oversight, and AI's value added to usual care significantly increased the likelihood of patient trust by 14.1% - 19.3% and acceptance by 13.3% - 17.9%. Subgroup analyses revealed variations based on patient characteristics such as familiarity with AI, health literacy, and recency of last medical checkup. The single profile factorial experiment showed that patients reported good label comprehension, and that information about provider oversight, regulatory approval, device performance, and AI's added value improved perceived credibility and effectiveness of the AI label (odds ratio [OR] range: 1.35 - 2.05), reduced doubts in the AI device (OR range: 0.61 - 0.77), and increased trust and intention to use the AI device (OR range: 1.47 - 1.73). However, information about data privacy and safety management protocols was less influential.

Conclusions: Patients value information about an AI device's performance, provider oversight, regulatory status, and added value during decision-making. Providing transparent, easily understandable information about these aspects is critical to support patient determinations of trust and acceptance of AI-enabled health care. Information elements' impact on patient trust and acceptance varies by patient characteristics, highlighting the need for a tailored approach to address the concerns of diverse patient groups about AI in health care.

KEYWORDS

artificial intelligence; health communication; health decision-making; patient preference; patient-centered care; AI labeling

Introduction

Artificial intelligence (AI) and machine learning (ML) are increasingly being integrated into health care products and services due to their potential to enhance diagnostic accuracy, improve treatment planning, increase efficiency of health care systems, reduce costs, and ultimately improve patient outcomes [1-3]. Cardiology, in particular, has seen a surge in AI/ML-enabled clinical tools, aiding clinical decision-making across the care spectrum [4-6]. While there are many promising applications of AI/ML in health care, effective approaches to inform patients about these technologies have not been established. This hinders informed patient decision-making and public trust in AI/ML-enabled medical devices.

Recent research on patient perspectives regarding AI in health care indicates that patients are generally receptive to the use of AI in their health care, but that certain conditions must be met [7,8]. Patients want clear and accessible information about how AI is used in their care, its benefits and limitations, how decisions are made, and the roles of AI and health care providers in AI-informed decisions [9-11]. Patients value human oversight over AI and want to ensure that health care decisions are ultimately made by a human [12-14]. Patients also want assurance that their data are protected and used responsibly [15-17]. Finally, they want AI to be unbiased in its training data and outputs and desire equitable access to AI applications to prevent against underrepresentation of minoritized and disadvantaged population groups in AI research [18-20]. These nuances underscore the complexity of information needed to support informed patient use of AI and effective communication between patients, clinicians, and health systems regarding the use of AI in care.

Recent efforts to understand how to communicate transparently about AI in health care have focused on clinical and technical audiences. As a result, there is growing research on best practices for transparent and standardized documentation, reporting, and communication of AI/ML models for clinicians [21-25]. However, research efforts focusing on identifying and prioritizing patients' specific information needs remain limited [26-28]. It is important to note that it is not always feasible or desirable to present all information about an AI-enabled medical device with equal prominence in patient-facing communication. In practice, patient education materials, including labels, decision aids, and informed consents, must balance completeness with cognitive load. Overwhelming patients with too much information can reduce comprehension, informed decision-making, and psychological well-being [29-32]. Similarly, patient-facing labels for AI-enabled medical devices are highly constrained by space and by the cognitive burden on users [33-35]. Thoughtful organization and prioritization of information are key to avoiding information overload and making it easier for patients to grasp the implications of AI in their care [36]. Thus, to ensure patient safety, autonomy, and informed decision-making, it is essential to understand patients' core information needs and present information in a transparent and accessible manner.

This study is part of a broader research project aimed at bridging the knowledge gap in effective communication about AI in health care by identifying the essential components of patient-facing information labels for these technologies. Information labels are structured summaries that provide users with key details about a device or technology, including its purpose, functionality, benefits, limitations, and risks [37]. The overarching goal of this project is to provide empirical evidence to inform strategies and regulatory policies that facilitate patient-centered adoption of AI in health care. For the purposes of our study, an AI device refers to a cardiology device equipped with an ML model designed to assist in decision-making across the continuum of care. Prior to this study, we conducted qualitative research, including a rapid literature review and 3 qualitative studies with patients and clinicians, to identify core information needs that contribute to patient and clinician trust in AI devices in health care, focusing on their use in diagnosing, treating, and monitoring cardiovascular conditions [34,38,39]. This work identified eight elements reported by patients as influential to their trust in the AI device, including (1) data privacy and security, (2) performance, (3) AI's added value compared with usual care, (4) regulatory approval, (5) expert endorsement, (6) generalizability and limitations, (7) device safety, and (8) health care provider (HCP) oversight. However, no evidence-based guidance currently exists on how to prioritize among them in patient-facing communication. Understanding what information patients prioritize allows AI developers, health care systems, and regulators to emphasize the most critical information elements while ensuring transparency, clarity, and comprehension. To address this knowledge gap, this study used 2 survey experiments in which participants evaluated a short, hypothetical scenario ("vignette") featuring AI label prototypes to achieve the following specific aims: (1) determine the relative importance of various information elements on patient trust and acceptance of an AI device in cardiology; (2) examine how the effects of information elements vary due to differences in patient characteristics, including familiarity with AI, medical mistrust, health literacy, and sociodemographic characteristics; and (3) assess patients' evaluation of the informational content of the AI label prototypes, perceived effectiveness of the AI label prototypes in informing decision-making about the use of the AI device, trust in the device, and intention to use the device in their health care.

Methods

Clinical Context for Experimental Vignettes

We selected a hypothetical AI-enabled smartwatch and smartphone app designed to detect potential episodes of atrial fibrillation as the AI device example for our experimental vignettes. This choice was informed by input from our clinical and regulatory collaborators as well as feedback from both clinicians and patients during our formative qualitative research. The clinical problem and AI technology in the vignette were deemed appropriate by clinician collaborators given its direct relevance to patients and accessibility to a broad population. In addition, during formative qualitative research, this AI device prompted rich discussion among patient and clinician participants, underscoring its relevance and making it a strong

candidate for use as the clinical context for the experimental vignettes.

Experimental Design

Overview

To robustly examine how AI label informational content influences patient perceptions and decision-making, we conducted 2 vignette experiments through a web-based survey. The use of vignette experiments is a widely accepted approach in health communication and medical decision science research [40-43]. This method is especially useful when studying emerging technologies for which standardized communication practices are not yet established. The vignette experiment approach offers important advantages over simply asking participants to rank or rate the importance of various information elements [41]. By presenting information elements in concrete vignettes, we create a context that more closely resembles how decisions are made in real-world health care settings. It also allowed us to control for confounding factors and precisely isolate the causal effect of each information element on psychological and behavioral outcomes such as trust and acceptance. Moreover, simply asking participants what is important to them is highly susceptible to social desirability bias; by examining how participants respond to concrete situations, the vignette experiment approach minimizes social desirability bias and offers a clearer picture of the factors that shape patient preferences and decisions. To capture both patient priorities under conditions requiring trade-offs and their evaluations of AI label informational content in a more reflective context, we implemented 2 complementary vignette experiments: a discrete choice experiment (DCE) and a single profile factorial experiment (SPFE).

DCEs are being increasingly used in medical and health services research to systematically examine people's preferences regarding health care services by assessing how much they value the specific attributes of the service [44-47]. In a typical DCE, participants are presented with 2 or more discrete hypothetical alternatives (eg, treatment A or treatment B), each consisting of multiple attributes with varying values. By analyzing the choices participants make among these alternatives, researchers can estimate the contribution of each attribute to decision-making. In this study, by observing how participants make trade-offs when choosing between competing label configurations, the DCE allowed us to (1) determine the relative importance of different information elements influencing patient trust and acceptance of an AI device and (2) examine how the effects of information elements vary due to differences in patient characteristics. This method uncovers underlying priorities and preferences that might not be evident when participants simply rate or rank information elements individually.

In contrast, the SPFE asked participants to review AI label prototypes one at a time and respond to a series of rating measures on perceived comprehension, cognitive effort, effectiveness in supporting decision-making about the AI device, trust in the device, and intention to use it in their health care. This method was chosen for 2 key reasons. First, the single profile design mirrors real-world patient decision-making regarding AI device use in health care more closely as in real life, patients typically consider a single device rather than make direct comparisons among alternatives. Second, the SPFE allows rating-based outcome measures (eg, 1=very unlikely to accept to 5=very likely to accept) that provide more direct and fine-grained insight into participants' evaluation of the label prototypes as well as the psychological and behavioral impacts of the information elements. This dual-experiment approach allows us to gain a richer and more nuanced understanding of patient preferences regarding AI device labeling and the factors that are critical for effective communication and adoption of AI technologies in health care.

For these experiments, we created AI label prototypes based on the hypothetical AI device that varied on the following eight informational elements: (1) data privacy and security, (2) performance, (3) AI's added value, (4) regulatory approval, (5) expert endorsement, (6) generalizability and limitations, (7) device safety, and (8) HCP oversight. We varied the informational content along these 8 elements based on prior qualitative research conducted with clinicians and patients, which identified these as important information needs influencing patient trust in AI [38,39]. For experimental design efficiency, each of these elements has 2 levels (ie, 2 variations): either in 2 different versions or as either present or absent. See Table 1 for additional details about these 8 elements.

Table . Label information elements and levels.

Elements	Definitions	Levels and examples
Elements with varying levels		
X1. Data privacy and security	What patient data are collected by AI[a]; how the patient data are being collected, stored, and shared.	Level 1: opt-in data sharing; level 2: opt-out data sharing
X2. Performance	True-positive: device accuracy when the patient DOES have A-fib[b]; true-negative: device accuracy when the patient DOES NOT have A-fib	Level 1: high performance; level 2: low performance
X3. AI's added value	Improvement in patient care due to the AI-enabled device; effectiveness of the AI-enabled device in comparison with non–AI-enabled tests or conventional health care.	Level 1: information absent; level 2: information present
X4. Regulatory approval	Whether the AI device received clearance, approval, or certification from a regulatory body regarding its safety and/or effectiveness.	Level 1: information absent; level 2: information present
X5. Expert endorsement	Endorsement of the device for safety and effectiveness issued by medical experts such as health care providers.	Level 1: information absent; level 2: information present
X6. Generalizability and limitations	How generalizable is the device to patients with varying demographics and characteristics; what are the conditions or contexts where the device should not be used?	Level 1: internal validation; level 2: external validation
X7. Device safety	What are the risks of malfunction, bugs, and errors from the AI device (both the AI algorithm and the supporting software)? How will these risks be managed?	Level 1: proactive auditing; level 2: reactive auditing
X8. HCP[c] oversight	Whether the results or decisions from the AI-enabled device have been verified by your health care provider.	Level 1: information absent; level 2: information present
Elements to be displayed in the same way across all labels		
1. Purpose	What is the purpose of the AI device, for what types of patients and conditions, when and in what context should the device be used?	"This AI-enabled smartwatch and smartphone app is designed to identify a potential episode of atrial fibrillation (A-fib). A-fib is an irregular and often very rapid heart rhythm that can lead to blood clots in the heart."
2. Directions	How to use the AI device, recommended actions for patients, how to interpret results (eg, what is "normal" for pt. like me); what warrants discussion with provider; next steps by AI if any (eg, AI will automatically alert HCP)	"- Wear your smartwatch - It will provide an alert when it detects a potential episode of A-fib - Talk to your doctor if you received an alert from the app"

[a]AI: artificial intelligence.

[b]A-fib: atrial fibrillation.

[c]HCP: health care provider.

Discrete Choice Experiment

We used a fractional factorial design to rate a selection of possible alternatives because a full factorial design (2^8 alternatives) would not be feasible to implement. To minimize the cognitive burden for participants and maximize statistical efficiency, each choice task consisted of 2 alternatives, and each participant was asked to consider 16 choice sets, comprising 32 unique label prototypes in total [48]. We used the R package idefix [49] to select an optimal design based on D-efficiency criterion, a commonly used metric for efficient experimental design construction to maximize statistical efficiency and precision [50-52]. Multimedia Appendix 1 summarizes the choice sets. Figure 1 shows an example choice set.

Figure 1. Example choice set for the discrete choice experiment. A-fib: atrial fibrillation; AI: artificial intelligence.

Name	A-Fib Watch
Purpose	This AI-enabled smartwatch and smartphone app is designed to identify a potential episode of atrial fibrillation (A-fib). A-fib is an irregular and often very rapid heart rhythm that can lead to blood clots in the heart.
Directions	• Wear your smartwatch • It will provide an alert when it detects a potential episode of A-fib • Talk to your doctor if you received an alert from the app

	Device A	Device B
Data Privacy and Security	The information you provide in the app will be used to improve the tool. Your deidentified data will be shared unless you visit the settings menu to turn off the sharing option.	The information you provide in the app will be used to improve the tool. You will be asked to opt into sharing your deidentified data when you first open the app.
Performance True-positive: device accuracy when the patient DOES have A-fib True-negative: device accuracy when the patient DOES NOT have A-fib	 90% (9 out of 10) people with A-fib will be correctly identified as having A-fib.  80% (8 out of 10) people without A-fib will be correctly identified as NOT having A-fib.	 80% (8 out of 10) people with A-fib will be correctly identified as having A-fib.  70% (7 out of 10) people without A-fib will be correctly identified as NOT having A-fib.
Added value		Appropriate use of the tool, response to alerts, and treatment may reduce risk of heart failure and stroke.
Regulatory approval	This device acquired regulatory authorization, which means that this device is as safe and effective as other regulated device(s).	
Expert endorsement		A panel of doctors has reviewed and endorsed this device for use.
Validation	The clinic where you receive care has tested and validated this device.	An independent research lab unaffiliated with the clinic where you receive care has tested and evaluated this device.
Tool safety	This device will be audited by developer team every 4 weeks.	If doctors or patients report any issues with the device, the developer team will assess and fix them promptly.
Oversight from your doctor	Your doctor will review the AI results along with your medical history.	

Single Profile Factorial Experiment

The SPFE used a 2^{8-3} resolution IV fractional factorial design to evaluate the label prototypes. We used the R package FrF2 [53] to generate the 32 experimental conditions (Multimedia Appendix 2). Each participant was randomly assigned to evaluate 4 label prototypes displayed in a randomized order. After viewing each label prototype, participants answered a series of questions on label evaluation, AI trust, and behavioral intention using 5-point Likert-style scales. Figure 2 shows an example label prototype.

Figure 2. Example label prototype for the single profile factorial experiment. AI: artificial intelligence.

Name	A-fib Watch
Purpose	This AI-enabled smartwatch and smartphone app is designed to identify a potential episode of atrial fibrillation (A-fib). A-fib is an irregular and often very rapid heart rhythm that can lead to blood clots in the heart.
Directions	• Wear your smartwatch • It will provide an alert when it detects a potential episode of A-fib • Talk to your doctor if you received an alert from the app
Data Privacy and Security	The information you provide in the app will be used to improve the tool. You will be asked to opt into sharing your deidentified data when you first open the app.
Performance True-positive: device accuracy when the patient DOES have A-fib	 80% (8 out of 10) people with A-fib will be correctly identified as having A-fib.
True-negative: device accuracy when the patient DOES NOT have A-fib	 70% (7 out of 10) people without A-fib will be correctly identified as NOT having A-fib.
Added value	Appropriate use of the tool, response to alerts, and treatment may reduce risk of heart failure and stroke.
Regulatory approval	This device acquired regulatory authorization, which means that this device is as safe and effective as other regulated device(s).
Expert endorsement	A panel of doctors has reviewed and endorsed this device for use.
Validation	The clinic where you receive care has tested and validated this device.
Tool safety	This device will be audited by the developer team every 4 weeks.
Oversight from your doctor	

Pilot Testing

We conducted cognitive interviews (via Zoom [Zoom Communications, Inc]; 30‐45 minutes in length) with 4 participants to assess whether the information elements, variations, presentation, and survey questions were easy to understand and meaningful to participants. The interviewer shared the web-based survey with participants via shared screen and asked participants to verbally answer the survey questions and share their thought processes. The interviewer also asked participants to explain the information elements in their own words. The interviews were audio-recorded, and the interviewer took notes on reflections and observations. We revised the survey questionnaire based on interview notes.

Following the cognitive interviews, we pilot tested the revised Qualtrics web-based survey with 30 participants to examine the feasibility and data quality of the 2 vignette experiments. The vignette experiments consisted of 3 sections: DCE, SPFE, and participant characteristics. The presentation order of the 2 experiments was randomized to mitigate order effect. For the DCE, participants first completed a warm-up task to familiarize them with the DCE procedure. They were then given the following instructions for the main DCE on AI information labeling:

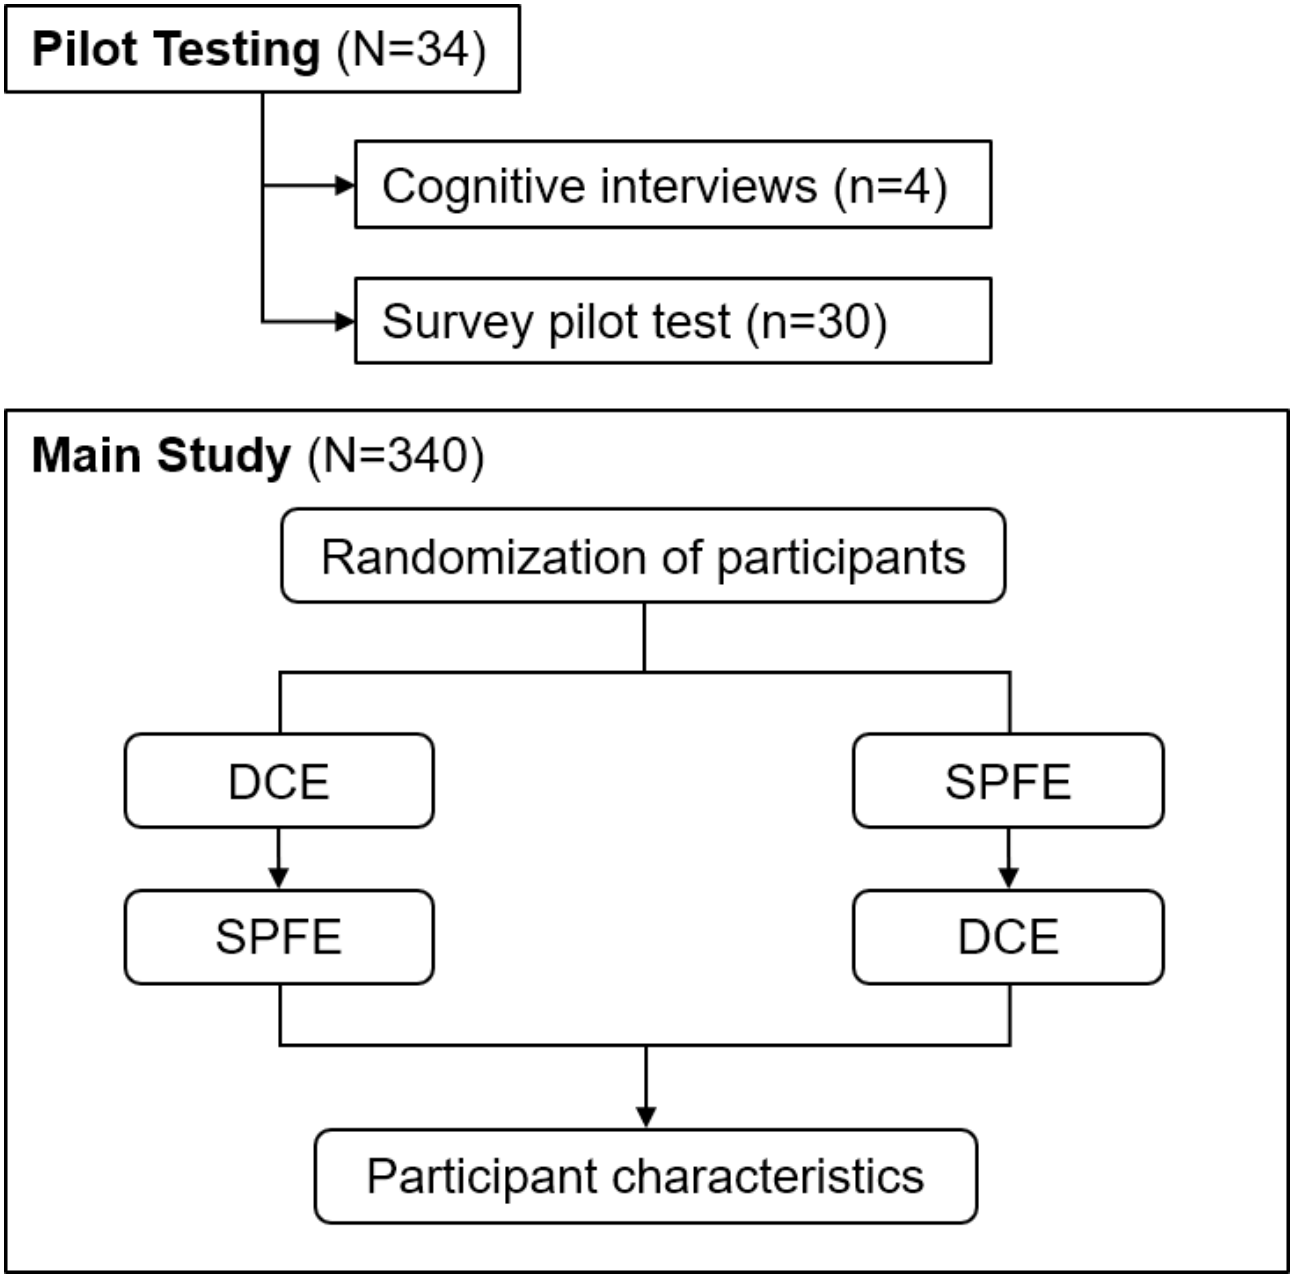
> *Next, you will be asked to choose between 2 AI-enabled device options with similar or different characteristics.*
>
> *AI-enabled devices in health care are medical devices that use AI and specifically the subset of AI known as machine learning. Some examples of AI-enabled devices in health care include smartwatches that can monitor your heart rate for problems, smart robots that guide surgeries, or AI programs that can provide information to a physician to help with diagnosis, among many other types of technologies.*
>
> *Imagine that your health care provider recommended you using an AI-enabled smartwatch or smartphone app to help track your cardiac functions and identify potential episodes of atrial fibrillation. You were given 2 options. The 2 options were developed by the same company and provide the same functions. Please consider the 2 options below and choose the device you prefer the most.*

Participants then proceeded to complete 18 choice tasks, including 16 experimental choice tasks and 2 validity check tasks. The order of the 16 experimental choice tasks was randomized.

In the SPFE, participants were randomly assigned to evaluate 4 of 32 label prototypes, presented in a random order. They were given the following instructions at the beginning of the

section, "In this section, you will see 4 information labels about AI-enabled devices one at a time. After reading each information label, you will be asked a series of questions about your opinions on the label." For each label prototype, participants answered questions on label evaluation, trust in the AI device, and intention to use the device in health care. After completing the experiments, participants provided information on their sociodemographic and health care characteristics. Figure 3 summarizes study procedure.

Figure 3. Study procedure. DCE: discrete choice experiment: SPFE: single profile factorial experiment.



Main Study

For the main study, participants completed the finalized web-based Qualtrics survey, which incorporated refinements from the pilot phase. The survey experiments followed the same procedures described in the "Pilot Testing" section, and the randomization procedure and data collection methods and materials remained consistent with the piloted version.

Measures

Label preference was measured through participants selecting their preferred label prototype in a choice task based on trust ("Which device would you trust more?") and acceptance ("If you were given the option, which device would you be more likely to use in your health care?").

Label evaluation included six items on a 5-point Likert scale (1=strongly disagree to 5=strongly agree) that assessed (1) legibility ("This label is easy to read"), (2) comprehensibility ("This label is easy to understand"), (3) information overload ("Reading this label is too mentally demanding for me"), (4) credibility ("I trust the information on this label"), and (5) effectiveness of the label in informing patients about the AI device ("This label gives me all the information I need about

the AI device" and "This label helps me decide whether the AI device should be used in my care").

Participants' trust in the AI device was measured with three items on a 5-point Likert scale (1=strongly disagree to 5=strongly agree), including (1) "I would trust the results from this AI device," (2) "I would have doubts about this AI device," and (3) "I would seek a second opinion." Participants' likelihood of using the device was assessed on a 5-point Likert-type scale (1=very unlikely to 5=very likely). In addition, participants provided feedback on each label prototype through an optional open-ended question.

Participant characteristics were measured in terms of the need for cognition, which reflects motivation to process complex information and engage in effortful thinking [54,55], familiarity with AI, medical mistrust [56], health literacy [57-59], last routine medical checkup, health insurance coverage, and demographics (eg, age, gender, race or ethnicity, education level, and household financial status) [60].

Sample Size

We conducted an a priori power analysis to estimate the smallest sample size required for the main study. Because the DCE is more statistically efficient than the SPFE, we based our estimation on the SPFE design. The analysis showed that a sample of 288 participants would allow us to detect a main effect with a standardized regression coefficient of 0.167 or higher with 80% power at an α level of .05, which is sufficient for the DCE [61]. The total sample size needed for the pilot and main studies is 323. We planned to recruit 350 participants in total to account for attrition and incomplete responses.

Recruitment

We recruited participants from ResearchMatch [62], a national health volunteer registry that was created by several academic institutions and supported by the US National Institutes of Health as part of the Clinical Translational Science Award program. ResearchMatch has a large population of volunteers who have consented to be contacted by researchers about health studies for which they may be eligible. Inclusion criteria for this study include being an adult aged 18 years or older, being proficient in reading and writing in English, and having had a primary care or cardiology care visit within the past 3 years. We oversampled racial and ethnic minority patients to ensure that their representation was comparable with that of non-Hispanic White patients. This supported our ability to draw meaningful conclusions about diverse patient populations while accounting for historical underrepresentation in health research. Participants received a message describing our study via the ResearchMatch platform, where they could then decide to opt in to be contacted and receive a link to our survey. ResearchMatch provided contact information (ie, name and email address) for participants who opted in. Participants who opted in received an email invitation with a link to complete the online survey.

Ethical Considerations

Review and approval for this study and all procedures were obtained from the Mayo Clinic Institutional Review Board (IRB; 21-012302). The IRB granted a waiver of written documentation of informed consent. The first page of the survey displayed an IRB-approved informed consent cover letter which provided information about the study, including its purpose, the investigator, the estimated length of the survey, data storage procedures, and contact information for the study team and the Mayo Clinic IRB. Participants were instructed to review this information and were informed that by proceeding to the survey, they were providing informed consent. No personal information was collected or stored with the survey responses. Study data were secured on institutionally approved and controlled access electronic storage. Participants received a US $10 gift card as remuneration for completing the survey.

Statistical Analysis

We used mixed effects binary logistic regression to analyze the data from the DCE. Our analysis focused on how different information factors influenced the probability of individuals trusting and accepting the AI device in their health care. We included individual-specific intercepts to account for heterogeneity in individual preferences. We reported average marginal effect (AME), which shows the average change in predicted probabilities (percentage point increase or decrease) of the outcome variable across all participants when moving from one level of the information factor to another, while holding all other variables constant. In addition, we conducted subgroup analyses to explore how the effect of top preferred information factors on patient trust and acceptance of the AI device varied based on participants' AI familiarity, openness toward medical AI, health literacy, medical mistrust, and sociodemographic characteristics.

We used mixed effects ordinal logistic regression (cumulative link mixed model) to analyze the data from the SPFE. Our focus was on how different information factors influenced participants' evaluation of the AI label's legibility, comprehensibility, information overload, information credibility, perceived effectiveness in informing about the AI device, trust in the AI device, and intention to use it in health care. We included individual-specific intercepts to account for repeated measurements within individuals. For models on AI device trust and intention to use, we adjusted for participants' evaluation of the AI label's legibility, comprehensibility, information overload, information credibility, and perceived effectiveness in informing about the AI device. We used "flexible" thresholds in our models to allow the distance between the 4 cut points of the 5-point scales to vary freely. We reported odds ratios (ORs) for the effect of information factors.

All analyses were performed in R (version 4.3.1; R Core Team) [63]. "tidyverse" [64] was used for data wrangling and visualization, "lme4" [65] was used for fitting mixed effects binary logistic models, "ordinal" [66] was used for fitting mixed effects ordinal logistic models, and "marginaleffects" [67] was used for calculating AME.

Reporting Guidelines

This study is reported in accordance with the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) [68].

Results

Participant Characteristics

A total of 340 participants who completed at least 75% of the survey questions were included in the analysis. Table 2 summarizes participant characteristics. Participants were aged 18 - 34 (122/328, 37.19%), 35 - 54 (114/328, 34.75%), and 55 years or older (92/328, 28.05%). Nearly half were women (158/326, 48.47%), 48.77% (159/326) were men, and 2.76% (9/326) identifying as nonbinary or another gender. The majority were non-Hispanic White (206/327, 63.00%), followed by Black or African American (76/327, 23.24%), Hispanic or Latinx (44/327, 13.46%), Asian or Asian American (30/327, 9.17%), and Native American or Indigenous (13/327, 3.98%). Regarding education, 49.09% (161/328) had a bachelor's degree, 28.96% (95/328) held a master's degree or higher, and 20.73% (68/328) had some college or an associate degree. Financially, 53.54% (174/325) reported having disposable income after paying bills, 29.85% (97/325) had little spare money, and 16.62% (54/325) struggled to pay bills.

Table . Participant characteristics (N=340).

Characteristics	Values, n (%)
Age (years)	
18 - 24	18 (5.49)
25 - 34	104 (31.71)
35 - 44	72 (21.95)
45 - 54	42 (12.80)
55 - 64	52 (15.85)
≥65	40 (12.20)
Missing	12 (3.52)
Gender	
Man	159 (48.77)
Woman	158 (48.47)
Nonbinary/other	9 (2.76)
Missing	14 (4.12)
Race and ethnicity[a]	
White/Caucasian	206 (63.00)
Black/African American	76 (23.24)
Hispanic/Latina/Latino	44 (13.46)
Asian/Asian American	30 (9.17)
Native American/American Indian/Alaska Native/Indigenous	13 (3.98)
Middle Eastern/North African/Arab American	8 (2.45)
Native Hawaiian/Pacific Islander	2 (0.61)
Other race	6 (1.83)
Missing	13 (3.82)
Education level	
High school or less	4 (1.22)
Some college or associate's degree	68 (20.73)
Bachelor's degree	161 (49.09)
Master's degree or higher	95 (28.96)
Missing	12 (3.52)
Perceived household financial status	
After paying the bills, I still have enough money for special things that I want	174 (53.54)
Have enough money to pay the bills but little spare money to buy extra or special things	97 (29.85)
Have enough money to pay the bills but only because I have cut back on things	28 (8.62)
Having difficulty paying the bills, no matter what I do	26 (8.00)
Missing	15 (4.41)
Health insurance coverage	
Private	207 (65.51)
Public	103 (32.59)
No insurance	6 (1.90)
Missing	24 (7.06)

Characteristics	Values, n (%)
Last routine checkup	
Less than a year ago	212 (66.88)
>1 year, <2 years	53 (16.72)
>2 years, <5 years	41 (12.93)
≥5	6 (1.89)
Never had routine checkup	5 (1.58)
Missing	23 (6.76)

[a]The percentages may add over 100% because participants can select multiple races.

Most participants had private health insurance (207/316, 65.51%), while 32.59% (103/316) had public coverage. In addition, 66.88% (212/317) had a routine medical checkup within the past year.

DCE Results

Importance of the Information Factors for Patients' Trust in the AI Device

Figure 4 visualizes the relative importance of the information factors for participants' trust in the AI device. The 4 information factors that produced the greatest increase in participants' trust in AI devices were inclusion of information about regulatory approval (AME=19.34%, 95% CI 15.97%-22.72%), information about high versus low performance (AME=16.62%, 95% CI 14.40%-18.85%), inclusion of information about HCP oversight (AME=15.50%, 95% CI 12.56%-18.44%), and inclusion of information about the AI's added value compared with usual care (14.06% increase, 95% CI 12.16%-15.96%). Including information about opt-in (vs opt-out) data privacy protocol, expert endorsement (vs information absent), and information about external (vs internal) validation less strongly increased the probability of trusting the AI device (9%, 7.32%, and 2.76%, respectively). Effect of information about proactive versus reactive device safety management protocol on participants' trust was not statistically significant (Table 3).

Figure 4. Difference in probability of AI device being trusted by attribute level. AI: artificial intelligence; HCP: health care provider; Info: information; TPR: true-positive rate.

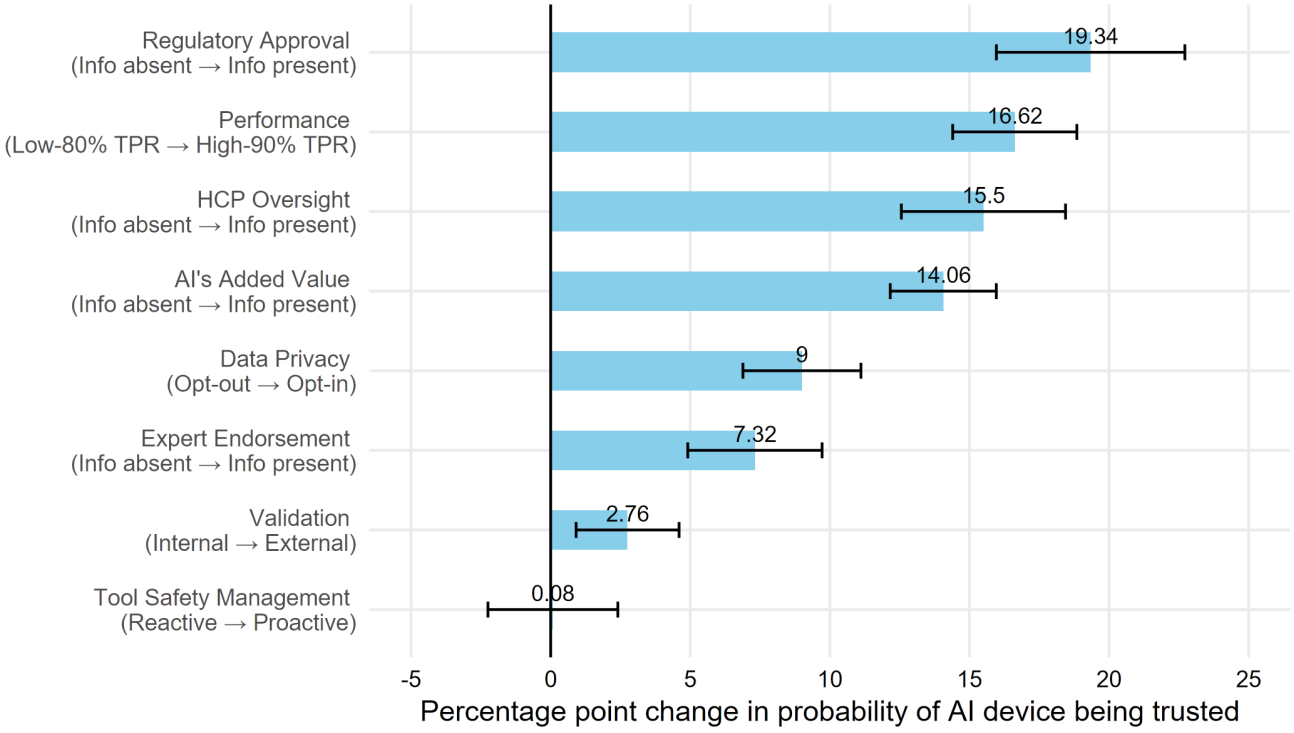


Table . Effects of information elements on the probability of the artificial intelligence device being trusted and accepted.

	Trust	Acceptance
	AME[a] (95% CI), percentage points	AME[a] (95% CI), percentage points
Added value (information absent→information present)	14.06 (12.16 to 15.96)	15.58 (13.28 to 17.88)
Data privacy (opt out→opt in)	9.00 (6.89 to 11.11)	10.92 (8.30 to 13.53)
Expert endorsement (information absent→information present)	7.32 (4.91 to 9.72)	9.03 (6.73 to 11.32)
HCP[b] oversight (information absent→information present)	15.50 (12.56 to 18.44)	17.86 (14.98 to 20.75)
Performance (low→high)	16.62 (14.40 to 18.85)	14.85 (12.65 to 17.06)
Regulatory approval (information absent→information present)	19.34 (15.97 to 22.72)	13.29 (9.96 to 16.63)
Device safety (reactive→proactive)	0.08 (–2.25 to 2.41)	0.74 (–1.82 to 3.29)
Validation (internal→external)	2.76 (0.91 to 4.60)	3.64 (1.56 to 5.72)

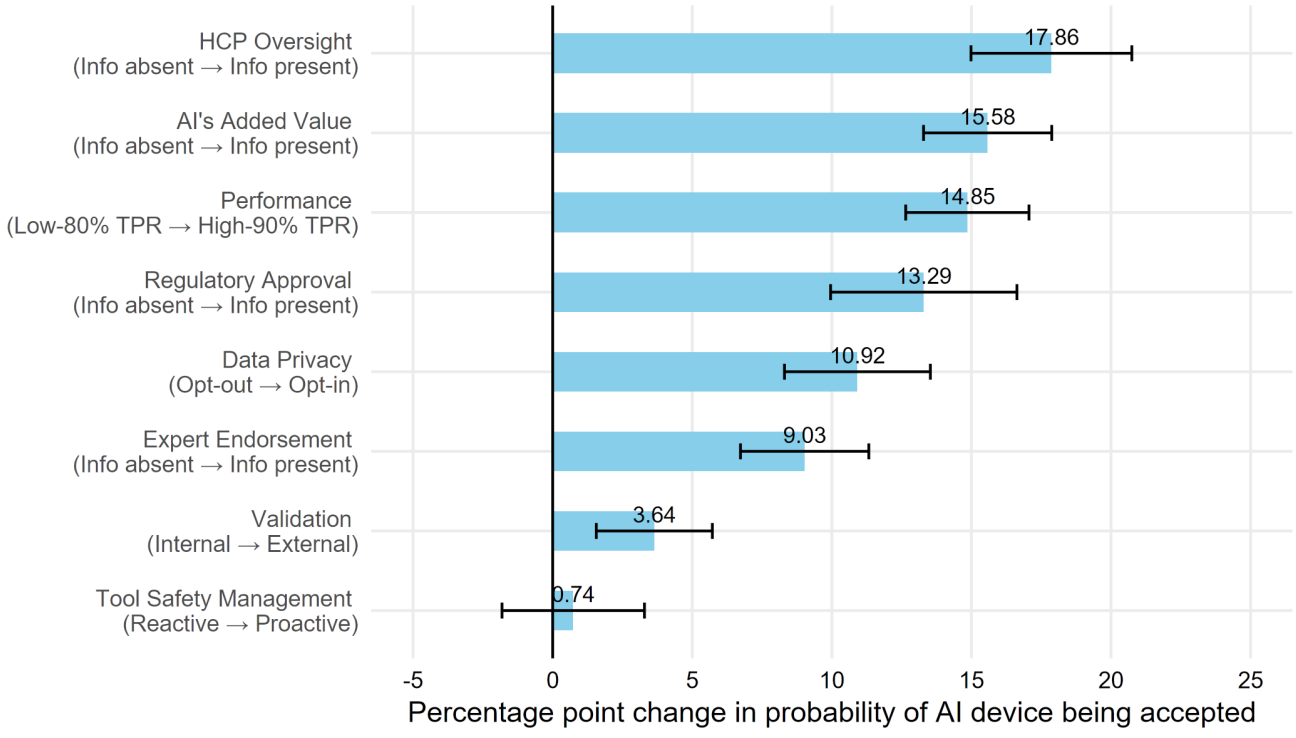
[a]AME: average marginal effect. It is the average change in the predicted probabilities (percentage point increase or decrease) of the artificial intelligence device being trusted or accepted across all participants when moving from one level of the information factor to the other, keeping all other variables in the model constant.

[b]HCP: health care provider.

Importance of the Information Factors for Patients' Acceptance of the AI Device

Figure 5 visualizes the relative importance of the information factors for participants' willingness to use the AI device in their health care (ie, acceptance). The 4 information factors that produced the greatest increase in participants' acceptance in using AI devices were inclusion of information about HCP oversight (17.86% increase, 95% CI 4.98%-20.75%), inclusion of information about the device's added value (15.58% increase, 95% CI 13.28%-17.88%), information about high versus low device performance (14.85% increase, 95% CI 12.65%-17.06%), and inclusion of information about regulatory approval (13.29% increase, 95% CI 9.96%-16.63%). Including information about opt-in (vs opt-out) data privacy protocol, expert endorsement (vs information absent), and information about external (vs internal) validation less strongly increased the probability of the AI device being accepted (10.92%, 9.03%, and 3.64%, respectively). The effect of information about proactive versus reactive device safety management protocol on device acceptance was not statistically significant (Table 3).

Figure 5. Difference in probability of artificial intelligence device being accepted by attribute level. AI: artificial intelligence; HCP: health care provider; Info: information; TPR: true-positive rate.



Subgroup Differences in the Effect of Top Preferred Information Factors on Patient Trust and Acceptance

Subgroup Differences in Patient Trust

Our analyses revealed subgroup differences in how the top 4 most important information factors affected trust in AI devices, based on participants' level of familiarity with AI, level of reading health literacy, level of need for cognition, recency of last routine medical checkup, age group, and gender (Multimedia Appendix 3).

AI's Added Value

Specifically, having information about AI's added value (vs information absent) had a stronger positive effect on participants' trust in AI devices with a high (vs low) level of need for cognition (AME=16.21% vs 12.23%; *P*=.04).

HCP Oversight

Having information about HCP oversight (vs information absent) had a stronger positive effect on the probability of AI device being trusted for participants who reported not at all to somewhat (vs very or extremely) familiar with AI (AME=19.27% vs 11.30%; *P*=.01), for participants whose last routine checkup was less than a year ago (vs 1 or more years ago) (AME=18.27% vs 11.63%; *P*=.007), and for participants aged 55 years or older (vs aged 35 - 54 or 18 - 34 years) (AME=23.44% vs 10.34% or 15.25%; *P*<.001; *P*=.03).

High Device Performance

Information about high (vs low) device performance had a stronger positive effect on the probability of AI device being trusted for participants with a high (vs low) level of reading health literacy (AME=22.02% vs 11.06%; *P*<.001), for participants whose last routine checkup was less than a year ago (vs 1 or more years ago) (AME=20.09% vs 10.38%; *P*=.048), and for participants who identified as women (vs men) (AME=19.38% vs 12.85%; *P*=.005).

Regulatory Approval

Having information about regulatory approval (vs information absent) had a stronger positive effect on the probability of AI device being trusted for participants with a high (vs low) level of reading health literacy (AME=25.07% vs 13.63%; *P*=.001) and for participants whose last routine checkup was less than a year ago (vs 1 or more years ago) (AME=23.29% vs 12.92%; *P*<.001).

Subgroup Differences in Patient Acceptance

There were subgroup differences in how the top 4 most important information factors affected acceptance of AI device, based on participants' reported level of familiarity with AI, level of reading health literacy, level of numeracy, recency of last routine medical checkup, gender, and race or ethnicity (Multimedia Appendix 4).

AI's Added Value

Specifically, having information about the device's added value (vs information absent) had a stronger positive effect on the probability of the AI being accepted for participants who reported being not at all to somewhat familiar (vs very or extremely) with AI (AME=18.06% vs 11.49%; *P*=.005), for participants with a high (vs low) level of reading health literacy (AME=19.34% vs 11.96%; *P*=.002), for participants whose last routine checkup was within the last year (vs 1 or more years ago) (AME=19.19% vs 8.81%; *P*<.001), for participants who identified as women (vs men) (AME=18.94% vs 11.38%; *P*=.002), and for participants who identified as a person of color (vs non-Hispanic White) (AME=19.64% vs 12.01%; *P*=.001).

HCP Oversight

Providing information about HCP oversight (vs information absent) had a stronger positive effect on the probability of AI device being accepted for participants who reported not at all to somewhat familiar (vs very or extremely) with AI (AME=25.34% vs 9.59%; *P*<.001), for participants whose last routine checkup was within the last year (vs 1 or more years ago) (AME=21.92% vs 13.31%; *P*<.001), and for participants aged 55 years or older (vs aged 35 - 54 or 18 - 34 years) (AME=30.13% vs 13.05% or 13.77%; *P*<.001; *P*<.001).

High Device Performance

Information about high (vs low) device performance had a stronger positive effect on the probability of AI device being accepted for participants who reported not at all to somewhat familiar (vs very or extremely) with AI (AME=18.18% vs 10.58%; *P*<.001), for participants with a high (vs low) level of reading health literacy (AME=21.41% vs 7.66%; *P*<.001), for participants with a high (vs low) level of numeracy (AME=19.38% vs 9.77%; *P*<.001), for participants whose last routine checkup was within the last year (vs 1 or more years ago) (AME=18.91% vs 7.03%; *P*=.004), for participants who identified as women (vs men) (AME=18.71% vs 9.57%; *P*<.001), and for participants aged 55 years or older (vs aged 35 - 54 or 18 - 34 years) (AME=20.88% vs 12.80% or 11.82%; *P*=.006; *P*=.002).

Regulatory Approval

Providing information about regulatory approval (vs information absent) had a stronger positive effect on the probability of AI device being accepted for participants with a high (vs low) level of reading health literacy (AME=19.93% vs 5.82%; *P*<.001), for participants with a high (vs low) level of numeracy (AME=15.79% vs 9.16%; *P*=.004), for participants whose last routine checkup was within the last year (vs 1 or more years ago) (AME=18.65% vs 3.96%; *P*<.001), and for participants who identified as women (vs men) (AME=16.58% vs 9.43%; *P*=.04).

SPFE Results

Descriptive Statistics

Table 4 summarizes the descriptive statistics of the AI label evaluation measures. Most participants reported that the AI labels were easy to read (perceived legibility; 86.7%) and understand (comprehensibility; 84.2%). They also reported that reading the labels was not too mentally demanding (no information overload; 63.9%). Effects of the information factors on perceived legibility, comprehensibility, and information overload were not statistically significant (Table 5).

Table . Descriptive statistics of the artificial intelligence label evaluation measures.

	5-point Likert scale, n (%)				
Measure	1	2	3	4	5
This label is easy to read (perceived legibility)[a]	15 (1.12)	67 (5.00)	96 (7.16)	474 (35.37)	688 (51.34)
This label is easy to understand (comprehensibility)[a]	18 (1.34)	73 (5.44)	121 (9.02)	498 (37.14)	631 (47.05)
Reading this label is too mentally demanding for me (information overload)[a]	524 (39.13)	332 (24.79)	125 (9.34)	202 (15.09)	156 (11.65)
I trust the information on this label (information credibility)[a]	30 (2.24)	94 (7.01)	220 (16.41)	597 (44.52)	400 (29.83)
Label gives all information needed about the AI[b] device (perceived label effectiveness)[a]	44 (3.28)	243 (18.13)	177 (13.21)	502 (37.46)	374 (27.91)
Label helps me decide whether the device should be used in my care (perceived label effectiveness)[a]	15 (1.12)	83 (6.19)	162 (12.09)	600 (44.78)	480 (35.82)
I would trust the results from this AI device[a]	38 (2.83)	138 (10.29)	218 (16.26)	642 (47.87)	305 (22.74)
I would have doubts about this AI device[a]	128 (9.55)	351 (26.17)	274 (20.43)	405 (30.20)	183 (13.65)
I would seek a second opinion[a]	84 (6.26)	162 (12.08)	256 (19.09)	489 (36.47)	350 (26.10)
Use the AI device if offered the option[c]	22 (1.64)	125 (9.31)	229 (17.06)	521 (38.82)	445 (33.16)

[a]1=strongly disagree; 2=somewhat disagree; 3=neither agree nor disagree; 4=somewhat agree; 5=strongly agree.

[b]AI: artificial intelligence.

[c]1=very unlikely; 2=somewhat unlikely; 3=undecided; 4=somewhat likely; 5=very likely.

Table . Effects of information element on perceived legibility, comprehensibility, information overload, information credibility, and perceived effectiveness of the label in informing decision-making.

	Perceived legibility[b]	Comprehensibility[b]	Information overload[b]	Information credibility[b]	Perceived effectiveness of the label in informing decision-making[a]

[a]Model adjusted for perceived eligibility, comprehensibility, information overload, information credibility, and patient characteristics that were statistically significantly associated with the outcome.

[b]Model adjusted for patient characteristics that were statistically significantly associated with the outcome.

[c]AI: artificial intelligence.

[d]OR: odds ratio.

[e]HCP: health care provider.

Credibility

Having information about added value (OR 1.35, 95% CI 1.05-1.73), expert endorsement (OR 1.37, 95% CI 1.07-1.76), HCP oversight (OR 1.60, 95% CI 1.25-2.05), high (vs low) performance (OR 1.45, 95% CI 1.14-1.85), and regulatory approval (OR 1.55, 95% CI 1.21-1.99) were associated with higher levels of perceived credibility of the information (Table 5).

Perceived Effectiveness of Label

Information about added value (OR 1.36, 95% CI 1.06-1.74), HCP oversight (OR 1.48, 95% CI 1.16-1.89), and regulatory approval (OR 2.05, 95% CI 1.60-2.63) were associated with higher likelihood of participants reporting that the label gives them all the information they need about the AI device. Information about opt-in versus opt-out data privacy protocol (OR 0.71, 95% CI 0.56-0.91) was associated with lower likelihood of participants reporting that the label gives them all the information they need about the AI device. Information about HCP oversight (OR 1.41, 95% CI 1.09-1.81) was associated with higher likelihood of participants reporting that the AI label helps them decide whether the AI device should be used in their care (Table 5).

Trust and Intentions to Use AI

Information about expert endorsement (OR 1.30, 95% CI 1.01-1.68) and high (vs low) performance (OR 1.48, 95% CI 1.16-1.90) were associated with higher levels of trust in the results from the AI device. Information about high (vs low) performance (OR 0.77, 95% CI 0.61-0.98) and regulatory approval (OR 0.61, 95% CI 0.48-0.78) was associated with lower likelihood of participants reporting having doubts in the AI device. Information about HCP oversight (OR 0.75, 95% CI 0.57-0.97) and regulatory approval (OR 0.63, 95% CI 0.48-0.83) were associated with lower likelihood of participants reporting needing a second opinion. Information about HCP oversight (OR 1.47, 95% CI 1.12-1.94), high (vs low) performance (OR 1.59, 95% CI 1.22-2.07), and regulatory approval (OR 1.73, 95% CI 1.31-2.30) were associated with higher intention to use the AI device if offered the option (Table 6).

Table . Effects of information element on patient trust in the artificial intelligence device and intention to use the artificial intelligence device.

	Trust in the AI device[a], OR[b] (95% CI)			Intention to use the AI device if offered the option[a], OR (95% CI)
	I would trust results from this AI[c] device	I would have doubts about this AI device	I would seek a second opinion

[a]Model adjusted for perceived eligibility, comprehensibility, information overload, information credibility, perceived effectiveness of the label in informing decision-making, and patient characteristics that were statistically significantly associated with the outcome.

[b]OR: odds ratio.

[c]AI: artificial intelligence.

[d]HCP: health care provider.

Discussion

Overview

To our knowledge, this is the first study to apply 2 experimental methods, DCE and SPFE, to elicit patient preferences for information about the use of AI devices in their health care. Our study provides important evidence and insights for health care and AI professionals and policy makers on the relative importance of various information factors to patient decision-making, trust, and acceptance regarding an AI device in cardiology and on subgroup differences in the impact of top preferred information factors. This work is a first step toward developing effective communication strategies about AI in health care that ensure transparency and accessibility to facilitate informed decision-making and patient-centered adoption of AI applications.

Study Design Considerations

Before delving into our findings, we first address the use of the vignette experiment approach, the hypothetical AI device, and the nonclinical study sample. While vignette experiments are a well-established method in health communication and medical decision science research, they are not without limitations. In particular, the artificial nature of vignettes can raise concerns about ecological validity, as hypothetical scenarios may not fully capture the complexities of real-world decision-making.

As a result, there is a risk that the study findings cannot be generalized directly to real-world settings [40-43].

However, in the context of our study, the use of the vignette experiments with a hypothetical AI device and a nonclinical study sample was both methodologically necessary and ethically appropriate. Methodologically, this approach allowed us to standardize and systematically manipulate the information elements of interest, while holding all other aspects of the scenario constant. This level of experimental control is often impossible to achieve with a real AI device due to the presence of a range of uncontrolled confounding influences on patient decision-making, including prior experiences, provider communication, and exposure to media or marketing. Importantly, the ecological validity of vignette experiments depends not on literal replication of real-world settings but on whether the vignettes activated the same psychological processes that occur during real-life decision-making [41]. To enhance the realism and credibility of our vignettes, we designed the hypothetical AI device scenario in consultation with clinical and regulatory collaborators and informed by formative qualitative research with both clinicians and patients. We also sought clinician review on the vignette drafts to ensure clinical accuracy and appropriateness and then further refined their clarity and relevance by piloting through cognitive interviews with patients. These steps strengthened both the internal and ecological validity of our study design and increased the applicability of our findings to real-world AI communication contexts.

Moreover, testing experimental manipulations involving actual patients making real-time medical decisions may raise ethical concerns, particularly when issues surrounding patient trust, understanding, and decision-making about AI in health care are still evolving [69]. Our experiment focuses on comparing different information factors presented for the same device within a consistent clinical scenario. Conducting an empirical study using an actual AI device while manipulating its label would involve providing false information, such as presenting different performance metrics for the same AI device to different patients, which would constitute deception and be unethical. This approach would undermine patient autonomy in decision-making and could erode trust in their clinicians and health care system [70]. To ensure that the hypothetical scenario was relevant to study participants and consistent with real-world decision-making, we recruited adults who reported recent health care experiences through either a primary care or cardiovascular care visit within the past 3 years. Importantly, our study goal was to understand general patient preferences and responses to AI labeling across a diverse sample, which is a necessary first step before testing specific AI implementations in particular clinical populations.

Key Findings

Results from the 2 experiments offer complementary insights into the key factors shaping patients' decision-making about use of an AI device in cardiology. Results from the SPFE showed that most participants found the AI label prototypes easy to read and understand and not mentally demanding. The effects of information factors on perceived legibility, comprehensibility, and information overload were not statistically significant, indicating that patient preferences were not due to a lack of understanding of these labels. Results from the DCE showed that information about provider oversight, regulatory approval, high device performance, and AI's added value were the most influential in increasing patient trust in the AI device and their willingness to use the device in their health care. Patients placed less importance on information about opt-in versus opt-out data privacy protocol, expert endorsement, external versus internal validation protocol, and proactive versus reactive device safety management protocol.

Results from the SPFE reinforced these findings. First, information about AI's added value, expert endorsement, HCP oversight, high performance, and regulatory approval was linked to higher perceived credibility of the AI label. In addition, information about added value, HCP oversight, and regulatory approval increased the likelihood that participants felt that they had all the necessary information about the device. Interestingly, information about HCP oversight was the only factor that significantly influenced participants' perception of the label's usefulness in deciding whether to use the device in their care. Information about expert endorsement, high performance, and regulatory approval was also associated with greater trust in the AI device's results and reduced doubts about the device. Furthermore, information about HCP oversight and regulatory approval lowered the likelihood of participants seeking a second opinion. Finally, information about HCP oversight, high performance, and regulatory approval contributed to a higher intention to use the AI device if offered.

The DCE also showed that participant characteristics, including recency of last medical checkup, familiarity with AI, health literacy, numeracy, need for cognition, age, gender, and race or ethnicity, shaped how strongly information about AI's added value, device performance, HCP oversight, and regulatory approval impacted trust and acceptance of the AI device. Information about AI's added value had greater effects among participants who had more recent medical checkups, were less familiar with AI, had higher health literacy, had higher need for cognition, identified as women, or identified as people of color. Similarly, information about high device performance had stronger effects among those with more recent medical checkups, lower familiarity with AI, higher health literacy or numeracy, older age, or identified as women. Information about HCP oversight had stronger effects among participants with more recent medical checkups, lower familiarity with AI, or older age. Finally, the effects of information about regulatory approval were stronger among those with recent checkups, higher health literacy or numeracy, or women.

Implications for Practice

Our findings have important implications for the implementation of AI in health care. To start, providing transparent and accessible information about HCP oversight, regulatory approval, device performance, and the device's added value is critical for building patient trust and acceptance of AI technology [27]. These 4 information elements were the most influential in shaping patients' willingness to use an AI device, highlighting the need for health care systems to clearly

communicate them when introducing AI devices to patients. Health care systems could consider developing decision aids that allow patients to explore different aspects of a specific AI device in collaboration with their providers, helping them weigh the benefits and risks of using the device in their care [26]. This is especially important for patients with lower baseline trust or limited familiarity with AI.

Our findings also highlight the critical importance of information about endorsement and oversight from regulatory bodies and HCPs in boosting patients' confidence and reducing doubts about the AI device's effectiveness and safety, which can lead to higher trust in the device and lower likelihood of needing second opinions. This strong preference for human oversight and approval echoes literature on algorithm aversion, which shows that people are often reluctant to trust algorithmic decision-making systems even when they outperform humans [71,72]. This aversion is especially pronounced in decisions involving high uncertainty [73] and for tasks perceived as subjective [74]; however, it can be mitigated when there is room for human oversight and modification [75]. While algorithm aversion may initially make patients hesitant to trust AI, patient trust in their provider and the health system can lead to inflated expectations of AI's positive impact on care and potentially result in overreliance when patients lack the expertise to judge when to rely on it. Transparency and patient engagement are therefore critical to calibrating trust appropriately [28,76]. Notably, information about HCP oversight was particularly influential in helping patients decide whether an AI device should be used in their care. This finding is consistent with previous research showing that patients are more receptive to AI technologies when AI supports, rather than replaces, the decisions of trusted human HCPs, underscoring the value of a "human in the loop" approach to AI implementation that provides patients a sense of accountability and assurance regarding the safety and effectiveness of these technologies [12-14,18,77,78]. To improve patient engagement and acceptance of AI devices, patient-facing communications should explicitly emphasize providers' active role in reviewing, interpreting, and overriding AI outputs.

Three information elements, opt-in versus opt-out data privacy, external versus internal validation, and proactive versus reactive device safety management protocols, were found to be relatively less influential in shaping participants' trust and decision-making regarding the AI device. This variation in the prioritization of information elements reflects how patients actively calibrate trust in AI technologies and advances beyond prior empirical work that was limited to identifying information relevant to patient trust [26,28,39,79]. Specifically, patients tend to anchor their trust in the AI device on signals that are personally meaningful from a layperson's perspective, such as information about HCP oversight, regulatory approval, expert endorsement, and device performance, rather than the more abstract procedural indicators such as data privacy, validation, and safety management. While critical from a policy and ethical standpoint [38], these issues may be too abstract or poorly understood by a layperson to effectively translate into meaningful differences in care [80]. In addition, the terms used in the descriptions of these elements, including "deidentified data," "tested and evaluated," "fix issues promptly," and "device will be audited," may have signaled to participants that basic privacy, validity, and safety protections were in place, especially in the presence of a strong credibility cue [81]—the study instruction that their HCP recommended the AI device. As a result, many participants may have relied on heuristics to reassure themselves about privacy, validity, and safety and focused their mental effort on other aspects that are more directly related to the benefits and risks of using the device in their care [82,83]. These findings echo previous research showing that increasing transparency alone is insufficient for calibrated trust, and such information must also be accessible and meaningful to users [35,80,84]. Technical or abstract aspects of the AI device should be contextualized in terms of impact on the patient's care and communicated in accessible and relatable ways, for example, through plain language summaries, visuals, and metaphors, ideally developed through an iterative process of co-design and testing with patients [85-88]. These findings also highlight a potential tension between what patients find most useful in decision-making and what is required by regulators or ethics guidelines. For example, although data privacy is a central focus in recent AI regulations [89], participants in our study placed relatively lower importance on it. This suggests that patients may not benefit from regulatory-required information in the same way as other stakeholders and may sometimes prefer information that is not routinely made available as part of regulatory clearance processes. To support appropriately calibrated trust of AI technologies in health care, patient-facing communication strategies should emphasize the information patients value most, while also clearly addressing critical ethical and regulatory considerations [90]. Importantly, to make the abstract concepts more relatable, ethical and regulatory features should be framed in terms of their tangible benefits and risks to patients. Communication efforts must also strike a careful balance: offering reassurance while avoiding overstating benefits or certainty, which could create misplaced confidence in AI technology [76,91].

Moreover, patient-facing communication and education about AI in health care should be tailored to meet the unique needs and preferences of different patient groups [92,93]. For example, information about a device's added value was found to be particularly influential for patients who were less familiar with AI, had high reading health literacy, had recent routine checkups, and identified as women and people of color. Emphasizing the role of HCPs in overseeing AI use was found to be especially important for patients who are less familiar with AI, had recent routine checkups, and were aged 55 years or older. To effectively address these diverse patient needs and preferences, communication strategies could include tailoring language to patient reading levels and incorporating visual aids, infographics, and videos to help patients better understand complex information about the AI device and make informed decisions about their care. In addition, engaging patients, patient advocacy groups, and community organizations in co-designing patient-facing AI communication and educational materials including AI device labels could help address concerns from underrepresented groups who may have different levels of comfort with and trust in AI technologies and the health care system [94]. Providing AI communication and education

materials in various formats and at different time points may improve the accessibility of information about AI and better meet the diverse needs of different patient groups. Health care systems can consider offering in-person consultations during clinical visits, along with printed and digital materials for patients to take home, ensuring that patients have the opportunity to review and understand the information at their own pace [39]. Moreover, it is the responsibility of health care systems to ensure that providers are well informed about AI devices and are capable of communicating their benefits and risks effectively to diverse patient populations. Health care systems could establish standardized guidelines and best practices for patient-facing communication and education about AI in health care. Training providers on how to effectively discuss AI devices with diverse patient populations and address their concerns would be instrumental in ensuring that patients receive clear, transparent information that aids informed decision-making and builds merited trust in AI technologies. Table 7 summarizes key findings and implications for practice.

Table . Summary of key findings, implications, and recommendations.

Findings	Implications and recommendations
High impact information • Information about HCP[a] oversight, regulatory approval, high device performance, and AI's[b] added value led to largest increases in trust and willingness to use. • These elements also boosted the AI label's credibility, increased trust in the results, reduced doubts, and enhanced patient confidence in having enough information about the device for decision-making.	• Patients prioritize personally meaningful, concrete information over abstract procedural details. • Clearly communicate information about HCP oversight, regulatory approval, device performance, and added value, as these elements are crucial for building patient trust and enabling acceptance of AI technologies. • Develop decision aids that help patients and providers explore the benefits and risks of specific AI devices together, especially important for patients with lower baseline trust in or limited familiarity with AI.
Lower impact information: Participants placed less importance on information about opt-in versus opt-out data privacy, model validation protocol, and safety management protocol.	• Abstract issues may be poorly understood, so patients rely on heuristics and focus on aspects directly related to benefits and risks. • Technical or abstract aspects should be contextualized for patient care and communicated via plain language, visuals, and metaphors. • Communication should emphasize what patients value while addressing critical ethical and regulatory considerations.
Role of human oversight: Information about HCP oversight and regulatory approval consistently boosted patient confidence, reduced doubts, increased trust, lowered the need for second opinions, and increased intention to use the AI-enabled device if offered.	• Patients prefer AI that supports, rather than replaces, human decision makers, underscoring the importance of a "human in the loop" approach. • Communicating provider oversight can inflate expectations of AI's benefits; transparency and engagement are key to calibrating trust based on human oversight. • Patient-facing communication should emphasize providers' role in reviewing, interpreting, and approving or overriding AI outputs. • Ensure that providers are well informed about AI devices and can effectively communicate benefits, risks, and limitations to patients.
Subgroup differences: Impact of information elements varied by participant characteristics. • Added value: stronger effect for recent checkups, low AI familiarity, high literacy or need for cognition, women, and people of color. • High performance: stronger for recent checkups, low AI familiarity, high literacy or numeracy, older age, and women. • HCP oversight: stronger for recent checkups, low AI familiarity, and older age. • Regulatory approval: stronger for recent checkups, high literacy or numeracy, and women.	• Tailor language to patient reading levels and use visuals, infographics, and videos to explain complex AI information. • Co-design materials with patients, advocacy groups, and community organizations to address diverse trust levels and concerns. • Provide materials in multiple formats and at different time points to meet diverse patient needs. • Establish standardized guidelines and best practices for patient-facing AI communication. • Train providers on how to effectively discuss benefits, risks, and limitations of AI devices with diverse patient populations.

[a]HCP: health care provider.

[b]AI: artificial intelligence.

Strengths, Limitations, and Future Directions

This research has several strengths. First, we used innovative experimental methods to elicit patient preferences for information about AI in health care, which could be applied to other use cases and medical specialties. Our methods can also be used to develop and evaluate other patient-facing AI communication and education materials. We applied a rigorous process for selection of information elements, including a rapid literature review and 3 qualitative studies, which strengthened the validity of our findings.

Our findings should be interpreted in the context of the limitations. The study sample, recruited from ResearchMatch.org, is a convenience sample and may not necessarily represent the US adult population. To address this, we intentionally oversampled racial and ethnic minority

populations to ensure their representation and enable comparisons between people of color and non-Hispanic White patients in AI information preferences. Since nearly all participants had health insurance, caution is needed when generalizing the findings to uninsured populations. In addition, while selection bias might be a concern, we lack data to compare participants with nonparticipants, which may impact the generalizability of our findings. Nonetheless, our methods of evaluating the importance of information elements can be applied to other AI devices, medical conditions, and other types of AI communication and education efforts.

Our study sample may not closely reflect the demographic and clinical characteristics of patients most likely to use AI-enabled cardiology devices. While all study participants reported having had a primary care or cardiology visit within the past 3 years, we could not clinically verify that they were seeking cardiovascular care during the study period. Therefore, findings may not generalize to clinical populations actively facing decisions about AI-enabled cardiac care. Future research should replicate this work among clinical populations to validate and extend the findings. Furthermore, we used a hypothetical AI-enabled cardiology device to maintain experimental control and isolate the effects of specific information elements. However, this approach may not fully capture the complexity and nuance of real-world patient decision-making. As a result, the ecological validity of our findings may be limited. To build upon and extend the current findings, future research should examine how patients actively seeking cardiovascular care respond to labeling content for real-world AI-enabled devices in clinical practice.

Our study focused on the impact of patient-facing informational content in AI labeling, and it did not directly assess how provider recommendation might influence patient trust and acceptance of AI technologies. To hold provider recommendation constant across experimental conditions, we instructed all participants to assume that their provider had recommended the use of the hypothetical AI device. We acknowledge the important role of provider recommendation in patient adoption of AI technologies and encourage future research to explore how provider recommendation and label content interact to shape patient decision-making.

We examined patient information preferences and responses to AI label prototypes at a single time point prior to actual use of an AI device. As AI technologies become more integrated into routine health care and daily life, patients may gain greater familiarity with AI and shift information priorities after repeated exposure and use. Future research should adopt longitudinal study designs to examine how patient information needs, preferences, trust, and acceptance evolve over time and across different stages of their health care journey.

The information elements presented to participants were informed by our prior qualitative research; however, they may not fully reflect the complete range of information that could appear on an actual AI device label. In addition, because our study focused solely on the informational content of AI labels, the format, layout, and visual design of the label prototypes were simplified and standardized for ease of delivery through a web-based survey and may not fully reflect the look or feel of AI device labels used in real-world clinical practices. Future research is needed to examine how variations in display format (eg, static vs interactive), information modality (eg, textual vs infographic), delivery channel (eg, digital vs printed), and timing (eg, previsit, point-of-care, postvisit) influence patient comprehension, trust, and decision-making regarding AI technologies in health care. Finally, it is critical to involve patients in co-designing and testing AI communication strategies to ensure that the materials are accessible, engaging, and aligned with the needs and preferences of diverse patient populations.

Conclusions

Through experimental studies, our research underscores the critical importance of transparent and accessible patient-facing information about AI devices and their impact on patient trust and acceptance. Information on HCP oversight, regulatory approval, device performance, and its added value emerged as pivotal factors influencing patient decision-making. Tailoring communication to meet the diverse needs and preferences of patient subgroups is essential for effective and equitable AI adoption in health care. Patient-centered communication strategies, coupled with comprehensive education for HCPs, would ensure that AI technologies are integrated into health care in a way that empowers patients to make informed choices and support overall patient care.

Funding

This work was supported by the US Food and Drug Administration (FDA) of the US Department of Health and Human Services (HHS), award number U01FD005938, totaling US $712,431 with 100% funded by FDA/HHS. Abstract

Background: The rapid growth of social media as an information channel has enabled the swift spread of inaccurate or false health information, significantly impacting public health. This widespread dissemination of misinformation has caused confusion, eroded trust in health authorities, led to noncompliance with health guidelines, and encouraged risky health behaviors. Understanding the dynamics of misinformation on social media is essential for devising effective public health communication strategies.

Objective: This study aims to present a comprehensive and automated approach that leverages large language models (LLMs) and machine learning techniques to detect misinformation on social media, uncover the underlying causes and themes, and generate refutation arguments, facilitating control of its spread and promoting public health outcomes by inoculating people against health misinformation.

Methods: We use 2 datasets to train 3 LLMs, namely, BERT, T5, and GPT-2, to classify documents into 2 categories: misinformation and nonmisinformation. In addition, we use a separate dataset to identify misinformation topics. To analyze these topics, we applied 3 topic modeling algorithms—Latent Dirichlet Allocation, Top2Vec, and BERTopic—and selected the optimal model based on performance evaluated across 3 metrics. Using a prompting approach, we extract sentence-level representations for the topics to uncover their underlying themes. Finally, we design a prompt text capable of identifying misinformation themes effectively.

Results: The trained BERT model demonstrated exceptional performance, achieving 98% accuracy in classifying misinformation and nonmisinformation, with a 44% reduction in false-positive rates for artificial intelligence–generated misinformation. Among the 3 topic modeling approaches used, BERTopic outperformed the others, achieving the highest metrics with a Coherence Value of 0.41, Normalized Pointwise Mutual Information of −0.086, and Inverse Rank-Biased Overlap of 0.99. To address the issue of unclassified documents, we developed an algorithm to assign each document to its closest topic. In addition, we proposed a novel method using prompt engineering to generate sentence-level representations for each topic, achieving a 99.6% approval rate as “appropriate” or “somewhat appropriate” by 3 independent raters. We further designed a prompt text to identify themes of misinformation topics and developed another prompt capable of detecting misinformation themes with 82% accuracy.

Conclusions: This study presents a comprehensive and automated approach to addressing health misinformation on social media using advanced machine learning and natural language processing techniques. By leveraging LLMs and prompt engineering, the system effectively detects misinformation, identifies underlying themes, and provides explanatory responses to combat its spread. The proposed method was tested on an English language COVID-19–related dataset and has not been evaluated on real-world online social media data; the experiments were conducted offline.

Introduction

Misinformation and inaccurate beliefs and knowledge about health can substantially undermine well-being by fueling confusion, eroding trust in reliable medical advice, and prompting risky behaviors such as rejecting vaccines, turning to scientifically unproven home remedies, or neglecting protective measures amid clear dangers [1-8]. These inaccuracies often circulate rapidly via social media, exploiting emotional narratives that overshadow fact-based content and leading individuals to question the legitimacy of evidence-based interventions [5,8-11]. Repeated exposure to misinformation reduces health literacy and can reinforce people's belief in falsehoods, making them more likely to view credible health authorities with skepticism [12-14]. As a result, misinformation weakens the success of prevention and treatment strategies, paving the way for heightened disease transmission, avoidable complications, and deteriorating outcomes at both individual and community levels [15-18].

An illustration comes from the COVID-19 pandemic, which saw an unprecedented surge of misinformation and conspiracy theories—labeled an "infodemic" by the World Health Organization (WHO) [1,12]. False remedies, unverified claims on the origins of the virus, and politicized narratives about preventive measures severely hampered containment efforts [19-21]. While proven strategies such as mask wearing, vaccination, and physical distancing were promoted by scientific authorities, social media rumors cast doubt on vaccine safety and the reality of the virus itself, discouraging people from getting vaccinated or seeking appropriate medical care [2,22-24]. This breakdown in adherence prolonged outbreaks, overloaded health infrastructures, and ultimately jeopardized global health and economic stability [25].

A parallel can be drawn from discussions around the human papillomavirus (HPV) vaccine, which has proven crucial in preventing various HPV-related cancers, including cervical cancer that claims thousands of lives each year [26-29]. Widespread misinformation about adverse effects and conspiracies regarding its necessity led to a significant portion of unvaccinated adolescents, heightening the likelihood of HPV infection and future malignancies [30]. This trend not only increased the burden on public health systems but also underscored the power of misinformation to undermine trust in legitimate medical counsel.

In recent years, social media has become a central and highly accessible source of information for millions of users worldwide [31]. However, its ability to rapidly disseminate content—including unfounded claims—creates fertile ground for large-scale propagation of misinformation. Given the sheer volume of posts, manual monitoring and analysis of such content are impractical [31,32] Consequently, developing and using automated, data-driven methods to understand and manage the dynamics of digital misinformation are essential for preserving accurate information and safeguarding public trust.

In this study, we propose an automated system designed to identify whether a given text contains misinformation. If misinformation is detected, the system analyzes the theme of the misinformation and provides a refutation argument (inoculation) to help prevent its spread on social media and enhance public health awareness. To achieve this, we leverage a large language model (LLM) to detect misinformation effectively. Furthermore, we demonstrate that enriching datasets significantly improves the detection of misinformation generated by both humans and AI. Recent advances in LLMs, such as ChatGPT, have enabled the generation of increasingly sophisticated misinformation, which poses challenges for traditional machine learning (ML) methods in distinguishing AI-generated misinformation [33,34]. While prior research has highlighted the effectiveness of deep learning methods in classifying health-related misinformation, these efforts have predominantly focused on content generated by humans [35,36]. Moreover, our proposed process generates sentence-level descriptions of misinformation topics, eliminating the need for manual interpretation. However, prior approaches relied on ML-based methods that produced word-level topic representations, which required manual interpretation to form coherent sentence-level topics—introducing potential human errors and subjective biases [1,22]. Similar challenges arise in other ML-based applications, such as optimizing models in industries where manual calibration of parameters can lead to inefficiencies and errors. For example, recent research has demonstrated that data-driven models can enhance predictive accuracy and automate decision-making, reducing human intervention in systems that rely on complex data streams [37-40]. Inspired by these advances, our process generates sentence-level descriptions of misinformation topics, eliminating the need for manual interpretation. In addition, we introduce an algorithm to assign documents to the most relevant topics. This addresses the limitation of many ML-based topic modeling algorithms, which often leave some documents unclassified. Our process also identifies overarching themes of misinformation topics automatically, providing a high-level understanding of the underlying reasons for misinformation categorization. Although the COVID-19 pandemic serves as our illustrative case due to its scale and data availability, the underlying challenges we address—rapid online spread, emotionally charged narratives, and declining trust—are common across other health contexts (eg, HPV vaccines) and beyond. Our approach does not rely on COVID-specific lexicons or handcrafted rules. Instead, the proposed Misinformation Detection and Inoculation Process (MDIP) is domain-agnostic. It ingests free English text, induces topics using standard models, transforms word lists into sentence-level descriptors through targeted LLM prompting, organizes them into hierarchical themes (guided by coherence, diversity metrics, and generic embeddings), and maps themes to refutation templates. Each stage has the potential to be applied to other health domains and misinformation settings, provided that the AI is properly trained with the topic- or domain-specific data.

Many previous studies have focused on individual aspects of the misinformation problem, such as detection or topic analysis [1,35,41], but have not integrated these steps into a unified framework for intervention. Our MDIP and Misinformation Detection and Inoculation System (MDIS) frameworks unify misinformation detection, topic modeling, thematic refutation, and public health intervention into a single, automated

workflow. This end-to-end approach enables health teams to move beyond merely identifying misinformation to actively and effectively countering it.

In the study by He et al [42], a method was proposed to generate per-claim counterresponses. While generating responses tailored to each specific piece of misinformation can be more informative and persuasive, such approaches require paired datasets of misinformation posts and response arguments for model training—datasets that are difficult to construct. Moreover, misinformation often mutates through paraphrasing and subtle edits; claim-specific pipelines are fragile in the face of such variation [43,44]. By contrast, our theme-level refutation approach is robust to these surface changes. More recently, LLM-based topic modeling approaches, such as TopicGPT [45] and other methods [46,47], have leveraged the capabilities of powerful pretrained models such as ChatGPT and LLaMA. While these methods benefit from the models' deep understanding of language, they often require passing entire documents through parameter-rich models, which leads to increased latency and computational costs compared with traditional pipelines. Furthermore, they typically yield only single-level sets of word topics. In contrast, our hybrid framework balances efficiency and expressiveness: we first use a traditional topic inducer to efficiently uncover the underlying structure and then apply LLM prompting (via ChatGPT) where it provides the added value. Specifically, the LLM is used to transform word lists into sentence-level topic labels and to organize topics into hierarchical themes. This targeted use of LLMs preserves computational efficiency while producing richer, hierarchical, and deployment-ready representations that are well suited for downstream tasks such as detection, monitoring, and refutation.

Methods

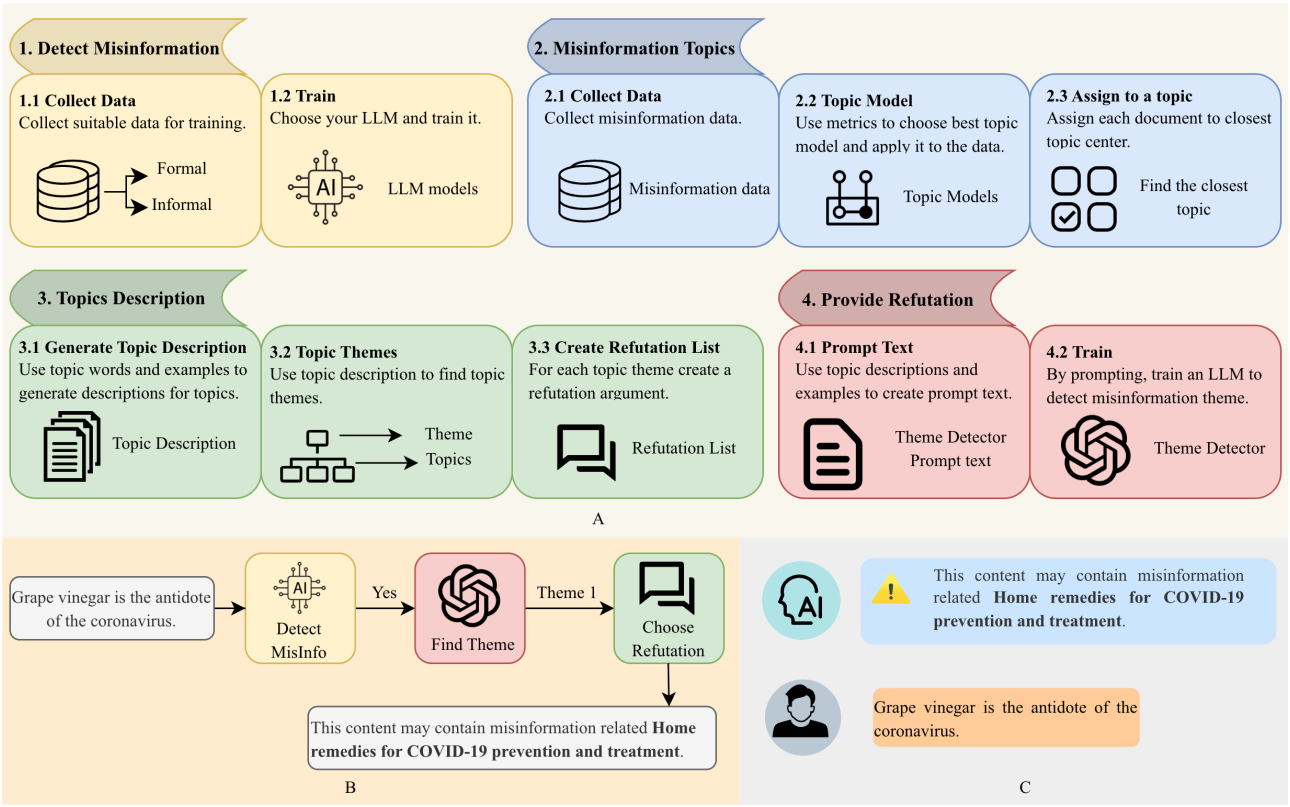
Study Design

In this study, we propose the MDIP, a comprehensive framework designed to analyze the dynamics of misinformation automatically and develop an MDIS. The MDIS end-to-end pipeline (1) flags misinformation, (2) explains what it is about via topics and higher-level themes, and (3) returns a concise, theme-matched refutation. The components are modular and feed one another in a simple data flow. No step in MDIP and MDIS uses disease-specific features; inputs are raw text and model hyperparameters chosen by intrinsic criteria (topic coherence and diversity). This makes the pipeline directly applicable to other misinformation corpora after swapping in the relevant documents. The MDIP framework is structured into four interconnected sections, each addressing a critical aspect of misinformation management:

1. *Detect misinformation*: Collect a labeled dataset and then train LLMs to classify text documents as either misinformation or nonmisinformation, providing a foundation for identifying false narratives.
2. *Misinformation topics*: Here, a topic modeling algorithm is applied to uncover the key topics within misinformation datasets. This step helps categorize misinformation into specific subject areas, enabling a better understanding of its thematic structure.
3. *Topic descriptions*: This section uses prompt engineering and the results of the previous section to enhance interpretability by generating sentence-level representations for each topic, moving beyond traditional word-level outputs. These descriptive summaries provide meaningful context for understanding the essence of each topic.
4. *Provide refutation*: In the final step, topic descriptions and extracted themes are used to design a specific prompt that identifies the underlying themes of misinformation. The system then generates clear and contextually relevant refutation arguments tailored to the detected misinformation themes. These arguments are designed to counter false narratives, improve public understanding, and mitigate the spread of misinformation. The refutations are a key component in the psychological inoculation-based misinformation mitigation intervention. As a metaphor to medical vaccination, the typical inoculation strategy consists of an attack message (ie, as a small weakened or deactivated dose of the virus) and refutation or counterarguments against the attack message (ie, as the immune system's reaction to the vaccine when it is injected or otherwise enters the human body) [48].

By integrating these components, MDIP enables the development of MDIS, an intelligent and automated system capable of detecting misinformation, identifying its themes, and delivering refutations to combat its impact on public health. The overall architecture of the proposed framework is illustrated in Figure 1. Figure 1A outlines the 4 stages of the MDIP: supervised detection of misinformation, topic modeling, generation of interpretable topic descriptions, and theme-based refutation. Figure 1B presents the end-to-end workflow of the MDIS, which processes new text inputs to produce a misinformation classification, assign the text to a thematic category, and generate a matched refutation. Finally, Figure 1C provides an example of the user-facing output, demonstrating how the system delivers both a misinformation warning and a concise, contextually relevant refutation.

Figure 1. (**A**) Overview of the Misinformation Detection and Inoculation Process (MDIP) integrates four main stages: (1) misinformation detection through supervised classification, (2) topic modeling of misinformation texts and assignment of outliers, (3) generation of interpretable topic descriptions and aggregation into higher-level themes, and (4) theme detection and provision of theme-linked refutations via prompt engineering for detected misinformation. (**B**) Misinformation Detection and Inoculation System (MDIS) workflow: For any new text, the system outputs (1) the misinformation decision, (2) its most likely theme, and (3) a theme-matched refutation. (**C**) Example: Illustration of how the system delivers the final user-facing output, providing a warning about misinformation and the matched refutation text. LLM: large language model.



Detect Misinformation

Misinformation detection in text documents has become a critical area of research due to the growing prevalence of misleading or false information online. To address this challenge, we use classifiers based on LLMs. These LLMs are trained to categorize text into 2 classes: misinformation and nonmisinformation, as shown in the first part of Figure 1A.

Our classifier was trained using 2 complementary datasets, each providing diverse linguistic characteristics to enhance performance in detecting misinformation. The first dataset, the AAAI 2021 Competition Dataset [49], consists of misinformation sourced from social media platforms such as Facebook and X (formerly known as Twitter). This dataset reflects the informal, conversational style of social media, characterized by casual tone, nonstandard grammar, and the use of slang. The second dataset, COVID_19FNIR [50], includes misinformation presented in formal, structured language, offering a stark contrast to the informal nature of the first dataset. By incorporating these 2 datasets, we trained 3 different LLMs to detect misinformation effectively across a wide spectrum of communication styles. The blend of informal and formal language enabled the model to better generalize, achieving improved accuracy and robustness in identifying misinformation, whether generated by humans or artificial intelligence (AI).

Traditionally, researchers collect human-written data from social media platforms such as Twitter and Facebook, label them as misinformation or nonmisinformation, and then train a deep neural network to classify such documents [35,36,51,52]. However, recent studies have demonstrated that deep neural networks trained exclusively on human-written datasets exhibit weaker accuracy in detecting AI-generated misinformation compared with human-written misinformation. This discrepancy arises because AI-generated misinformation often adopts formal language styles similar to accurate information shared by credible sources such as the WHO and the Centers for Disease Control and Prevention (CDC) on official social media accounts [33,34].

In this research, by combining a dataset with formal language and another with informal language (enriching the dataset with different language types and more misinformation), we demonstrate that LLMs achieve reasonable accuracy in detecting AI-generated misinformation. This approach ensures better generalization and robustness, bridging the gap in identifying misinformation across diverse linguistic styles.

Misinformation Topics

As outlined in the second section of Figure 1A, our approach involves 3 key steps. First, we collect misinformation data. Next, we select and compare topic modeling algorithms based on specific features and metrics to identify the most effective model. Finally, we design an algorithm that assigns topics to new or unclassified documents.

To identify misinformation topics, we used one of the largest datasets of verified COVID-19 claims, the IFCN dataset, which has been extensively used in related research [41,53,54]. We applied 3 topic modeling algorithms—Latent Dirichlet Allocation (LDA) [55], Top2Vec [56,57], and BERTopic [57,58]—to analyze this dataset.

To evaluate and compare the performance of these algorithms, we selected 3 metrics: Coherence Value (CV) [59], Normalized Pointwise Mutual Information (NPMI) [59], and Inverse Rank-Biased Overlap (IRBO) [60]. CV and NPMI measure the coherence of the topics, ensuring that they are logically consistent, being human interpretable, and meaningful. IRBO, on the other hand, evaluates the diversity of the topics generated by the model, which is crucial for ensuring broad coverage of the dataset's content. Since our focus is on misinformation within health-related social media data, coherence and diversity are particularly important to ensure that topics are both interpretable and representative.

After selecting the best-performing topic model, we developed an algorithm to address the issue of unclassified documents. This algorithm assigns topics to new or previously unassigned documents, ensuring comprehensive topic coverage and improved usability of the model for real-world applications.

Topic Description

Topic modeling algorithms typically produce word-level representations for each topic. While these representations provide insight into the most relevant words associated with a topic, they often lack the semantic depth necessary to precisely identify the specific topic within a document. This limitation arises because word-level outputs fail to capture the context and relationships between words that define the overarching theme of a topic [51].

Recent advancements in LLMs have demonstrated their ability to generate high-quality, contextually relevant outputs with minimal or zero additional training by designing carefully crafted inputs—referred to as prompt engineering [61]. Leveraging this capability, we address the limitations of word-level representations by using prompt engineering techniques to generate sentence-level representations for each topic. These sentence-level representations capture the context and essence of the topic, enabling a more accurate and interpretable understanding of the document content.

Subsequently, these sentence-level representations are used to identify and articulate the overarching themes of the topics, also at the sentence level. This approach provides a more comprehensive view of the thematic structure within the document corpus. Finally, recognizing that all documents within the dataset share a common underlying reason for being classified as misinformation, we develop a tailored response list for each topic theme. The third section of Figure 1A illustrates these 3 steps.

Provide Refutation

In the final step of our proposed method, as illustrated in the final part of Figure 1A, we identify the overarching theme of misinformation and provide a corresponding response from a preconstructed response list. This response list is developed in the preceding step based on the identified themes.

To determine the themes of misinformation, we use prompt engineering techniques. By designing carefully crafted and contextually appropriate prompt text, we effectively extract the underlying themes associated with misinformation. This approach allows us to translate complex word-level or sentence-level representations into meaningful thematic insights.

By identifying misinformation themes and providing precise, theme-based responses, our method aims to enhance public health knowledge and reduce the spread of misinformation. This proactive approach not only mitigates the risks associated with false or misleading information but also fosters a more informed and resilient society.

Proposed System

Following the completion of four foundational steps—(1) detecting misinformation, (2) identifying misinformation topics, (3) describing topics, and (4) providing refutations—we develop our comprehensive MDIS, which consists of three key components.

1. *Detection of misinformation*: The system begins by determining whether a given document is misinformation.
2. *Identification of misinformation themes*: If the document is classified as misinformation, the system analyzes its content to identify the underlying misinformation themes. This process involves extracting thematic representations that provide a clearer understanding of the document's misleading aspects.
3. *Providing refutations*: Finally, the system generates a detailed refutation argument for the identified misinformation themes. These arguments are derived from a predesigned response list tailored to address specific misinformation themes effectively.

All 3 components of the system are demonstrated with a practical example, as illustrated in Figure 1B and C. This example highlights how the system operates cohesively to detect misinformation, uncover its thematic structure, and deliver accurate refutations, ultimately contributing to a more informed and resilient public.

Ethical Considerations

This study did not involve human participants, human tissue, or the collection of identifiable private information by the authors. All analyses were conducted on previously collected, publicly available, and deidentified datasets, obtained solely for research purposes. Specifically, the data sources include: (1) the AAAI 2021 COVID-19 Fake News Detection Competition dataset, originally released as part of the AAAI Conference on Artificial Intelligence shared task, in which all social media content was anonymized and distributed for noncommercial research use only [49]; (2) the COVID-19 FNIR (Fake News and Information Reliability) dataset, introduced by prior studies for misinformation detection research and released in deidentified form for academic use [50]; and (3) the International Fact-Checking Network (IFCN) COVID-19 fact-checking corpus, which aggregates publicly available

fact-check articles produced by IFCN-certified organizations and contains no personal or sensitive individual-level data [62]. According to the US Department of Health and Human Services Common Rule (45 CFR §46.104(d)), secondary research involving publicly available, deidentified data does not constitute human subjects research and is therefore exempt from Institutional Review Board review [63]. The research complied with all relevant ethical standards and data use policies and poses no risk to individuals or communities. The study's sole objective is to advance computational methods for understanding and mitigating the spread of health misinformation.

Results

Text Classification

Due to the exceptional performance of LLMs across a wide range of AI tasks, we leveraged 3 prominent LLMs to fine-tune them for COVID-19 text classification. These models—BERT (Bidirectional Encoder Representations from Transformers), GPT-2 (Generative Pre-trained Transformer 2), and T5-base (Text-to-Text Transfer Transformer)—are renowned for their ability to understand and process natural language with high accuracy and contextual awareness.

BERT is particularly effective in handling text classification tasks due to its bidirectional context understanding, which allows it to capture nuanced language patterns [64]. GPT-2 excels in text generation and classification by leveraging its autoregressive architecture to predict sequences in a given context [65]. Finally, T5-base under a unified framework that reformulates all NLP tasks as a text-to-text problem, making it versatile and effective across various domains [66].

To conduct this study, we combined the AAAI 2021 competition dataset with the COVID-19 FNIR dataset. The data were split into training, testing, and validation sets with proportions of 67%, 17%, and 16%, respectively.

Accuracy, F_1-score, Recall, and Precision are standard metrics for evaluating classification models. Accuracy measures the proportion of all predictions that are correct, providing an overall performance indicator but sometimes masking class imbalances. Precision quantifies the fraction of predicted positives that are truly positive, reflecting how often the model avoids false alarms. Recall (or sensitivity) measures the fraction of actual positives that the model successfully identifies, highlighting its ability to capture relevant cases [67]. F_1-score is the harmonic mean of precision and recall, balancing the trade-off between the two. In health-related text classification tasks such as misinformation detection, reasonable thresholds are often set required due to the risks of misclassification—for instance, aiming for Accuracy >0.80, F_1-score ≥0.75, Recall ≥0.75, and Precision ≥0.70—to ensure both reliable detection and practical usability in downstream inoculation public health applications. Table 1 shows the evaluation metrics, including Accuracy, F_1-score, Recall, and Precision, for all 3 models on the test dataset. Among these, BERT achieved the highest performance, with an accuracy of *98%* on the test data. This result highlights BERT's ability to handle complex linguistic structures and its effectiveness in fine-tuning for domain-specific tasks such as COVID-19 text classification.

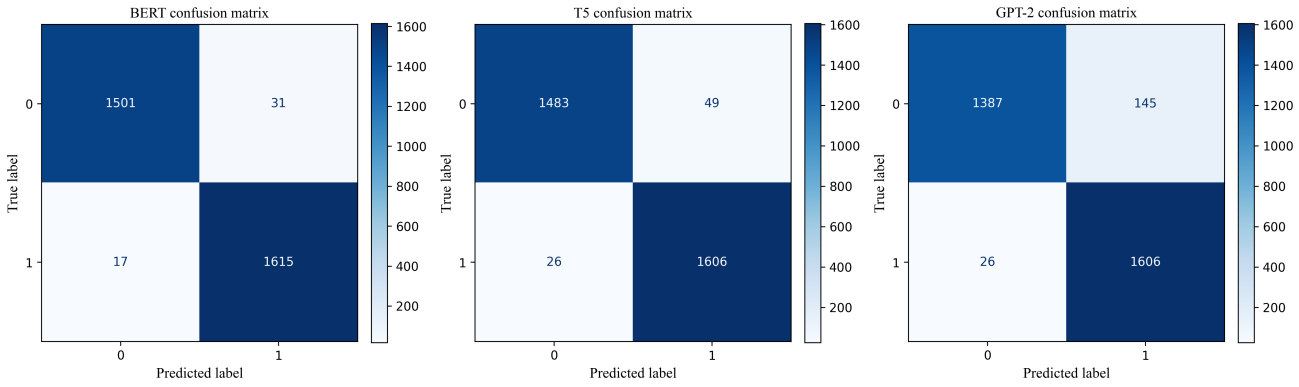
The confusion matrices in Figure 2 for BERT, GPT-2, and T5-base further illustrate the performance of these models, providing a detailed breakdown of true positives, true negatives, false positives, and false negatives, which helps in understanding their classification strengths and potential areas for improvement.

Table . Performance metrics (Accuracy, F_1-score, Recall, and Precision) on the test dataset for 3 models: BERT-base, GPT-2, and T5-base.

Model	Accuracy	F_1-score	Recall	Precision
BERT	0.9848	0.9854	0.9896	0.9812
GPT-2[a]	0.9460	0.9495	0.9841	0.9117
T5-base (Generic Condition)	0.9763	0.9763	0.9763	0.9764

[a]GPT-2: Generative Pre-trained Transformer.

Figure 2. Confusion matrices illustrate the performance of the 3 binary classification models (BERT, GPT-2, and T5-base). GPT-2: Generative Pre-trained Transformer.



To evaluate the accuracy of our model on AI-generated data, we used the dataset provided in the study by Du et al [35]. We tested our fine-tuned BERT model on this dataset, and the results are shown in Table 2. The findings indicate a significant reduction in the number of false positives, decreasing from 27 to 15, representing a 44% improvement. In addition, Figure 3 shows the confusion matrix for our fine-tuned BERT model when applied to the AI-generated misinformation dataset.

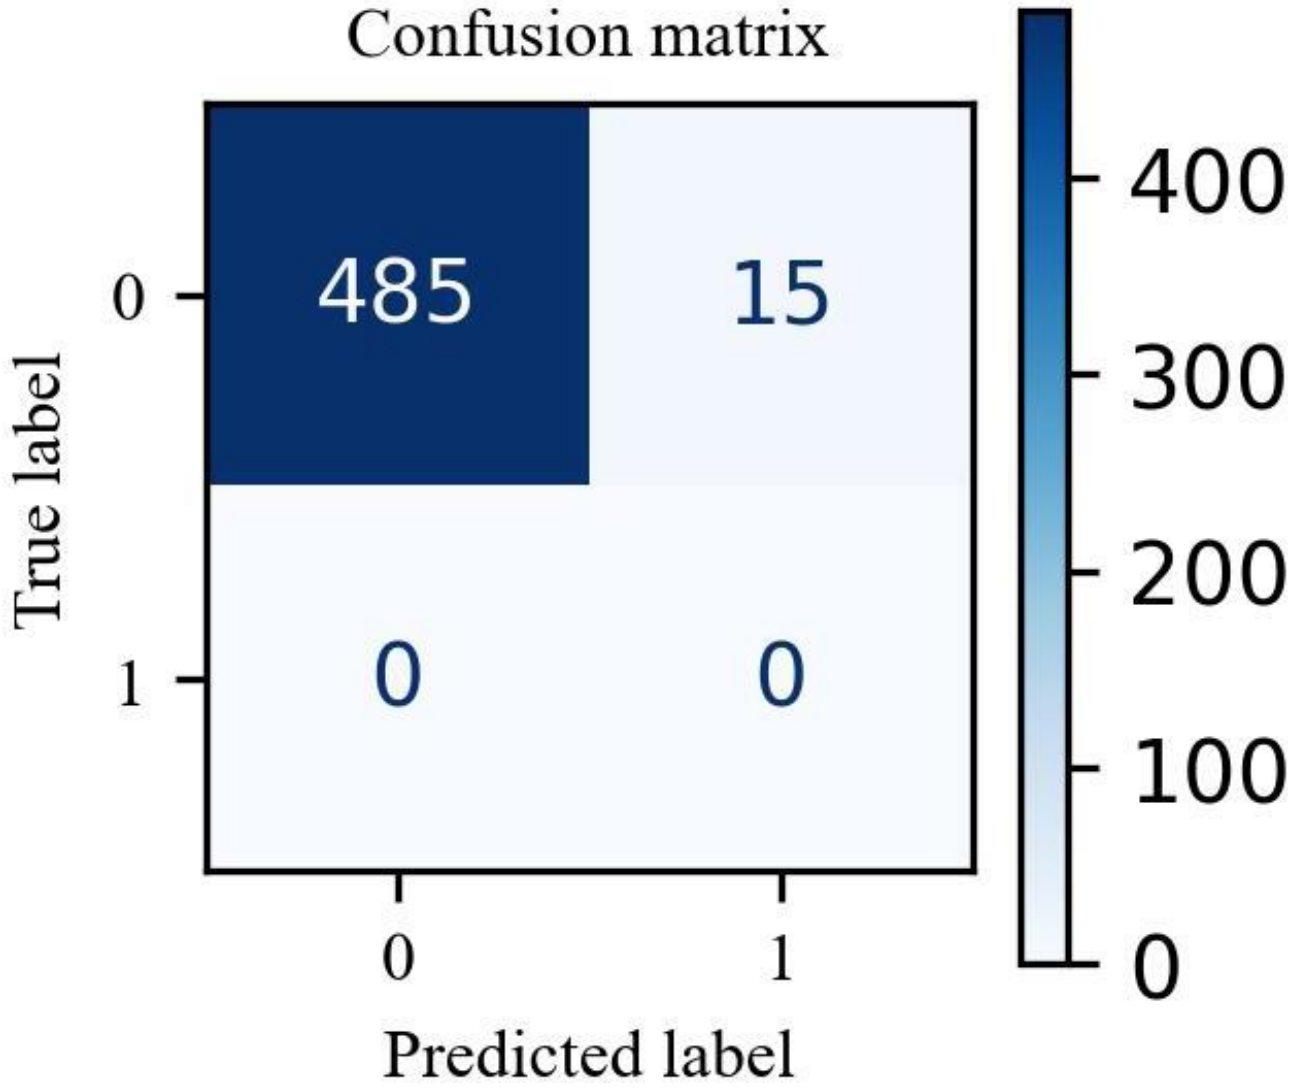
Table . False-positive and true-negative results obtained from testing the fine-tuned BERT model on our combined dataset, compared with the results reported in the study by Zhou et al [33].

Model	FP[a]	TN[b]
Our	15	485
Zhou et al [33]	27	473

[a]FP: false-positive.

[b]TN: true-negative.

Figure 3. The figure displays the confusion matrix of our fine-tuned BERT model evaluated on the artificial intelligence–generated dataset [3].



Topic Models

We used the IFCN dataset, one of the largest datasets on COVID-19 pandemic, to apply and evaluate topic modeling approaches. Three models were tested: LDA, Top2Vec, and BERTopic. After applying each topic model, the top 10 words associated with each topic were selected, and the 3 metrics—CV, NPMI, and IRBO—were computed to compare the models. Table 3 summarizes the results across these metrics. Among the models, BERTopic achieved the highest scores across all metrics, leading to its selection for further analysis. In practice, the reported metrics indicate that the topics are moderately coherent and interpretable but not perfectly tight. A coherence score of 0.41 means that the top words in each topic tend to appear together often enough for human analysts to assign clear labels, although some mixing of subthemes is expected. The NPMI of −0.086 is close to neutral, which is typical for short, fragmented social media posts, and suggests that while not every

word pair strongly co-occurs, the overall topics remain meaningful. Combined with the high IRBO score (0.99), these results imply that the model generates a broad, nonredundant set of topics that cover diverse misinformation themes while remaining practically usable for labeling, interpretation, and downstream health communication tasks. Since in the health-related domain, it is important to cover as many diverse topics as possible, an IRBO value above 0.7 can be considered acceptable, while a CV value equal to or above 0.4 and an NPMI close to 0 or higher are reasonable.

Table . Performance of 3 topic modeling approaches—LDA, Top2Vec, and BERTopic—evaluated across 3 metrics: Coherence Value, Normalized Pointwise Mutual Information, and Inverse Ranked Based Overlap[a].

Model	CV[b]	NPMI[c]	IRBO[d]
LDA	0.39	−0.35	0.96
Top2Vec	0.35	−0.29	0.89
BERTopic	0.41	−0.086	0.99

[a]For all metrics, higher values indicate better performance.

[b]CV: Coherence Value.

[c]NPMI: Normalized Pointwise Mutual Information.

[d]IRBO: Inverse Ranked Based Overlap.

Many topic modeling approaches, including BERTopic, often encounter limitations when applied to real-world datasets, as they are unable to assign topics to all documents. This can leave a subset of documents unclassified, reducing the overall effectiveness of the model. To address this issue, we have used the algorithm in Textbox 1, a method for ensuring comprehensive topic assignment across the dataset [68].

Textbox 1. Algorithm: assign a document to the closest topic.

1. Input:
   - Raw text documents X={d1,d2,...,dn},
   - BERTopic model parameters.
2. Topic modeling:
   - Compute topics using the BERTopic model:
     - Topics {Yj}j=1T, = BERTopic(X,P)

     where T is the number of topics and Y_j contains documents that are assigned to the topic j.
3. Sentence embeddings:
   - Transform documents X into vector representations using a sentence transformer such as BERT embedding.
4. Dimensionality reduction:
   - Apply Uniform Manifold Approximation and Projection for dimensionality reduction on the vector representations.
5. Cluster centers:
   - For each topic j, compute the center of the cluster:

   (1)tj=∑i∈ jxinj

     where n_j is the number of documents in topic j, and x_i is the reduced vector representation of document.
6. Topic assignment for unassigned documents:
   - For every document d_i that is not assigned to a topic by the BERTopic model, or for any new document:
     - Assign the document to the topic j that maximizes the cosine similarity between the document vector x_i and the cluster center t_j :

   (2)Argmax jxi · tj ‖ xi ‖ ‖ tj ‖

This approach not only ensures that every document in the dataset is assigned a topic but also enhances the interpretability and usability of the topic modeling results. By leveraging the semantic structure of the dataset, our algorithm effectively

bridges the gap between unassigned documents and existing topic clusters, making it a robust solution for comprehensive topic coverage.

Topic Description

As described in the "Methods" section, topic modeling algorithms typically produce word-level representations of topics. While useful for identifying key terms associated with a topic, these representations often lack sufficient contextual information, making interpretation challenging. To overcome this limitation, we developed a structured prompt framework (outlined in Textbox 2 and used the advanced capabilities of LLMs, specifically ChatGPT-4.0, to generate sentence-level representations for the identified topics. These sentence-level representations provide richer context and more interpretable descriptions, enabling a deeper understanding of the topics.

Textbox 2. The prompt structure and 1 example to find topics description.

Topic description prompt structure:

System role:

Topic main words: [Top 10 words]

Topic document examples: [5 closest examples to the center of the topic]

User role:

"Describe topic in a short phrase?"

Topic description prompt example:

System role:

Topic main words: ["masks," "mask," "face," "wearing," "wear," "use," "oxygen," "hypoxia," "cause," and "you''].

- Topic document examples:
  1. Centers for Disease Control and Prevention (CDC) does not recommend wearing masks.
  2. The US CDC contradicted itself by advising people to wear cloth masks against the novel coronavirus while also saying masks do not stop smoke inhalation during a wildfire.
  3. The World Health Organization changed its mind about masks and now says that they can increase the risk of infection.
  4. Nonmedical masks are ineffective in preventing the spread of the disease, are circulating online.
  5. Whether CDC had scheduled announcement that all should wear masks for everyday life.

User role: "Describe topic in a short phrase?"

Output answer: "Controversies and debates over mask wearing and its effectiveness"

The prompt includes the top 10 most representative words for each topic as identified by the topic modeling algorithm, and to add context and depth to the topic descriptions, we select 5 documents that are closest to the center of the corresponding topic cluster. The selection of these documents is guided by cosine similarity, performed using equations 1 and 2, which measure the proximity of documents to the cluster center in the semantic space. An example of this process is provided in Textbox 2, illustrating how the top words and representative documents are integrated into the prompt to produce a high-quality sentence-level representation.

By combining these elements, we construct detailed and context-rich prompts that guide ChatGPT-4.0 in generating coherent and semantically accurate sentence-level topic representations. This approach ensures that the abstract themes identified by topic modeling are translated into human-readable and interpretable descriptions.

To evaluate the quality of the generated topic descriptions, we engaged 3 independent raters to assess the descriptions based on 3 categories: appropriate, somewhat appropriate, and not appropriate. The evaluation results are shown in Table 4 and highlight that the majority of topic descriptions were well received. Specifically, the total proportion of accepted descriptions (the sum of those rated as appropriate and somewhat appropriate) was 99.6%. This acceptance rate demonstrates the effectiveness and reliability of the proposed method for generating meaningful and contextually relevant topic descriptions. There was perfect agreement in 144 out of 169 (85.2%) of the sentences. Two out of 3 raters agreed on category in 24 out of 169 (14.2%) of the sentences. There was a single instance in which no raters agreed in 1 out of 169 (0.6%) of the sentences.

Table . Percentage of topic descriptions rated as “appropriate,” “somewhat appropriate,” and “not appropriate” by each rater, along with the total number of accepted topic descriptions, calculated as the sum of those rated “appropriate” and “somewhat appropriate.”

Raters	Appropriate (%)	Somewhat appropriate (%)	Not appropriate (%)	Total accepted (%)
Rater 1	98.23	1.77	0	100
Rater 2	94.67	5.33	0	100
Rater 3	89.94	8.88	1.18	98.82
Average	94.28	5.32	0.39	99.6

After generating concise descriptions for each topic, we used the structured prompt framework outlined in Textbox 3, which includes a list of these topic descriptions. This structured prompt was then input into the ChatGPT-4.0 API to further refine and categorize the topics into overarching themes.

Textbox 3. Structure of the prompt for identifying topic themes.

Finding topic themes prompt structure:

System role:

The following are topics related to COVID-19 pandemic. Go through all topics and categorize them into relevant groups. Mention topics number for each category.

User role:

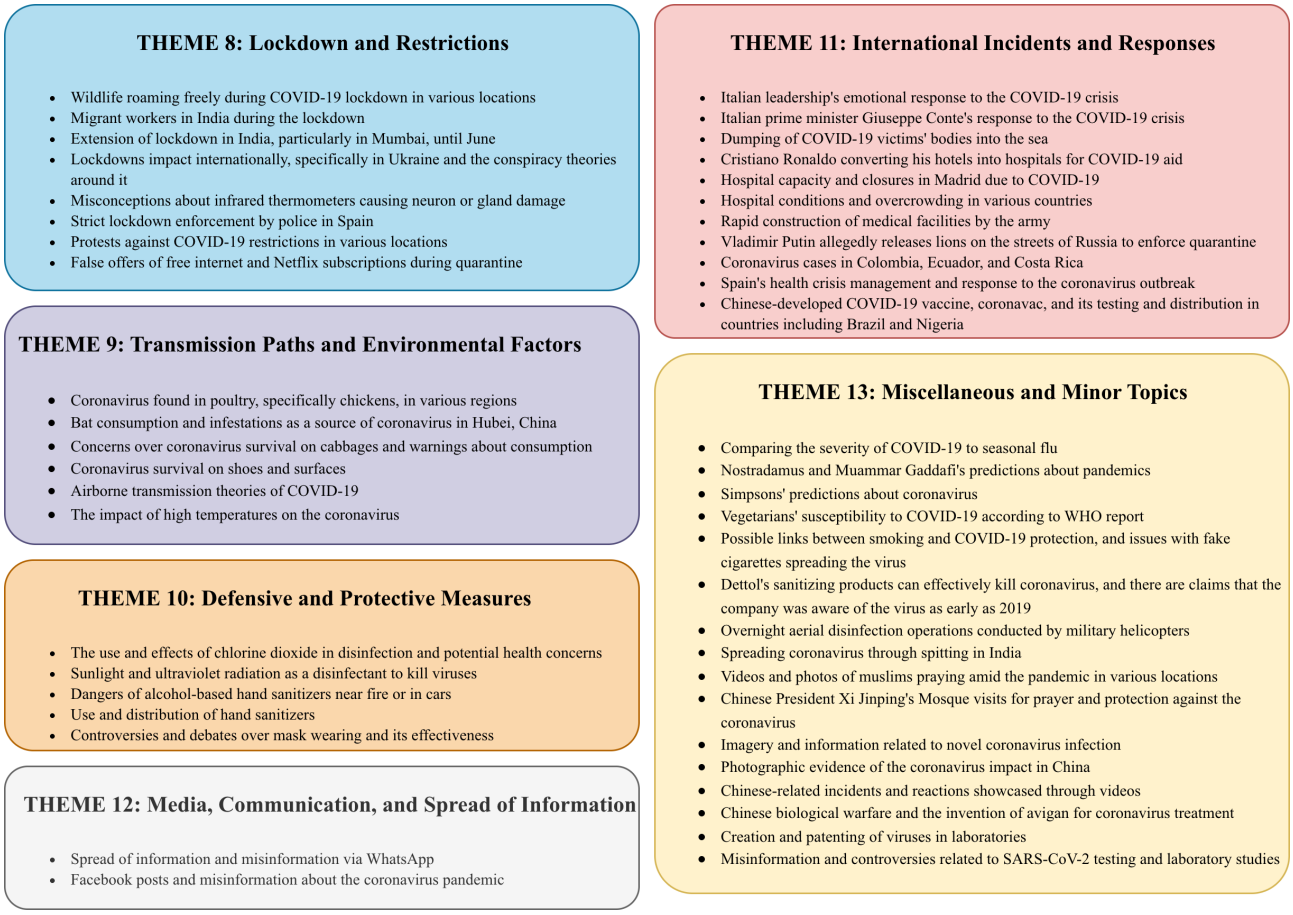
Topics description list

The output from this process not only provides a clear categorization of topics into distinct themes but also includes a concise description for each theme. This step ensures that the topics are grouped in a meaningful and interpretable way, facilitating a deeper understanding of the data’s thematic structure.

The categorized topics and their corresponding theme descriptions are provided in Figures 4 and 5, showcasing the effectiveness of the proposed method in generating coherent and insightful thematic groupings.

Figure 4. Descriptions of themes 1-7 along with the corresponding topic descriptions assigned to each theme. CDC: Centers for Disease Control and Prevention.

Figure 5. Descriptions of themes 8-13 along with the corresponding topic descriptions assigned to each theme.



Using the algorithm in Textbox 1, we assign each document to a topic, enabling us to determine the distribution of each theme. Table 5 shows the distribution of all themes, with theme 4 (Vaccines) and theme 3 (Conspiracy Theories) emerging as the first and second most prevalent misinformation themes. Here are all the themes and their percentages:

Table . Distribution of COVID-19 misinformation themes.

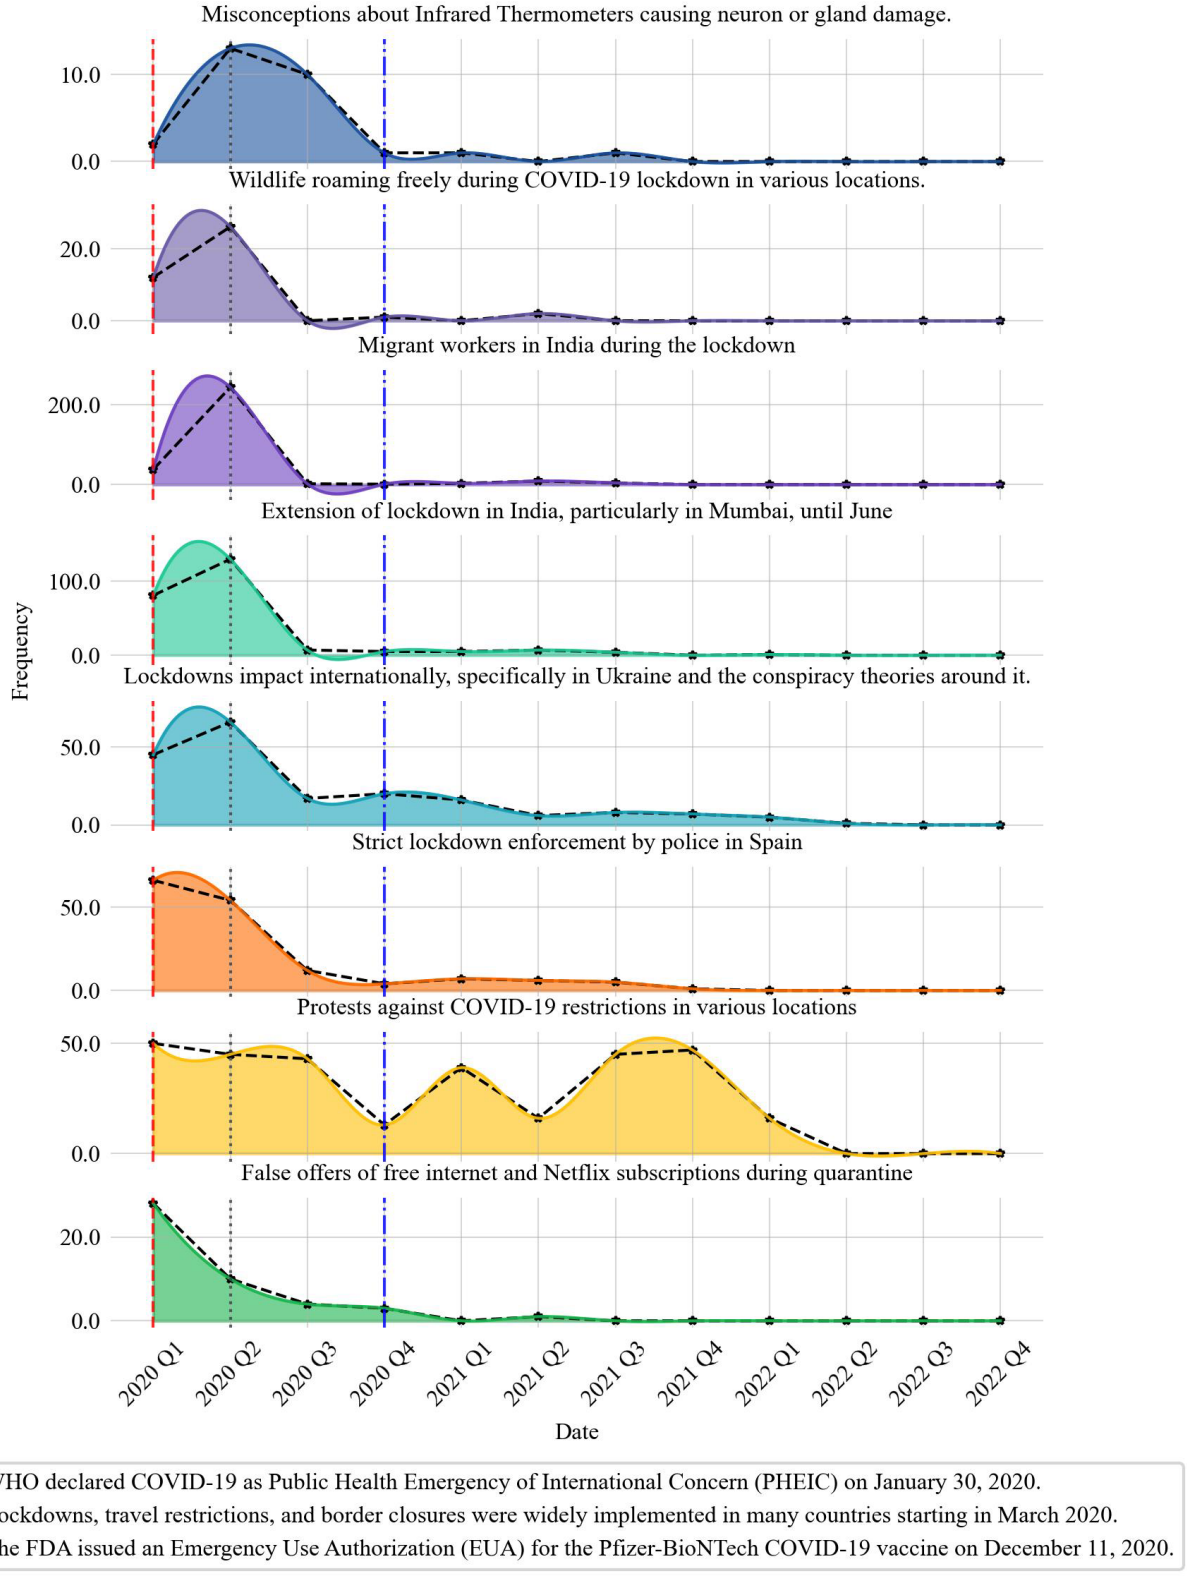
Theme	Values (N=18,018), n (%)
Theme 1: Home remedies	1334 (7.40)
Theme 2: Deaths and statistics	570 (3.16)
Theme 3: Conspiracy theories	3459 (19.20)
Theme 4: Vaccine	3595 (19.95)
Theme 5: Testing	546 (3.03)
Theme 6: Ivermectin	814 (4.52)
Theme 7: Government	2094 (11.62)
Theme 8: Lockdowns	1316 (7.30)
Theme 9: Transmission	297 (1.65)
Theme 10: Defensive	1269 (7.04)
Theme 11: International	891 (4.95)
Theme 12: Media	252 (1.40)
Theme 13: Minor topics	1581 (8.77)

Figure 6 shows the distribution of each topic within theme 8 over time, illustrating that protests against COVID-19 restrictions were the only misinformation topic that actively persisted even after the release of the COVID-19 vaccine.

After identifying the misinformation themes, we leverage the explanations provided in the IFCN dataset as a basis to draw refutation arguments to address these themes. For each identified theme, we develop a refutation that aligns with its context,

aiming to clarify the nature of the misinformation, its potential origins, and its impact. These refutations are shown in Textbox 4. The refutation arguments list for 13 themes, providing valuable insights into the underlying reasons for the misinformation.

Figure 6. Distribution of theme 8 topics during the time. FDA: Food and Drug Administration; WHO: World Health Organization.



Textbox 4. The refutation arguments list for 13 themes.

Refutation list:

1. This content may contain misinformation related to home remedies for COVID-19 prevention and treatment.
2. This content may contain misinformation related to COVID-19 deaths, statistics, and their relation to vaccination.
3. This content may contain conspiracy theories and misinformation related to COVID-19, including unverified claims, distorted facts, or manipulated content.
4. This content may contain misinformation related to COVID-19 vaccines, including false claims about safety, efficacy, and side effects.
5. This content may contain misinformation related to COVID-19 testing accuracy, including false claims about polymerase chain reaction tests and unscientific self-check methods.
6. This content may contain misinformation related to COVID-19 treatments, including exaggerated claims about ivermectin, hydroxychloroquine, or unproven supplements.
7. This content may contain misinformation related to government and political responses to COVID-19 pandemic, including distorted facts, fabricated claims, or misrepresentation of policies and actions.
8. This content may contain misinformation related to COVID-19 lockdowns and restrictions, including fabricated or misrepresented events, videos, or claims.
9. This content may contain misinformation related to COVID-19 transmission and survival in various environments, including unverified claims about foods, surfaces, or environmental factors.
10. This content may contain misinformation related to defensive and protective measures against COVID-19 pandemic, including false or exaggerated claims about masks, sanitizers, UV rays, or disinfectants.
11. This content may contain misinformation related to international incidents and responses to COVID-19 pandemic, including fabricated reports of government actions, health care capacity, or global cooperation.
12. This content may contain misinformation related to the spread of COVID-19 information on social media and messaging apps, including false claims about government policies, platforms, or media manipulation.
13. This content may contain miscellaneous misinformation related to COVID-19 pandemic, including distortions about products, religious practices, bioweapons, and other fabricated claims.

Provide Refutation

In the final stage of our process, we design a prompt text to enable ChatGPT-4.0 to detect specific misinformation themes. The prompt text includes a detailed description of the themes and a question-answer list. To create this question-answer list, we select the document closest to the center of each topic and associate it with the corresponding theme. Detailed information about the prompt text can be found in Textbox 5.

Textbox 5. Prompt structure and 1 example to find a document theme.

Finding document themes prompt structure:

System role:

"The following is the description of topic themes related to COVID-19 misinformation. Find the closest theme for the given text. Answer in a consistent style."

User role:

Themes description list

Assistant role:

Question-answer list

User role:

Input text

Finding topic themes prompt example:

System role:

"The following is the description of topic themes related to COVID-19 misinformation. Find the closest theme for the given text. Answer in a consistent style."

User role:

Themes description list

Assistant role:

Question-answer list

User role:

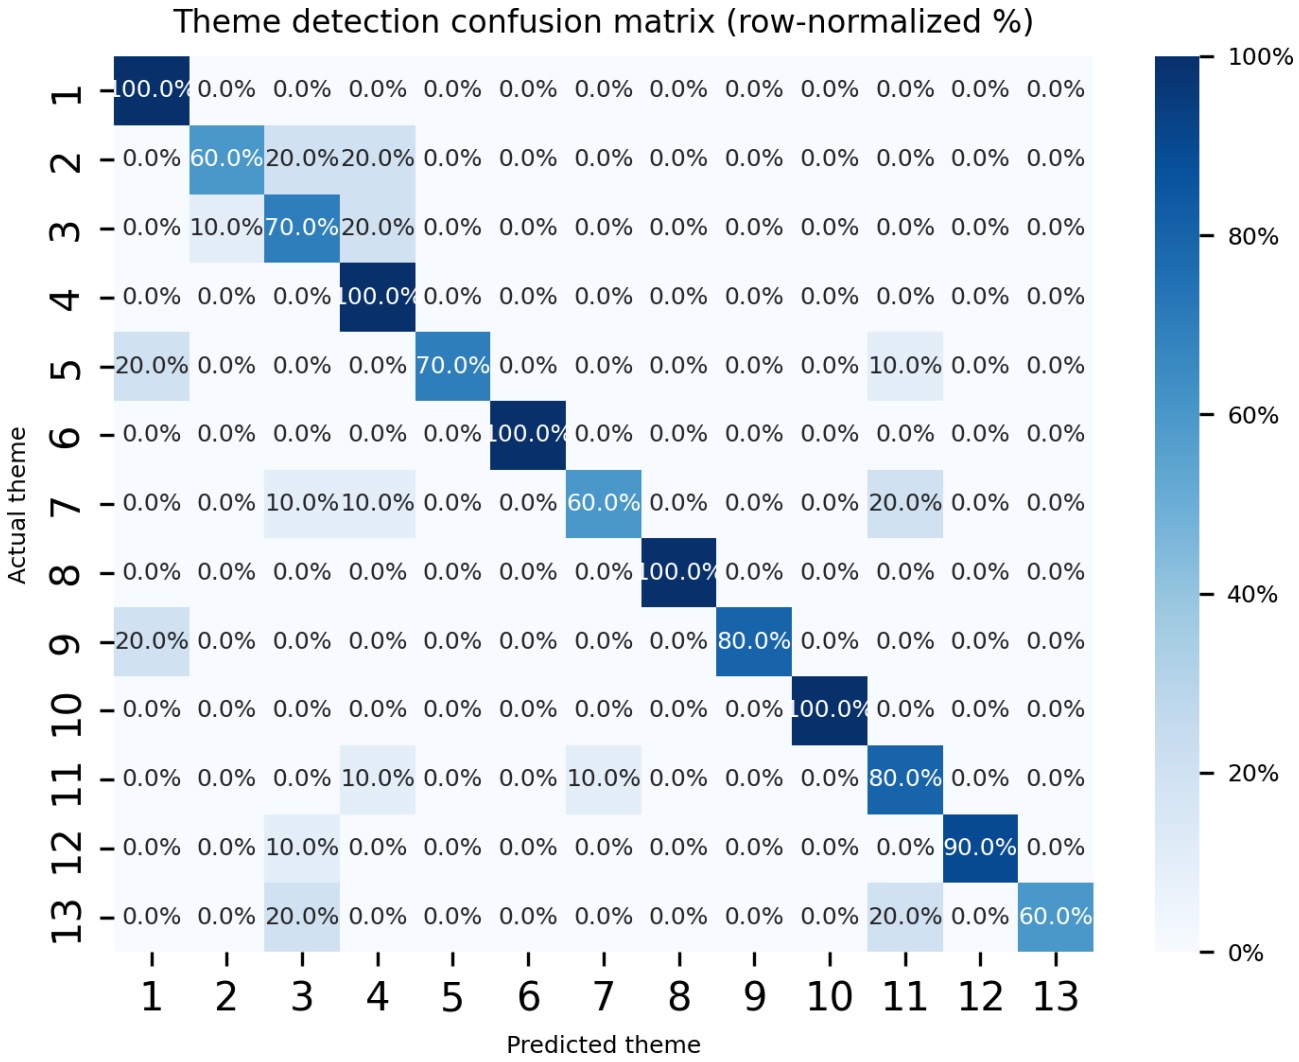
"A video shows that Bill Gates admits the vaccine will no doubt kill 700,000 people."

Output answer:

Theme 3: "Conspiracy Theories and Misinformation"

To evaluate our approach, we randomly selected 130 (10 documents per theme) documents from the IFCN dataset that are not included in the question-answer list. We then tested the prompting method with ChatGPT-4.0, achieving an 82% accuracy rate in detecting the correct themes. Moreover, as showing in Figure 7 the model struggled to detect themes 2, 7, and 13 in comparisons with other themes.

Figure 7. Confusion matrix of theme detector.



Proposed System

Based on the process we introduced, we propose the development of an MDIS. This system is designed to first determine whether a given text document contains misinformation or not. If the document is identified as containing misinformation, the system then detects its theme and provides a detailed refutation of the misinformation. The primary objectives of MDIS are to prevent the spread of misinformation and to enhance public health knowledge.

MDIS operates by integrating 3 key components. First, it uses a trained LLM to classify text documents as either misinformation or nonmisinformation. Next, it uses another trained LLM to detect the specific misinformation theme within documents identified as containing misinformation. Finally, it leverages a refutation list, which is generated during the theme description phase, to provide context and counternarratives for each detected theme. This comprehensive approach enables the system to effectively address misinformation while equipping users with accurate information.

Figure 1C illustrates an example of an input to MDIS and its corresponding output, demonstrating how the system analyzes a document, identifies misinformation, detects the associated theme, and presents an explanatory response.

Discussion

Principal Results

This study developed the MDIP, a structured workflow for analyzing health misinformation and generating explanatory counterarguments. Building on MDIP, we designed a prototype MDIS that combines detection, topic detection, theme identification, and refutation generation. While the system has not yet been deployed in real-world environments, the results illustrate its potential to support public health communication.

In the misinformation classification task, LLMs achieved reasonable performance, with BERT reaching 98% accuracy. Enriching training datasets also reduced false positives on AI-generated misinformation by 44% compared with prior baselines, suggesting improved robustness across different linguistic styles. Topic modeling experiments highlighted the advantages of BERTopic relative to LDA and Top2Vec, with higher coherence and diversity metrics. To address the issue of unassigned documents, the algorithm in Textbox 1 was used to assign outliers to their nearest topic cluster, thereby improving coverage of the dataset. To enhance interpretability, word-level topic outputs were converted into sentence-level descriptions through prompt engineering with ChatGPT-4.0. These descriptions were judged appropriate or somewhat appropriate

in 99.6% of cases by independent raters, indicating the value of sentence-level representations for clarity and interpretability. Building on these descriptions, topics were further grouped into broader themes and linked with theme-specific refutations.

Finally, a prompt-based detector for misinformation themes achieved 82% accuracy. These results demonstrate how detection, topic modeling, thematic grouping, and refutation can be integrated into a single workflow. The prototype system (MDIS) represents an illustration of concept, and while the findings are encouraging, validation is limited to English language, COVID-19–related data, and offline testing. Broader generalization, multilingual adaptation, integration into health communication workflows, and longitudinal evaluation remain important directions for future work.

Limitations

While this study presents a framework for detecting and addressing misinformation, several limitations should be acknowledged. First, the system's performance relies on the quality and diversity of the datasets that were used for training and topic modeling, which may not fully capture the linguistic and contextual nuances of misinformation in different regions, languages, or cultural contexts. This limitation introduces a potential bias: refutations that appear clear and persuasive in one sociocultural context may be ineffective—or even counterproductive—in another.

The model has been tested solely on English text–based misinformation, and it has not been evaluated for multilingual and multimodal adaptation, meaning its ability to detect misinformation and provide persuasive refutation across different languages and sociocultural contexts remains uncertain. Moreover, while the theme detection module achieved an accuracy of 82%, this leaves an 18% error margin, especially in ambiguous or overlapping themes, which can lead to inaccuracies in refutation and reduce the overall effectiveness of the generated warning texts. Developing and integrating more sophisticated algorithms to address overlapping in topic themes could substantially enhance the accuracy of theme detection. Improved theme separation would not only yield clearer and more coherent thematic structures but also strengthen the generation of precise and contextually relevant refutations. In turn, this refinement would enable more effective countermeasures against health misinformation, thereby improving the system's overall capacity to support public health communication and trust. False positives and negatives remain a concern, particularly when misinformation contains opinion-based, satirical, or context-dependent elements. Although the generated refutations follow a systematic structure, they may not always be contextually relevant, persuasive, or ethically suitable for diverse audiences. In the absence of a human-in-the-loop or oversight mechanism, the system may produce counterarguments that fail to resonate with users or could be perceived as unreliable. In addition, the system has not yet been extensively tested in real-world applications, which limits understanding of its practical impact on misinformation spread and public health outcomes. Furthermore, misinformation evolves over time, and a model trained on past narratives may require periodic retraining to remain effective against emerging falsehoods, including AI-generated misinformation. Using pretrained LLMs such as ChatGPT depends on the current version of the model and its accessibility to users. Therefore, it is necessary to update the system regularly when the model is changed or becomes unavailable. Moreover, since passing datasets through third-party platforms may compromise the security of the framework, future work could focus on developing an in-house solution by training a dedicated model for our specific tasks, thereby eliminating the reliance on external platforms. Finally, the reliance on automated methods raises potential concerns about interpretability and transparency, which are crucial for fostering trust and adoption by end users.

Comparison With Prior Work

The proposed MDIP and the resulting MDIS build upon and advance the body of research focused on misinformation detection and mitigation. The proposed method transforms raw posts into *actionable units*—sentence-level topic labels, aggregated themes, and paired refutations—linking detection outputs directly to message design and response playbooks used by health teams. Previous research has demonstrated the efficacy of ML models, particularly deep learning approaches, in detecting misinformation. They used ML techniques to classify fake news using textual features, demonstrating the value of automated detection methods [49,52,69]. Our study extends these efforts by integrating enriched datasets containing both formal and informal language styles, ensuring better generalization across diverse linguistic sources, including AI-generated misinformation.

Topic modeling techniques such as LDA have been used in prior studies to analyze misinformation [35,53,55]. Our approach improves on these works by addressing limitations in document assignment and theme interpretation. We used an algorithm to assign every document to the most relevant topic, resolving the common issue of unclassified documents in topic modeling. In addition, we moved beyond word-level topic representations to generate sentence-level descriptions, offering richer and more interpretable insights. By tracking shifts in sentence-level topics and theme distributions, communicators can conduct pre-/postassessments of campaigns or platform policy changes, complementing survey-based outcomes. Finally, we designed an effective prompt text to automatically identify the themes of misinformation. This automated approach reduces reliance on manual interpretation, minimizing human bias and increasing scalability.

Many prior studies have addressed misinformation detection or topic analysis in isolation. They analyzed misinformation using sentiment analysis but did not integrate detection with thematic analysis and did not provide a framework for counteracting misinformation [11,35,70]. Our work unifies detection, topic modeling, thematic refutation, and public health intervention in a single framework. The MDIS framework automates the end-to-end process, offering a scalable solution to tackle the complexity of misinformation dynamics.

Conclusions

This work contributes a methodological framework for infodemiology and digital health operations. We transform

misinformation into actionable units—themes and refutations—so that health teams can act (communicate, triage, and evaluate). Moreover, analyzing misinformation using a hierarchical (2-level) sentence-level description and assigning all documents to topics makes it possible to observe theme and topic distributions over time, providing a broad and sensible overview of misinformation. Sentence-level topics and theme distributions serve as measurable indicators for surveillance and intervention evaluation (eg, pre-/postcampaign shifts and surge detection). We introduce MDIP and MDIS that enable rapid response playbooks and reduce analyst workload. To support adoption, we release prompt templates and code as implementation artifacts that teams can readily adapt. Real-world deployment, however, requires governance mechanisms (human-in-the-loop review and audit logs), multilingual extensions, and prospective trials with health agencies or platforms to quantify downstream impact (eg, reduced spread and improved literacy). Ultimately, these contributions orient detection toward operational use—prioritizing interpretability and intervention design—so that public health actors can move from finding misinformation to effectively countering it.

Funding

This research is supported in part by a research grant from the Investigator-Initiated Studies Program of Merck Sharp & Dohme Corp (MISP #102050). The opinions expressed in this paper are those of the authors and do not necessarily represent those of Merck Sharp & Dohme Corp.

Data Availability

All implementation codes can be accessed through the GitHub repository [71].

Abstract

Background: Structured medication reviews (SMRs) are an essential component of medication optimization, especially for patients with multimorbidity and polypharmacy. However, the process remains challenging due to the complexities of patient data, time constraints, and the need for coordination among health care professionals (HCPs). This study explores HCPs' perspectives on the integration of artificial intelligence (AI)–assisted tools to enhance the SMR process, with a focus on the potential benefits of and barriers to adoption.

Objective: This study aims to identify the key user requirements for AI-assisted tools to improve the efficiency and effectiveness of SMRs, specifically for patients with multimorbidity, complex polypharmacy, and frailty.

Methods: A qualitative study was conducted involving focus groups and semistructured interviews with HCPs and patients in the United Kingdom. Participants included physicians, pharmacists, clinical pharmacologists, psychiatrists from primary and secondary care, a policy maker, and patients with multimorbidity. Data were analyzed using a hybrid inductive and deductive thematic analysis approach to identify themes related to AI-assisted tool functionality, workflow integration, user-interface visualization, and usability in the SMR process.

Results: Four major themes emerged from the analysis: innovative AI potential, optimizing electronic patient record visualization, functionality of the AI tool for SMRs, and facilitators of and barriers to AI tool implementation. HCPs identified the potential of AI to support patient identification and prioritizing those at risk of medication-related harm. AI-assisted tools were viewed as essential in detecting prescribing gaps, drug interactions, and patient risk trajectories over time. Participants emphasized the importance of presenting patient data in an intuitive format, with a patient interface for shared decision-making. Suggestions included color-coding blood results, highlighting critical medication reviews, and providing timelines of patient medical histories. HCPs stressed the need for AI tools to integrate seamlessly with existing electronic patient record systems and provide actionable insights without overwhelming users with excessive notifications or "pop-up" alerts. Factors influencing the uptake of AI-assisted tools included the need for user-friendly design, evidence of tool effectiveness (though some were skeptical about the predictive accuracy of AI models), and addressing concerns around digital exclusion.

Conclusions: The findings highlight the potential for AI-assisted tools to streamline and optimize the SMR process, particularly for patients with multimorbidity and complex polypharmacy. However, successful implementation depends on addressing concerns related to workflow integration, user acceptance, and evidence of effectiveness. User-centered design is crucial to ensure that AI-assisted tools support HCPs in delivering high-quality, patient-centered care while minimizing cognitive overload and alert fatigue.

KEYWORDS

structured medication reviews; medicine optimization; health technology; risk stratification; artificial intelligence; AI

Introduction

Background

The growing prevalence of multiple long-term conditions and complex polypharmacy among older adults poses significant challenges for health care systems globally. Structured medication reviews (SMRs) are a key clinical intervention, approved by the National Institute for Health and Care Excellence (NICE), designed to facilitate shared decision-making between clinicians and patients, optimize prescribing, and reduce medication-related harm in patients at high risk who are experiencing problematic polypharmacy [1,2].

General practitioners (GPs), pharmacists, and advanced nurse practitioners who meet training criteria can conduct SMRs. As a commissioned service, the prevailing expectation is for clinical pharmacists within primary care networks (PCNs) to proactively identify patients suitable for an SMR and conduct these reviews [3]. However, it is increasingly recognized that effective SMRs are difficult to implement clinically due to time pressures, fragmented clinical records, and the cognitive burden placed on clinicians when trying to assimilate information from various different sources in order to make shared, person-centered decisions [4].

Currently, in the United Kingdom, a few artificial intelligence (AI)–assisted tools are available to help health care professionals (HCPs) prioritize patients for SMRs. Tools available are usually based on predefined conditions or medications; the examples include Ardens Search [5] and Proactive Register Management Diabetes [4,6]. Prescribing safety indicators have also been used as a technology-based intervention to identify potentially inappropriate prescribing to reduce the number of patients at risk of hazardous prescribing [7,8]. However, primary care–embedded clinical decision support systems (CDSSs), such as audit and feedback tools, are often limited by data supply [9]. Emerging digital technologies, including AI, offer opportunities to enhance the efficiency and effectiveness of the SMR process through automation of routine tasks, rapid data extraction and synthesis, and highlighting clinical risks to support decision-making. However, the integration of AI into clinical workflows is in its infancy, and questions exist about its accuracy, clinical utility, usability, and trust. These implementation barriers are currently unexplored.

This study is part of a larger DynAIRx (AI for dynamic prescribing optimization and care integration in multimorbidity) project. Our research to date has highlighted the time-intensive nature of SMRs and the lack of AI-assisted tools to efficiently identify and prioritize patients [4]. Findings emphasized the need for an AI-assisted tool to identify, prioritize, and reduce the time needed to understand the patient journey in order to optimize medicines appropriately and reduce the risk of potential harm from medicines [4]. DynAIRx involves developing novel AI-assisted approaches to improve the efficiency of SMRs. The planned DynAIRx tool will comprise 4 main components: stratification of patients, clinical trial emulation to understand real-world risk of deprescribing, patient journey visualization through interactive timelines, and a knowledge support system integrating individualized patient risks to support decision-making. The deep learning AI component of this is to develop a tool to stratify patients most in need of an SMR. The DynAIRx stratification tool will compare 2 main approaches to identifying which patients are most at risk of medication-related harm: investigating the trade-off between model performance and explainability in the SMR context. First,

a simple logistic regression model not only gives a baseline performance level to assess the AI-based approach but also is clearly explainable and technically feasible to implement within clinical systems, such as EMIS and SystmOne. Second, a novel approach based on graph neural networks will be used to incorporate the sequence and timing of clinical events into predictions. This is likely to offer superior performance but will be difficult to explain and implement.

Large language models (LLMs), such as ChatGPT (OpenAI), are breaking new ground as an adjunct to support clinical decision-making. In radiological decision-making, ChatGPT recently showed impressive accuracy in the appropriate identification of imaging to support breast cancer screening [10]. There are several proof-of-concept AI-assisted tools in development to support complex polypharmacy. For example, the approach based on discriminator-enhanced encoder-decoder architecture for accurate prediction of adverse effects in polypharmacy is an AI model developed to predict adverse drug-drug interactions [11]. However, its effectiveness in a clinical setting has not yet been attempted. A new LLM based on retrieval-augmented generation has been developed to support pharmacists in identifying medicine errors [12]. User testing has been undertaken with simulation of complex scenarios and a multidisciplinary expert panel; however, true workforce implementation is still to be undertaken. Drug GPT is a specialized proprietary LLM tool for predicting medication safety events, developed by Oxford's AI for Healthcare Lab. It initially garnered popular attention upon the release of the preprint in 2023, including a review in the *Guardian* [13]. However, the preprint was subsequently removed by the authors, and its route to clinical implementation remains unclear [14]. Despite rapid progress, there remains limited understanding of what HCPs and patients actually need from such tools to support SMRs and, importantly, how to embed them into routine clinical practice, particularly in the context of multimorbidity and complex care.

While not all components of the DynAIRx polypharmacy tool will be AI assisted, the field of AI-assisted health technology is rapidly advancing. Consequently, it is critical to understand the user requirements for AI-assisted technologies now, as it may in fact be the case that simple, non-AI solutions can address the challenge in a straightforward and explainable way. Therefore, the health care sector is at a critical juncture when it comes to understanding end-user requirements for medication support.

This Study

This study aimed to explore the perspectives of both HCPs and patients on the potential role of AI in supporting SMRs, with a focus on identifying the core user requirements, anticipated benefits, and key barriers to implementation.

Methods

Participants and Recruitment

This study sought to recruit HCPs or management professionals from UK primary care (community based) and secondary care (hospital services) settings, for whom reviews of prescription medications form a routine part of clinical workload. Participants included those working in general practice; secondary care hospital services (geriatric medicine, clinical pharmacology, falls clinics, and mental health practitioners); clinical commissioning, service management (practice managers); and pharmacists, including PCN pharmacists who conduct SMRs across multiple GP practices. Patient participants included (1) those with mental and physical comorbidities, (2) those with complex multimorbidities, and (3) older people with frailty. In addition, patient and carer representatives from these 3 key multimorbidity groups were recruited, comprising adults aged >18 years with or caring for someone with multimorbidity (4 or more), coexisting mental and physical health problems, ≥10 or more prescribed medications, or frailty. Patient participants self-identified as not digitally engaged. As the General Data Protection Regulation was not required, we did not collect demographic data from patient participants.

Purposive sampling identified potential HCP participants actively involved in medicine optimization services through the researcher's clinical and professional networks. Snowball sampling, where current participants referred others, helped identify contacts through existing service providers and advertisements in GP forums and at national events related to clinical polypharmacy research. Patient representatives were recruited purposively via advertisements through the National Institute for Health and Care Research Applied Research Collaboration public advisor networks and research databases at the researcher's host institutions.

Ethical Considerations

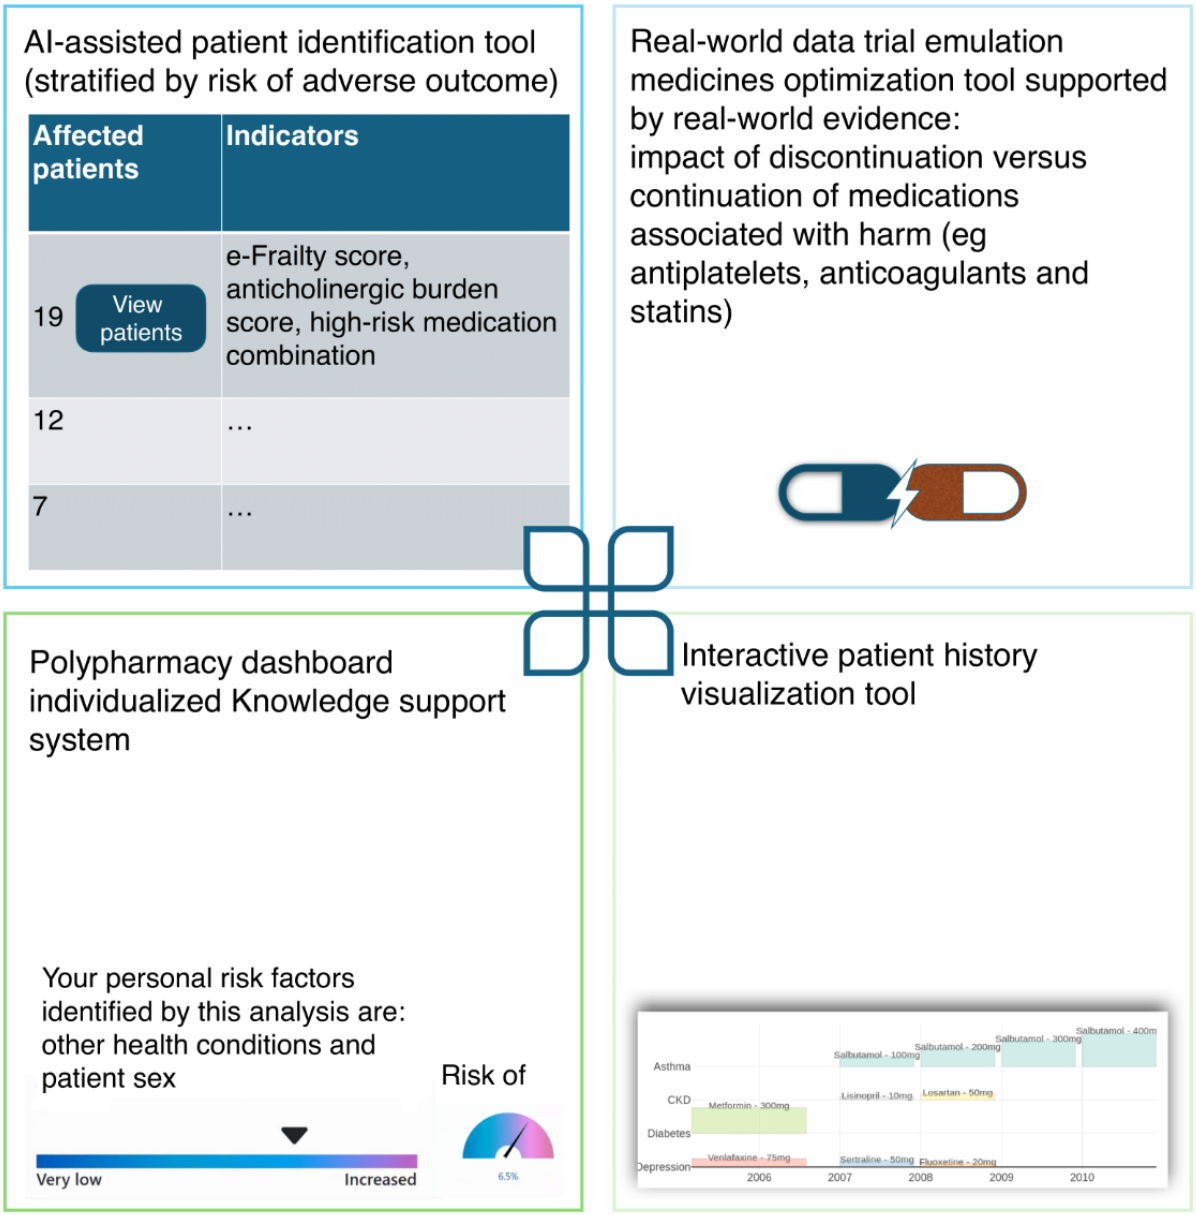
The Newcastle North Tyneside Research Ethics Committee (22/NE/0088) granted ethical approval for the DynAIRx study. Written consent was obtained before participation, and withdrawal of consent was permitted at any stage, including after data collection. Audio recordings were transcribed verbatim, anonymized to remove any potentially identifiable information, and assigned participant codes before recordings were subsequently deleted. All data were stored on secure servers in accordance with data protection regulations. Participants received modest compensation in the form of a voucher to acknowledge their time and contribution, consistent with ethical guidance. No participants withdrew consent for the use of their data in this study. Sessions were conducted in person and online (via Microsoft Teams), lasting from 49 to 109 minutes. Data collection and analysis occurred concurrently, adhering to the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist for comprehensive reporting (Multimedia Appendix 1).

Data Collection

Data collection occurred from November 2022 to November 2023. Focus groups (FGs) and semistructured interviews were conducted to gather participants' views. Patient participants were involved in FGs to discuss their shared experiences, while FGs and individual interviews were conducted with HCPs to accommodate time constraints. A semistructured topic guide was developed collaboratively by the research team, informed by existing literature and expert input. The topic guide focused on key elements relevant to the study aims and reflected the

literature and practical insights from clinical practice. This guide was used consistently across both FGs and interviews. Interviews were conducted to complement purposive sampling and address any gaps in representation. These took place either before FGs, to inform key discussion areas, or alongside them for participants unable to attend a group session. FG topic guides and interview schedules were developed and refined by the clinical members of the research team (LEW, AA, AAW, FSM, and AG) and tailored to HCP and patient groups. The topic guides explored the current challenges and limitations in the SMR process that existing advancements in AI and machine learning (ML) can address and the essential components for a user-friendly prescriber feedback system. We also asked participants questions to identify the key components and functionalities needed in a prescriber feedback system to ensure it is useful and user-friendly. Figure 1 depicts the visual representation of the proposed components of an AI-assisted tool (the DynAIRx tool).

Figure 1. Visual representation of proposed components of an artificial intelligence (AI)–assisted tool (the DynAIRx tool [AI for dynamic prescribing optimization and care integration in multimorbidity]).



Data Analysis

Data were analyzed thematically, with coding independently conducted by researchers (AA and SAW). Researchers read transcripts to familiarize themselves with the data. Initial coding, guided by inductive reasoning, was conducted by AA and SAW, who collated and examined codes to identify themes. The interview and FG transcripts were coded concurrently to capture both individual and group perspectives. The multidisciplinary coding team (AA, SAW, LEW, AAW, and FSM), comprising clinicians and researchers, engaged in regular coding clinics in a reflexive practice to ensure rigorous and transparent qualitative analysis. These sessions were used to discuss emerging codes, refine codes, and assess data saturation. Discrepancies were

resolved through discussion with the wider team of researchers and clinicians, ensuring diverse perspectives informed theme development and interpretation. This reflexive approach balanced interpretations and mitigated biases, grounding the analysis in participants' narratives. Themes were defined and supported by quotes, with detailed notes maintained to ensure analytic rigor and plausibility. The dataset underwent hybrid inductive and deductive thematic analysis, with iterative revisions of codes and themes. Data saturation was defined as the point at which no new themes or subthemes emerged from the data concerning the already existing themes, which were richly supported by the data. During coding clinics, the research team compared newly coded transcripts against the developing codes to assess whether additional data contributed to novel insights. Recruitment ceased once all team members agreed that no new codes or meanings emerged from successive transcripts, and the thematic structure was considered sufficiently rich to address the study aims and indicate thematic saturation.

Results

Overview

In total, 6 FGs with HCPs (n=21) and 3 FGs with patients (n=13) were conducted (Table 1). A further 5 semistructured interviews with HCPs took place (Table 2). The interviews were undertaken to explore topics in greater depth and address any gaps in purposive sampling. Moreover, the number of participants in each FG differed based on HCPs' availability. However, this did not impact data analysis or saturation, as all HCPs undertook SMRs and expressed their views and requirements for an AI-assisted tool to allow the SMR process to be more efficient and effective.

Table 1. Participant type and the number of participants who took part in the focus groups (FGs; n=34).

FGs	Participants, n (%)
General practitioner FG1	2 (6)
General practitioner FG2	6 (18)
Pharmacist[a] FG1	3 (9)
Pharmacist FG2	5 (15)
Clinical pharmacologist FG1	3 (9)
Psychiatrist FG (mix of secondary care and prison care)	2 (6)
Patient FG comprising individuals with mental and physical health comorbidities for whom prescribing for mental health improvement could lead to adverse physical health consequences	6 (18)
Patient FG comprising those with complex multimorbidity (≥4 long-term health conditions and taking ≥10 drugs)	4 (12)
Patient FG comprising older people with frailty who were at a high risk of adverse outcomes	3 (9)

[a]Mix of primary and secondary care pharmacists.

Table 2. Participant type and the number of participants who took part in the semistructured interviews (n=5).

Participant	Interviews, n (%)
Primary care pharmacist	1 (20)
Secondary care pharmacist	1 (20)
Policy maker	1 (20)
Secondary care psychiatrist	1 (20)
Postgraduate GP[a] trainee	1 (20)

[a]GP: general practitioner.

HCPs conducted SMRs either proactively or reactively, depending on staff capacity, organizational contracts, and practice size. The presence of a PCN pharmacist facilitated proactive SMRs by ensuring that patients meeting directed enhanced service requirements were identified and invited for an SMR. In contrast, GPs and secondary care clinicians often conducted opportunistic medication reviews. Regardless of how patients were identified for a medication review, HCPs described the significant preparation time required to gather and interpret patient information, citing the lack of efficient methods to identify patients at risk of medication-related harm who would benefit most from an SMR [4]. This prompted discussion on how AI approaches could be used to improve the SMR process, including the potential barriers to the uptake and use of AI-assisted tools to support SMRs.

The following 4 overarching themes were developed from the analysis:

1. Innovative AI potential
2. Optimizing electronic patient record (EPR) visualization
3. Functionality of the AI tool for SMRs
4. Facilitators of and barriers to AI tool implementation

Innovative AI potential referred to the emerging possibilities and future impacts of applying AI technologies in health care contexts. Optimizing EPR visualization concerned the enhancement of clarity, usability, and accessibility of clinical information presented within EPR systems. Functionality of the AI tool for SMRs examined how the AI-assisted tool operated and supported the delivery of SMRs. Finally, facilitators of and barriers to AI tool implementation encompassed the organizational, technical, and human factors that influenced the successful integration and effective use of AI-assisted tools in clinical practice.

These themes were not entirely discrete; they reflected interrelated aspects of participants' experiences and perspectives on AI integration in clinical practice, with points of overlap and influence between them. Aspects, such as system usability, functionality, and perceived potential, often interact within the broader context of AI-assisted tools in health care. Participants' perceptions and responses varied according to their professional or personal role (eg, GP, pharmacist, psychiatrist, and patient), highlighting the need for AI-assisted tools to be sufficiently adaptable to address the differing needs of key stakeholder groups.

Innovative AI Potential

Participants expressed their views on the potential utility and advantage of AI in identifying patients at risk of medication-related harm or those who might benefit most from an SMR. HCPs emphasized the need for a tool capable of comprehensively searching EPRs to identify patients with complex multimorbidity. Such a tool should dynamically adjust search outcomes in real time, prioritizing patients who require immediate SMRs.

There was a desire to see AI-assisted tools that could learn autonomously from the historical health care record to identify which factors are contributing to potential medication-related harm. Participants showed great interest in the incorporation of AI with a health care tool to automate tasks and reduce delays in risk prediction. In addition, participants wanted these tools to show patients' medical history in a holistic way using AI capabilities and have the AI be explainable to understand why and how the patient was triggered for a medication review:

> *If you had a funky IT program that looked at medication, looked at what other stuff was happening, looked at, you know, bloods, these are patients that I'm really worried about. So, you know you're talking about machine learning in your project, one of the things, you know, I think will be really interesting to do would be to actually ask the computer what the predictors for certain harms are. We know patients when they fall for multiple reasons, it's not just medicines, but actually wouldn't it be good to see that these are the key circumstances that patients fall under, and then if those circumstances ever happened that patient would be, you know, triggered for a review.* [Policy maker; interview]

> *It could potentially work in real time as well...having something which is live so constantly producing the order of patients who you should be reviewing based on, I don't know a patient might have been discharged from hospital last night that patient might become a bit more high risk and therefore it needs to review earlier. So it flags upon our systems as a, you know, using the AI that this patient will probably need to review in the next four or five days.* [Pharmacist 2; interview]

Leveraging data analytics with ML was viewed as an opportunity to flag patients on complex medication regimens by assessing their health records and prioritizing those patients at risk of medication-related harm. Moreover, aligning patient risk levels with the GP practices staff capacity within PCNs would ensure that those who need immediate attention are seen promptly:

> *That is a real issue for us. It's a real issue for practice actually. So this is why I think the tools have to be a bit more cleverer than just generating, you know, we can generate a list of patients today and that happens, and PCNs at the moment essentially do that, but what you have to do is almost match the list that's generated to the capacity of the build this so you can, the practice has to say that across my PCN I've got, you know, 100 appointments a week to deal with these sort of patients then the tool has to generate that...People would not switch it on if they felt that it could generate lots of patients you would not then see.* [Policy maker; interview]

The development of an AI-assisted tool to support the SMR process prompted discussions on how ML tools could predict risk, identify prescribing gaps, highlight lifestyle and family history risk predictors, and detect potential adverse drug reactions. Advanced digital health tools with AI-assisted features and data analytics could enhance patient engagement by enabling holistic discussions about the patient's risk trajectories and how their medicines can be optimized to reduce any medication-related risks:

> *There used to be a tool, I think it was developed in Australia or New Zealand, but basically it showed a graph of heart disease and trajectory towards symptoms. And you could have a discussion with patients and you can say well look, if we bring your blood pressure down by this much then this is your trajectory...if we stop you smoking, then this is your trajectory. If you develop diabetes then this is your trajectory, and that was probably the single most powerful tool I had to convince people to optimize things like blood pressure or cholesterol reduction.* [Participant 1; GP FG1]

> *I'm sure that having an AI trawl through drug prescribing gaps would tell us quite a lot about medication that may not be taken when it's supposed to have been. We kind of think about that in terms of people misusing analgesics but actually for the elderly population they'll very often just order it because they don't know how to tell us they don't like it or they don't want to take it anymore because they're very*

> *much of the mindset that doctor knows best and they don't want the conflict. But they'll very often forget to order medication and that can be a giveaway.* [Participant 5; GP FG1]

> *I'm thinking of an example where someone has attended an appointment and mentioned that they think a drug is causing a side effect for them, I would imagine that someone would document experiencing this? Being able to see that would be very helpful to try and further add to why things might have been stopped or why a patient might have stopped taking them and maybe not told anyone.* [Participant 2; pharmacist FG1]

> *We did a piece of work recently on familial hypercholesterolaemia and pulled up a lot of patients we didn't realize had family history of massive cholesterol levels and they hadn't realized it was potentially hereditary.* [Participant 5; pharmacist FG2]

Optimizing EPR Visualization

Participants pointed to the challenges associated with the time required to gather and interpret a patient's medical history, emphasizing the need for an AI-assisted tool that optimizes the presentation of relevant information within the EPR. This included reorganizing readily available data to provide a clearer view of the patient's medical history and social circumstances to produce accessible visualizations of the medication timelines, including what medications were prescribed for what condition. Several participants suggested displaying the patient's medical history in a timeline format, detailing key events, such as medication initiation, titration, or discontinuation, diagnosis dates, and recent relevant blood test results:

> *So something pictorially, which helps represent the information in a clearer way, I suppose. Yeah, maybe more longitudinal kind of...And representation of say, when medications were started and titrated up and previous medications, when they were brought in and when there were stopped.* [Psychiatrist; interview]

> *I suppose my top 5 would be: something that highlights previous courses of the same type of medication or the same class, so, for example, if I type in depression as a code, I want an automatic list of every antidepressant they've been on previously and how long they've been on it and which ones they haven't had, even the new ones that are coming on line. I want a list of when they had prednisolone last if they have chronic lung disease, [and] how many courses in the last year they've had without searching for it.* [Participant 1; GP FG1]

AI-assisted tools that reduce the time involved in routine tasks, such as finding information, calculating doses, or assessing disease risk, were welcomed. HCPs were conscious of ensuring that any AI-assisted tool did not overwhelm the user with excessive "pop-up" functions on the display and should not overburden the user's view. There was strong support for a visual timeline that would detail the patient's diagnosis and prescribing and deprescribing journey, along with relevant investigations, diagnostic letters, which specialty diagnosed the condition and started the medication, and the reasons for certain medicine changes. Figure 2 presents the suggested AI-assisted tool features:

> *I've been dreaming about the timeline you showed [laughs] to be able to, in the way that I've imagined it, at the click of a button know...when all the drugs were started and what else was diagnosed around that time [would be] great. And then I don't have to spend any time trying to put that together, that information is there for me. Thinking outside of a hospital setting, if I've got recent bloods and any sort of risk calculations that I want already there on the page from the most recent things, [that is] even better. The amount of time [it would save]; the computer system I work with tells me eGFR, [but] I spend a good chunk of my day calculating everyone's creatinine clearance.* [Participant 2; pharmacist FG1]

Participants also described the challenges around investigating the indication for each prescribed medicine, stating that any AI-assisted tool should incorporate the medication indication:

> *I think for me the most important thing that's missing is indication-based prescribing. Because when we are doing our medicine reviews just trying to work out why anyone's on, you know they could be on an ACE inhibitor, why are they on it, you know, they could be on citalopram, you know, why are they on it. And then it's almost impossible to stop it if you can't work out why someone started it to begin with. So, I think, for me that would be the key initial thing.* [Participant 1; polypharmacy FG]

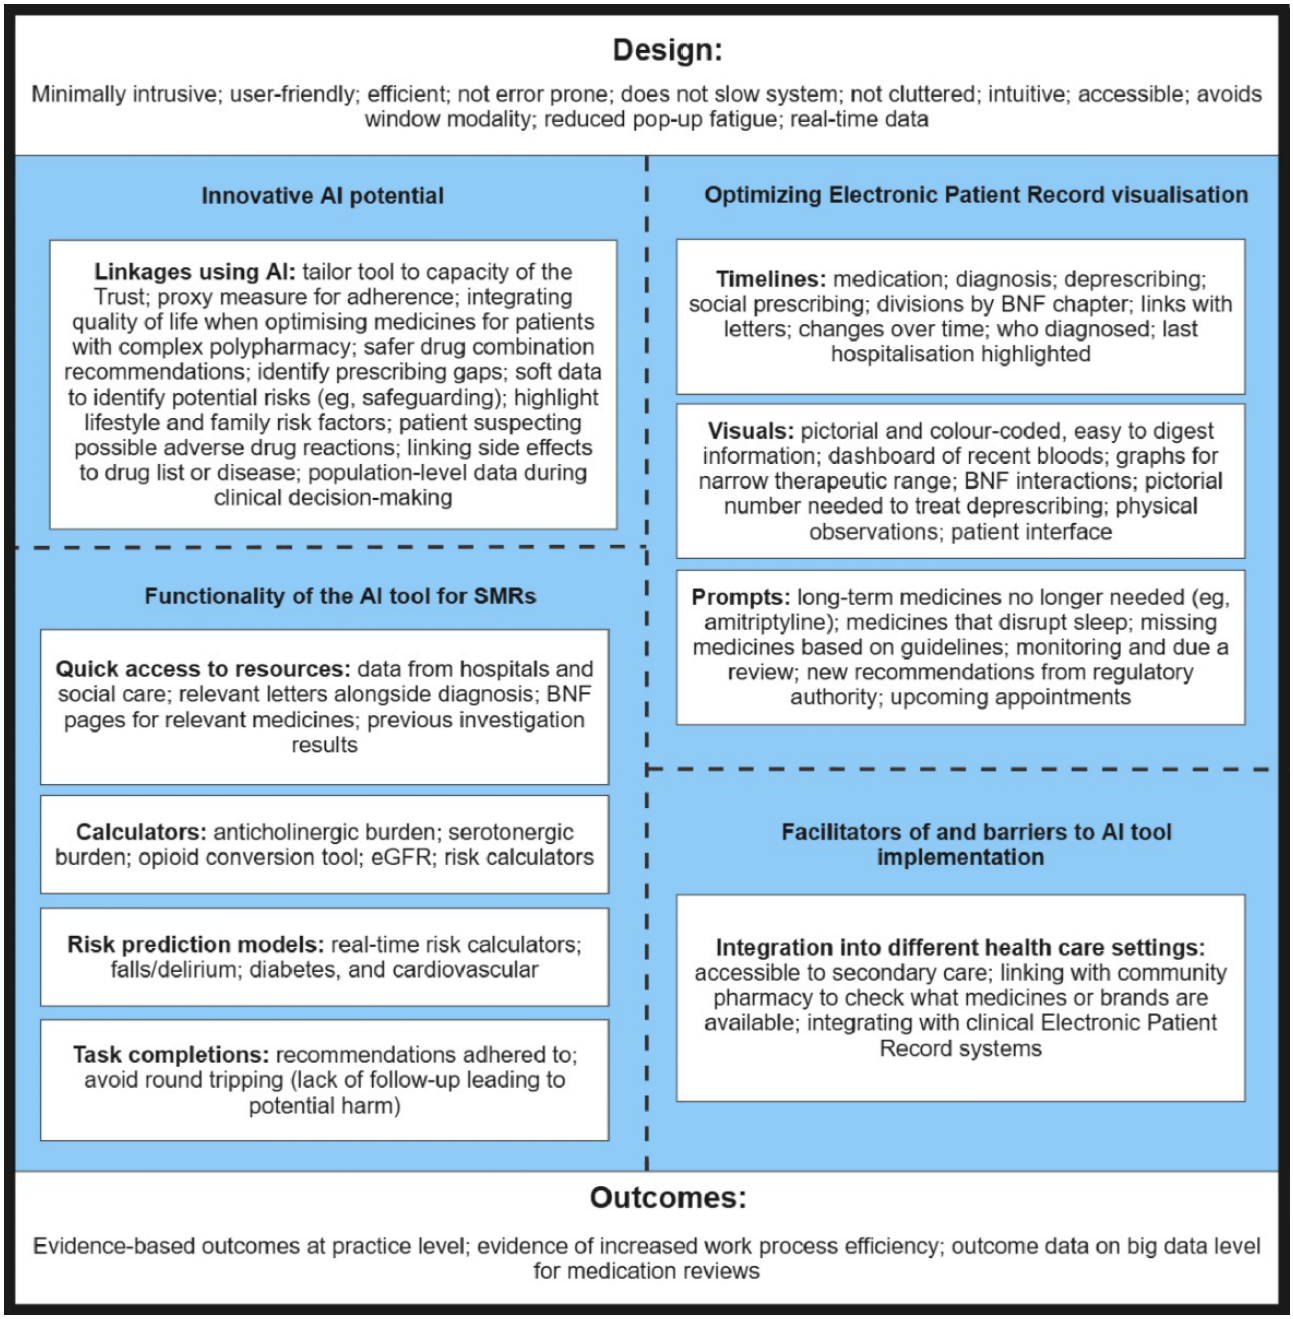
Participants described how information within a patient's EPR should be visualized, focusing on rearranging and presenting the information in a more intuitive and insightful way to enhance understanding of the patient's medical journey and provide the information in an easily understandable format to support decision-making. They recommended color-coding blood results, highlighting the most recent hospitalization or medication review, and flagging risky medication combinations. One participant noted the following:

> *Reviewing the bloods was quite time-consuming at times, but equally, it was color-coded, so if it was in red it means it's bad news. If it's not in red, it's OK. So, a quick eyeball of words can be often sufficient.* [Pharmacist 2; interview]

Another participant added the following:

> *The kind of things that we need [are] things like...when was their last medication review done or when was the last SMR done, for example? When was the last hospitalization event, for example? Have they been hospitalized or discharged recently? Then it'd be nice to visualize, you know, and the combinations of drugs which could be risky.* [Pharmacist 2; interview]

Figure 2. Suggested features for the development of an artificial intelligence (AI)–assisted tool for use in medication reviews. BNF: British National Formulary; eGFR: estimated glomerular filtration rate; SMR: structured medication review.



Functionality of the AI Tool for SMRs

Participants articulated their preferences for the functionality of the AI-assisted tool, particularly emphasizing the need to avoid "pop-up fatigue." They suggested implementing specific, targeted pop-ups rather than numerous interruptions that could disrupt workflow. One participant remarked as follows:

> *Any pop ups that you've just got to click through does add even seconds to your working day in each patient record so that can be annoying.* [Participant 1; GP FG2]

Instead, participants preferred notifications for critical issues, such as missing medications in a patient's record that align with guidelines. For example, a participant stated the following:

> *If a patient has recently had a myocardial infarction...it pulls out your main groups of drugs from the NICE guidelines and flash up oh they're not on an ACE inhibitor and you've got to say why.* [Participant 3; pharmacist FG1]

Similarly, they recommended notifications for medications needing review, such as long-term prescriptions of amitriptyline:

> *Just to make people think, actually. This thing which was started for sleep isn't helping.* [Psychiatrist; interview]

Participants also recommended pop-ups for new guideline recommendations:

> *To meet the Commission of Human Medicines and Medicines and Healthcare products Regulatory*

> *Agency recommendations that came in in December, a way of being able to see what antiepileptics have been tried for someone and how long they've been on valproate would really inform the review process.* [Participant 2; pharmacist FG1]

Participants valued AI-assisted tools that enhanced workflow productivity by providing quick access to resources, such as the *British National Formulary* or NICE guidelines based on prescribed medicines or flagged blood test results. One GP noted the following:

> *I want a dashboard of most recent blood tests and current guidance checked against that for where there's missing [medication] gaps, just those things alone would probably save about 2- or 3-weeks' worth of work across my practice per year.* [Participant 1; GP FG1]

In addition, participants highlighted the need for more efficient access to hospital discharge letters and relevant patient information, which often reside in separate electronic systems, such as EMIS (an EPR system) and Docman (document management system). One participant stated the following:

> *If you could draw up relevant letters alongside diagnosis so that you don't have to then trawl through a different system or then write to the GP to request added information on certain diagnosis.* [Psychiatrist; interview]

Furthermore, automated calculators for clinical decision-making, such as anticholinergic burden calculations, estimated glomerular filtration rate, and opioid conversion calculators, were seen as valuable tools to reduce time and enhance efficiency. For example, a GP shared the following:

> *I want automatic opioid conversion so that when they're on tramadol, co-codamol, oramorph, it just gives me a single figure to aim towards and show them, you know, we are at horse tranquilizing level or at dragon tranquilizing level and we need to kind of bring it down.* [Participant 1; GP FG1]

SMRs, whether proactive or opportunistic, often require multiple appointments and may necessitate further investigations by another HCP in a different setting, such as a hospital. Participants were concerned that current systems might fail to notify HCPs of patients needing follow-up care, potentially leading to harmful outcomes for the patient:

> *One of the big issues with medical software is not doing what you describe. Computer programmers call it "round tripping," so basically things aren't followed up and the loop isn't closed, and we see huge amounts of error in medicine because of it. For example, we will refer and then it's off our radar and it's on someone else's radar and then they don't show up at the hospital, and then all of a sudden six months down the line they end up with a malignancy, and then it's back to the original person who referred problem because that loop wasn't closed or the data wasn't followed up. So, having some form of checking system would hugely reduce error and risk within medicine, particularly when it comes to prescribing. So, for example, I've referred them to the physio, the physio then closes that loop when they seem them and then that's dealt with, or the physio does a hydrocortisone injection for example, which I may not need to know about unless I then send them somewhere else, or they are on anticoagulants, or something like that. So, having a tool that ties up those loose ends would be worth its weight in gold I think, particularly in terms of huge amounts of risk reduction.* [Participant 1; GP FG1]

Facilitators of and Barriers to AI Tool Implementation

Participants were curious to understand where DynAIRx might be embedded and how it will be adopted in practice. The main goal was to ensure that any new software does not interfere with current work processes. They described concerns about the cost of adopting it in practice, information governance, and potential medico-legal concerns:

> *I know that I understand X's point about having it that you are able to record what decisions you made within the tool but I wonder if it might be preferable to have a way of a text summary that could be then copied from the tool into the notes. Or, even a way of having a screen shot into letters so, you know, if there were every any questions what was it that you were looking at on the day what information was the tool giving you and if you then made an interesting decision based off that information, that's still your decision. But you've clearly got what is was that you could see.* [Participant 2; pharmacist FG1]

Incentivizing the use of the tool to improve uptake was seen as crucial, with participants suggesting that DynAIRx should be offered as an option to HCPs. They recommended explaining the benefits of using DynAIRx as an additional supportive tool alongside traditional EPR systems, providing examples, such as improvements in efficiency, ease of use, and quick access to information. In addition, HCPs recognized that technology is a double-edged sword, which could either reduce or increase the gap between the HCP and the patient. Consequently, HCPs were open to incorporating a patient interface that would present information pictorially to support shared decision-making. Patients indicated that they would find this useful as they were keen to take a more active role in decision-making. However, many patients were unaware of medication review–related services available to help optimize their medicines:

> *I have never been involved in a review either...Would it just be the GP?...I am going to ask this time whether I can be involved.* [Patient 3; patient, multimorbidity FG]

HCPs stated that, from their experience, patients are fairly comfortable with technology, which was echoed in the patient FGs:

> *I have no problem whatsoever with using [AI] tools, especially if it is to back up the thought process.* [Patient 4; patient, multimorbidity FG]

> *What I think, being a patient, is that you need to have the trust from the GP and the GP pharmacist, whoever is prescribing and using AI, they need to educate people. They need to raise awareness about it. And then you have the trust with the GP then you feel comfortable.* [Patient 1; patient, multimorbidity FG]

However, this did not necessarily mean that all patients were able to use technology themselves to communicate or provide feedback to HCPs through surveys and questionnaires, suggesting the need to consider potential digital exclusion:

> *Not digitally everybody, there are some barriers, language barriers, cultural barriers, and economic barriers for the disadvantaged so we have to think about equity as well. So these barriers are obviously not everything, but we should open up, give the opportunity to all those populations to have the opportunity to discuss and take it rather than have both, it should be both.* [Patient; complex multimorbidity FG]

While HCPs expressed a desire for risk-prediction tools within the DynAIRx software, some remained skeptical about these tools. They emphasized the importance of providing evidence that the model had been validated or that the software itself improved patient outcomes:

> *One of the reasons why people may not use it is that they, clinicians often ask for evidence, so they need to see evidence. A published paper or a trial of actually being useful. So does it improve outcomes with patients? These one of the biggest barriers that I've come across in my time with tools.* [Pharmacist 2; interview]

In addition, the need to ensure confidentiality and consent in AI-assisted tool use is paramount, given the amount of data that would be incorporated into DynAIRx. Patients were aware of the fast-paced innovations taking place in technology and the expectation that technology should be included in health care practice:

> *The world is changing. First we heard about the autopilot, now they are testing [cars] without a driver, virtual GP...now AI in the medical sector as well. The world is changing.* [Participant 2; patient]

Discussion

Principal Findings

Our study outlines the user requirements for the development of an AI-assisted tool to improve the process of conducting an SMR involving patients with complex multimorbidity and polypharmacy. This includes optimizing EPR visualization with a focus on developing patient timelines that outline the patient's medical journey to include when a condition was diagnosed, associated medicines prescribed for that condition, and any associated laboratory results, to name a few. Moreover, participants described the preference for evidence-based outcomes and the use of explainable AI to identify patients at risk of medication-related harm who would benefit from an SMR, determine their risk trajectory over time, and align those patients to practice staff capacity. By "explainable AI," we mean models or algorithms designed with transparent logic or post hoc interpretation methods (eg, feature-importance heatmaps and rule-based approximations) that allow HCPs to understand why a particular patient was flagged as high risk rather than relying on opaque "black box" predictions. From our findings, it is clear that HCPs require an AI-assisted tool that will streamline their work processes when conducting an SMR to easily find information related to the patient and incorporate any risk prediction models. Studies show that CDSSs have the potential to improve process outcomes [15,16]; however, access to CDSSs alone does not guarantee user acceptability or uptake [17]. Concerns remain that complex clinical decision-making, particularly for patients with multimorbidity and polypharmacy, may not be easily translated into algorithms [18] or, at the very least, may have HCPs view the validity of algorithms with some skepticism [19]. This can be seen in the literature that reflects HCP preference for knowledge-based CDSSs over non–knowledge-based CDSSs [19,20]. Despite this, studies show that the lack of algorithm complexity in CDSSs can frustrate HCPs, particularly in how information is presented [18,21]. Moreover, user-centered design is crucial in the development of a CDSS to optimize how information is presented to HCPs to manage cognitive load, alert fatigue, and the impact on workflow [22,23].

Comparisons With Prior Work

AI-assisted tools designed to assist in SMR processes must be tested to ensure they effectively identify both patients who are at risk of medication-related harm and those who have the greatest capacity to benefit from an SMR. These 2 groups are not necessarily synonymous, as some variables that may contribute to harm are not modifiable (eg, very advanced age and frailty), whereas the capacity to benefit from an SMR may be determined by modifiable factors (such as identification of prescribing cascades, drug-drug or drug-disease interactions, and adverse drug reactions). The tool must be sensitive when identifying patients at high risk and display medicines that could be optimized or deprescribed efficiently, enabling future evaluation of medication-related interventions using available data. Patients taking part in an SMR are also likely to have multiple appointments and be referred to different specialists, making it difficult for the HCPs who initiated the SMR to follow this journey. Few studies have explored the interoperability between primary and secondary health care settings, which is essential for effective communication and coordination between HCPs, and is perceived to have a high impact on patient safety [24,25]. Our findings indicate a clear need for an AI-assisted tool to support clinicians and patients during consultations. An integrated system within the EPR software could help summarize and visualize patient journeys and medicine-related information, present personalized risks of harms and benefits of medicines combinations [26], highlight the uncertainties in these risks, and support shared decision-making with patients. While the findings of this study are based on anticipated rather than observed experiences with an AI-assisted tool, engaging end users at the outset before tool development enables the design of an AI-assisted tool that is contextually relevant, cost-effective, and more likely to be adopted in practice [27,28].

Future stages of this work will involve the development and testing of a prototype to validate and refine these preliminary findings through direct user interaction and usability testing, as demonstrated by previous studies [29-32]. This iterative, user-centered process will help ensure that the AI-assisted tool is not only functional but also implementable in real-world settings.

Previous literature highlights the preference among HCPs for knowledge-based over non–knowledge-based CDSSs, which aligns with concerns about the validity and acceptability of algorithms in complex clinical scenarios [19,20]. While frustrations with simplistic CDSS algorithms have been noted [14], our study contributes additional evidence emphasizing the need for user-centered design to address cognitive load, alert fatigue, and workflow impact. The clinical decision support five rights model states that the right information should be presented to the right person, in the right format, via the right channel, and at the right time [16]. Studies on the development of CDSSs emphasize the importance of understanding the needs of users and receivers during the early stages of software development [17,18]. Interoperability between health care settings, while unexplored in previous work, emerged as a critical component for effective SMR implementation and improved patient safety in this study [10,19]. Integrated care boards link primary and secondary care data across their local areas with input from EPR vendors, such as EMIS and SystmOne. An approach consisting of fully linked local data, with minor regional differences in data formatting, may begin to emerge in the coming years as one way to proceed. Efforts, such as the National Health Service Federated Data Platform, aim to unify these actions across the nation and may provide additional clarity on this approach in the coming years. The next stage of the DynAIRx project will involve learning from the user requirements of our stakeholder groups to develop prototypes of an AI-assisted tool. We anticipate the developed prototypes to likely fall under the category of a knowledge support system, which provides HCPs with knowledge that already exists, such as contextual information about a patient drawn from several sources, including historic data on clinical outcomes from comparable patient groups, medical knowledge, and AI to support HCPs during consultations [29,33,34].

To bridge our user-centered requirements with real-world adoption, we recommend framing the development and deployment of the AI-assisted tool for SMRs within established implementation science frameworks, such as the Consolidated Framework for Implementation Research [35]. Under the Consolidated Framework for Implementation Research, the intervention characteristics (eg, usability, adaptability of the patient-timeline visualization, and risk-prediction algorithms), the inner setting (practice culture and EPR interoperability), the outer setting (national data-linkage initiatives, such as the National Health Service Federated Data Platform), the characteristics of individuals (clinician attitudes toward explainable AI), and the implementation process (engagement, training, and feedback loops) all warrant deliberate planning and tailoring.

A staged implementation approach could proceed as presented in Textbox 1.

Textbox 1. Staged implementation approach.

Before implementation (exploration and preparation)

- Conduct targeted workflow analyses in a small number of pilot practices to refine how the timeline and risk outputs map onto existing structured medication review processes
- Engage local electronic patient record vendors (eg, EMIS and SystmOne) to configure interoperability and data-security protocols

Implementation (initial rollout and training)

- Deploy the prototype in 3 to 5 “early adopter” practices, offering hands-on workshops and “superuser” support
- Establish a feedback channel (eg, biweekly focus groups) to iteratively refine

Sustainment (scale-up and longitudinal support)

- Expand to additional practices, embedding the tool within organizational reporting cycles
- Integrate decision-support outputs into routine safety audits and continuing professional development activities

Building on our staged implementation plan, future studies should focus on prospective validation of the AI-assisted tool for SMRs in live clinical settings. Key next steps include the following:

- Pilot effectiveness trials—randomized or stepped-wedge designs comparing standard SMR to SMR with AI support, measuring both process (eg, time per review and alert response rates) and patient-level outcomes (eg, incidence of medication-related harm)
- Usability and acceptability—mixed methods evaluations combining system-log analytics with qualitative interviews to understand how clinicians interact with features such as patient timelines and risk predictions
- Subgroup analyses—examining performance across different patient demographics and varying levels of multimorbidity complexity to ensure equitable benefit

Limitations

This research is part of a larger qualitative study exploring the barriers to SMRs and potential AI-assisted tools. Given the focus on digital-driven solutions, the HCP participants likely included those with a particular interest in such innovations, although efforts were made to include a diverse range of HCPs

from different practice backgrounds, regions, and care settings to mitigate this bias and help strengthen the generalizability of our findings within the context of SMR practices. Moreover, our eligibility criteria focused on recruiting HCPs who are actively involved in conducting medication reviews to explore the barriers to efficient and effective SMRs and how AI-assisted tools may address these barriers [4]. Some FGs had fewer participants due to the competing demands on clinicians' time. However, the data collected were rich and contributed significantly to achieving thematic saturation. While this study provides valuable insights into the user requirements for developing an AI-assisted tool, certain limitations should be acknowledged. First, the diversity of the patient group included in this study may not fully represent the broader patient population, particularly in terms of familiarity with AI-assisted tools. Patients' knowledge and understanding of such systems may vary significantly, potentially influencing the feedback provided. As a result, the findings may not fully capture the perspectives of patients with lower levels of digital health literacy or those who have more experience engaging with AI-assisted tools in clinical settings. Second, the study captures participants' hypothetical perceptions of the AI-assisted tool rather than their experiences of real-world implementation and use. While the findings highlight anticipated benefits and potential facilitators, they may not fully reflect the complexities of adoption and sustained use in practice. Consequently, the research team will develop a prototype based on our findings, which will be tested to validate results from this study and refine and iterate the prototype through a series of think-aloud sessions and semistructured interviews with HCPs. This will ensure the prototype is developed based on user requirements and allow the user to explore the utility of the tool. Moreover, we anticipate a future evaluation of the AI-assisted tool by implementing it into the HCPs' routine workflow. Future research involving live system implementation and longitudinal evaluation would be valuable in assessing the feasibility and actual impact of AI-assisted tool integration in health care settings.

Conclusions

This study highlights the potential of AI-assisted tools to enhance the SMR process for patients with complex multimorbidity and polypharmacy and the user requirements to develop an AI-assisted tool. AI-assisted tools may have the potential to improve patient identification for an SMR, assist the HCP to optimize patient medication by optimizing the EPR visualization of the patients' medical and social history, and support shared decision-making between HCPs and patients. In order to realize the full potential of AI-assisted tools for SMRs, national and local policy makers should consider earmarking targeted funding streams, such as through the National Health Service Digital's Innovation Accelerator or PCN transformation budgets, to subsidize early implementation and integration with EPR systems. Embedding AI-SMR competencies into continuing professional development requirements for pharmacists and GPs, alongside dedicated training grants, will help build workforce capability and ensure equitable uptake. Finally, linking reimbursement incentives (eg, enhanced quality and outcomes framework points to multimorbidity reviews that use validated AI support) could further drive adoption and standardize best practice across PCNs. However, to ensure successful implementation, it is essential to address concerns, such as cognitive load, alert fatigue, and system interoperability. The findings underscore the importance of developing explainable, evidence-backed tools that align with clinical workflows and demonstrate clear benefits to patient outcomes. Ultimately, integrating such tools into an EPR has the potential to improve the efficiency and effectiveness of SMRs, benefiting both patients and health care systems.

Abstract

Background: Developmental dysplasia of the hip (DDH) is a common pediatric orthopedic disease, and health education is vital to disease management and rehabilitation. The emergence of large language models (LLMs) has provided new opportunities for health education. However, the effectiveness and applicability of LLMs in education with DDH have not been systematically evaluated.

Objective: This study conducted an integrated 2-phase evaluation to assess the quality and educational effectiveness of LLM-generated educational materials.

Methods: This study comprised 2 phases. Based on Bloom's taxonomy, a 16-item DDH question bank was created through literature analysis and collaboration. Four LLMs (ChatGPT-4 [OpenAI], DeepSeek-V3, Gemini 2.0 Flash [Google], and Copilot [Microsoft Corp]) were questioned using standardized prompts. All responses were independently evaluated by 5 pediatric orthopedic experts using 5-point Likert measures of accuracy, fluency, and richness, the scales of Patient Education Materials Assessment Tool for Printable Materials, and DISCERN. The readability was measured by a formula. The data were examined using Kruskal-Wallis tests, ANOVA, and post hoc comparisons. In phase 2, an assessor-blinded, 2-arm pilot randomized controlled trial was conducted. A total of 127 caregivers were randomized into an LLM-assisted education group or a web search control group. The intervention included structured LLM training, supervised practice, and 2 weeks of reinforcement training. Measured at baseline, postintervention, and 2 weeks following, the outcomes were eHealth literacy (primary), DDH knowledge, health risk perception, perceived usefulness, information self-efficacy, and health information-seeking behavior. Cohen *d* effect sizes and linear mixed-effects models were used in an intention-to-treat manner.

Results: There were significant differences between the 4 LLMs concerning accuracy, richness, fluency, Patient Education Materials Assessment Tool for Printable Materials Understandability, and DISCERN (P<.05). ChatGPT-4 (median 63.67, IQR 63.67-64.67) and DeepSeek-V3 (median 63.67, IQR 63.33-64.67) generate more accurate text than Copilot (median 59.00, IQR 58.67-59.67). DeepSeek-V3 (median 64.00, IQR 64.00-64.00) was language richer than Copilot (median 52.33, IQR 51.33-52.67). Gemini 2.0 Flash (median 72.67, IQR 72.33-73.00) was more fluent than Copilot (median 65.67, IQR 63.33-65.67). In phase 2, the intervention group showed higher eHealth literacy at T1 (33.62, 95% CI 32.76-34.49; d=0.20, 95% CI 0.13-0.56) and T2 (33.27, 95% CI 32.38-34.17; d=0.36, 95% CI 0.01-0.80), greater DDH knowledge at T1 (7.87, 95% CI 7.48-8.25, d=0.71, 95% CI 0.33-1.11) and T2 (7.12, 95% CI 6.72-7.51; d=0.54, 95% CI 0.17-0.96), and slight improvements in health risk prediction and perceived usefulness.

Conclusions: Mainstream LLMs demonstrate varying capacities in generating educational content for DDH. They generated DDH caregiver education materials that were associated with modest improvements in eHealth literacy and knowledge. Although LLMs can address general informational needs, they cannot completely substitute clinical evaluation. Future research should focus on optimizing plain language, refining dialogue design, and enhancing audience personalization to improve the quality of LLMs' materials.

KEYWORDS

large language models; developmental dysplasia of the hip; health education; content generation; mobile phone

Introduction

Background

Developmental dysplasia of the hip (DDH) is a common pediatric orthopedic condition affecting 1%-3% of infants, with a higher prevalence in girls and more frequent involvement of the left hip [1]. If undiagnosed or untreated early, DDH can lead to gait abnormalities, chronic pain, and early osteoarthritis, substantially affecting the quality of life [2]. Early diagnosis and health education are critical for improving prognosis. Delayed diagnosis and treatment often require complex surgery, which not only increases the difficulty of treatment but may also result in further functional deterioration [3,4]. Traditional educational methods are limited by time and resources, making it difficult to meet patients' diverse informational needs. The emergence of artificial intelligence (AI) has provided new opportunities for health education.

In the broader field of digital health communication, AI-based conversational systems are increasingly being explored as tools to provide convenient and efficient services to meet people's diverse needs. Currently, large language models (LLMs), such as ChatGPT, Google Gemini, Microsoft Copilot, and DeepSeek, are applied in health communication, including disease diagnosis [5], treatment recommendation [6], health education [7], and clinical decision-making [8]. For example, ChatGPT enables interactive discussions that tailor standardized medical information to individual patient needs, helping bridge communication gaps between clinicians and patients [9,10]. Although AI has demonstrated great potential in medical education, its use in patient-facing communication raises concerns. LLMs may provide erroneous medical advice [11], propagate outdated medical views [12], or fabricate nonexistent medical cases to generate "hallucinations" [13]. At the ethical and regulatory levels, challenges arise from the model's "black box" decision-making, including unclear accountability, difficulties in defining legal responsibility, privacy breaches, and lagging regulatory frameworks. These issues directly jeopardize users' safety, potentially leading to misdiagnosis, delayed treatment, and other forms of direct harm. Furthermore, most generated content maintains a university reading level, which may pose comprehension challenges for users without higher education [14]. These risks underscore the need for systematic evaluation before integrating such tools into health education.

While prior studies have primarily examined the accuracy or readability of LLM-generated content [15], few have connected content quality with its actual educational impact on end users. The extent to which LLM-generated materials can effectively support caregivers' understanding and health literacy in specific conditions, such as DDH, remains unexplored. In DDH, caregivers have to not only comprehend specialized medical concepts but also actively recognize abnormal signs in children and make timely decisions [16]. Due to the professional complexity of orthopedic knowledge and the unique nature of pediatric disorders, basic health literacy abilities are necessary for caregivers. Therefore, the different levels of digital literacy among caregivers may make it more difficult for them to properly understand information produced by LLMs. To address this, the present study systematically evaluated multiple mainstream LLMs through expert assessment and a pilot randomized controlled trial (RCT) among caregivers. By integrating expert evaluation with caregiver validation, this study extends the current AI in health communication research from theoretical assessment to empirical verification.

Objective

Therefore, this study aimed to provide a comprehensive evaluation and verification of LLM-generated education materials for DDH. The first phase assessed the educational quality of the outputs generated by 4 mainstream LLMs (ChatGPT-4, DeepSeek-V3, Gemini 2.0 Flash, and Copilot) through expert ratings of accuracy, understandability, actionability, and readability. The second phase involved a pilot RCT among caregivers to evaluate the actual educational impact of these materials, including digital literacy, DDH knowledge acquisition, health risk perception, information self-efficacy, perceived usefulness, and health information-seeking behaviors. This study bridged the gap by integrating the quality assessment of LLMs with RCT to validate their content reliability and educational impact. It offered evidence for the safe and effective use of LLMs in clinical education.

Methods

Theoretical Framework

The taxonomy by Bloom et al [17] served as the guiding pedagogical framework for designing the educational content. The taxonomy organizes cognitive processes into 6 hierarchical levels: remember, understand, apply, analyze, evaluate, and create, which is widely used to structure learning objectives and instructional materials. As users often need to acquire not only

basic factual knowledge but also practical decision-making skills, this hierarchical model provided a structured approach for determining which levels of cognition should be targeted in education [18].

Guided by this framework, we developed a 16-item question bank that intentionally spanned different cognitive levels, ranging from foundational knowledge such as definitions and symptoms to more complex tasks such as interpreting clinical scenarios or making care decisions (Table 1). This ensured that the LLM-generated responses covered the breadth of learning needs relevant to caregivers. Bloom's taxonomy, therefore, supported the construction of a comprehensive and pedagogically meaningful learning set, helping align the generated content with education requirements.

Table 1. Question bank framework based on Bloom's taxonomy.

Bloom's taxonomy and part	Content
Remembering	
Basics	"What is [disease name]? Please explain its main features and potential effects in simple language."
Anatomy and effects	"Who is most likely to develop [disease name]? How common is it?"
Understanding	
Etiology and risk factors	"Will [disease name] have a long-term impact on my quality of life? What aspects should I pay special attention to?"
Symptoms and early recognition	"What parts of the body does [disease name] mainly affect? What do these parts do in a healthy state?"
Applying	
Physician examination and diagnosis	"What symptoms or consequences may arise if these parts are damaged? Can you provide specific examples?"
Emergencies	"What are the main causes of [disease name]? What risk factors may increase the chances of developing it?"
Analyzing	
Hospital treatment and rehabilitation	"What lifestyle habits or environmental factors increase the risk of developing [disease name]? How can I prevent it?"
Medication management	"If I have a family history, is my risk of developing [disease name] higher? What preventive measures should I take?"
Pain management	"What are the main symptoms of [disease name]? What signs indicate the disease is worsening? Should I seek immediate medical attention?"
Evaluating	
Postoperative management	"What methods do doctors usually use to confirm the diagnosis of [disease name]? What is the purpose of each test?"
Creating	
Daily living and health management	"What indicators are most important in test results? How do these results reflect the severity of the disease?"
Mental health	"After confirming the diagnosis of [disease name], do I need to schedule regular follow-ups? How often should I have them and what should be checked?"
Digital tools and management	"What symptoms indicate that I need to seek immediate medical attention?"
Expanding[a]	
Education and support resources	"How should I handle and self-monitor during an emergency situation?"
Social and economic impact	"What treatments will I receive during hospitalization? What is the purpose of each treatment?"
Future planning and visioning	"How can I prevent infections or other complications during hospitalization? What can family members do to assist with recovery?"

[a]Not part of Bloom's taxonomy; it is an extension of this study.

Study Design

The evaluation study had 2 phases. Phase 1 was a cross-sectional study in which physicians evaluated the answers provided by the LLMs. Phase 2 was a 2-arm pilot RCT comparing health education using LLMs with web-based searches.

Phase 1: Expert Evaluation Study

Model Testing

Based on Bloom's taxonomy, we collected and categorized common questions regarding DDH. We also reviewed clinical guidelines [19-23] to identify the key areas of knowledge. Using this information, an initial question bank was developed, which

was subsequently refined and finalized through expert review. Each question was guided by a harmonized prompt paragraph: "Using developmental dysplasia of the hip (DDH) in children as an example, answer the following questions in detail, ensuring the content is easily understandable for non-medical professionals. Life-like examples and situations can be incorporated to help readers better grasp the information. Please reduce the number of syllables to make the sentence simpler." All the generated texts and the complete question bank are provided in Multimedia Appendix 1. Each model generated educational materials based on 16 question banks, and the experiment was repeated 3 times for a total of 192 generations (4 models × 16 question banks × 3 times). Data were collected from January to February 2025. ChatGPT-4, DeepSeek-V3, Gemini 2.0 Flash, and Copilot were evaluated; no experimental, beta, or preview releases were included. The experiments were performed under the default settings of the web interfaces without modifying the generation parameters. To ensure reproducibility and independence of the outputs, each prompt was regenerated 3 times by establishing a new session for each run with the same original prompt. All outputs, including identical or similar responses, were retained to reflect the intrinsic variability of the models.

Assessment of Quality and Readability

Quality assessment tools as primary outcomes included (1) a Likert scale for assessing three items of accuracy, fluency, and richness of the material, scoring 16 questions on a scale from 1 to 5, with higher scores indicating better performance; (2) the DISCERN tool [24], which assessed the overall quality of the educational material, with a total of 16 entries, scoring on a scale from 1 to 5, with higher scores indicating better quality; and (3) the Patient Education Materials Assessment Tool for Printable Materials (PEMAT-P) [25], which contains 17 items measuring understandability and 7 items assessing actionability. These were reduced to 10 and 4 to accommodate the textual output with a 70% passing line based on the guidelines. During the evaluation process, each material was independently scored by 5 evaluators. The scores from evaluators were retained for subsequent data analysis.

Readability assessment tools as secondary outcomes included (1) the Flesch-Kincaid Reading Ease (FKRE), (2) the Flesch-Kincaid Grade Level (FKGL), and (3) the Simple Measure of Gobbledygook (SMOG) index, chosen for their widespread use and reliability in assessing text readability. All 3 score calculations involved the total number of words, sentences, and syllables. The FKRE measured the simplicity of the text, with scores ranging from 0 to 100, with higher scores indicating better readability. The FKGL represented reading level grade, with lower FKGL and SMOG indicating better comprehension and higher scores indicating more complex language. Scores above 60 or below sixth grade were the recommended reading levels for the general public. Readability scores were calculated using a web-based readability calculator (Readable; Added Bytes). The detailed formulas are provided in Multimedia Appendix 2.

Expert Evaluation

The material generated by the LLMs was independently assessed for quality. The material generated by the LLMs was independently assessed by 5 pediatric orthopedic physicians with expertise in DDH, selected through rigorous predefined criteria: (1) ≥10 years of clinical experience in DDH diagnosis or treatment; and (2) evaluators completed standardized training on the assessment rubric before this study, using the DDH guidelines as the gold standard [19-23]. To ensure blinding, the LLM outputs were made anonymous by an independent researcher who replaced the model names with random codes. The evaluators confirmed that they could not infer the identities of the LLMs or determine if repeated outputs came from the same model. Interrater reliability was assessed for each outcome dimension using the intraclass correlation coefficient (ICC). ICC values were interpreted as follows: <0.5=poor, 0.5-0.75=moderate, 0.75-0.9=good, and >0.9=excellent agreement.

Phase 2: Pilot RCT

Participants

Participants were recruited through digital media advertisements and physician referrals. Eligibility criteria included (1) being aged ≥18 years, (2) being caregivers of children aged 0-14 years, (3) having the ability to read and understand words, and (4) having internet access. Exclusion criteria included (1) having severe hearing or visual impairment; (2) having severe schizophrenia, major depression, bipolar disorder, and other mental illnesses; or (3) participation in other related studies.

Sample Size

Power analysis was performed using G*Power 3.1.9.7 based on similar educational intervention studies [26]. A medium effect size (Cohen d=0.65) was anticipated for the primary outcome of performance, with 2-tailed α=.05, power of 0.8, and at least 38 participants per group being required. Accounting for an expected 20% attrition rate, the target sample was 49 participants per group (total n=98). There were 127 participants in the final sample (62 in the control group and 65 in the intervention group).

Randomization and Blinding

Recruitment took place in the Third Affiliated Hospital of Southern Medical University and community support groups. The researchers generated a computer-generated list and sealed it in an opaque envelope. Before the start of the intervention, research assistants who were not involved in hospital assessments or interventions opened the envelopes and assigned participants at random to the intervention or control group. Following informed consent, eligible participants meeting the inclusion and exclusion criteria were randomly assigned in a 1:1 ratio to either the trial or control group. The blinding of participants was not feasible due to the nature of the intervention, but the research team remained unaware of group assignments until this study concluded. Data analysts who conducted the final analyses were masked to participant identities throughout. Due to the nature of the intervention, participant blinding was not possible. However, group allocations were not disclosed to the research team until the

trial was finished. Throughout, participant identities were concealed from the data analysts.

Control Group

Participants in the control group received standard web-based educational materials prepared by clinical experts. These materials were retrieved from official sources (eg, [27]). Participants were asked to read independently, simulating a typical web-based health information-seeking behavior.

Intervention Group

All researchers received standardized training to ensure consistent delivery of DDH-related information and LLM education. The intervention was delivered to participants by face-to-face communication. First, the participants were introduced to the foundational concepts of LLMs, including basic mechanisms, application categories, and core interaction capabilities. Second, a standardized consultation framework was introduced, covering device access, platform login, dialogue initiation, and structured prompt formulation. The required background information included demographic and clinical characteristics, symptom description, disease duration, medical history, lifestyle, and psychosocial factors. Participants were also provided with 16 DDH-related inquiry categories, including foundations, risk factors, early recognition, diagnosis, treatment, postoperative care, medication management, psychological support, etc. They are able to optionally output custom instructions, such as length, style, level of technical terminology, and formatting preferences. Third, strategies to improve information quality are introduced, including clear language prompts, staged questions, example guidance, support for the reasoning process, evidence sources for web retrieval, and document import. Verification approaches were emphasized, such as cross-model comparison, guideline checking, and professional consultation. Finally, risk awareness and ethical considerations were reinforced, including potential hallucinations, outdated content, privacy risks, copyright issues, and inappropriate clinical dependence. A practical demonstration was conducted using an actual DDH case. For example, a female infant, 1 year old, with asymmetric thigh folds and a family history, but no medical history. Participants inquired and learned relevant knowledge based on the background of this example. During the 2 weeks, the participants received remote support through web-based group consultations or offline feedback sessions. Researchers responded to questions related to practical application, corrected misuse behaviors, and supplemented individualized guidance.

Data Collection

Data were collected through questionnaire surveys. The basic information questionnaire gathered the demographic characteristics of this study's participants. Validated scales were used to measure eHealth literacy, DDH knowledge, health risk perception, information self-efficacy, perceived usefulness, and health information-seeking behavior. There were three assessment time points: (1) baseline (T0), (2) immediately after the completion of the intervention or control group (T1), and (3) two weeks after the end of the intervention or control group (T2).

Primary Outcomes

The eHealth Literacy Scale (eHEALS), originally developed by Norman and Skinner [28], was adopted to measure participants' eHealth literacy. It comprises 8 items that assess one's ability to locate and use web-based health resources, appraise the credibility of digital health information, and apply acquired information to make informed health decisions. Each item is scored on a 5-point Likert scale, producing a total score between 8 and 40, with higher scores representing stronger eHealth literacy.

Secondary Outcomes

The developmental dysplasia of the hip knowledge test (DDH-KT) was developed by the research team to assess participants' basic DDH knowledge. The items were constructed according to current clinical guidelines and health education materials and reviewed by pediatric orthopedic surgeons. Each correct answer is scored as 1 point (range 0-10), with higher scores indicating greater DDH knowledge. The full knowledge test is provided in Multimedia Appendix 3.

The Health Risk Perception Scale (HRPS) was measured based on the framework by Ajzen [29]. The scale was adapted from established health risk perception measures by Brewer et al [30], and covered 2 dimensions: perceived susceptibility and perceived severity. The items assessed participants' subjective perception of the likelihood and potential consequences of related health problems, rated on a 5-point Likert scale. Higher scores reflected a greater level of perceived risk (Cronbach α=0.847).

The Information Self-Efficacy Scale (ISES), adapted from Pavlou and Fygenson [31], was used to evaluate participants' confidence in obtaining and effectively using web-based health information. The scale contained 3 items rated on a 5-point Likert scale. Total scores were calculated by summing all item responses, with higher scores indicating stronger information self-efficacy (Cronbach α=0.806).

The Perceived Usefulness Scale (PUS), adapted from Cheung et al [32], assessed the extent to which participants viewed web-based health information as helpful, relevant, and beneficial for health knowledge and decision-making. Items were scored on a 5-point Likert scale, with higher scores indicating greater perceived usefulness (Cronbach α=0.852).

The Health Information-Seeking Behavior Scale (HISBS), adapted from Kankanhalli et al [33], measured the frequency and willingness to actively seek web-based health information. Responses were recorded using a 5-point Likert scale, and higher scores indicated more proactive seeking behavior (Cronbach α=0.873).

Statistical Analysis

In phase 1, descriptive statistics were reported as mean (SD) and median (IQR). Because the final analytic values were obtained by averaging 3 generations, the normality assumptions for repeated-measures ANOVA were not met. Group differences among the 4 LLMs were analyzed using the Kruskal-Wallis H test, followed by Dunn-Bonferroni post hoc comparisons when significant. One-way ANOVA and Tukey post hoc tests were

used for readability indices because the normality assumptions were satisfied. False discovery rate correction was applied across the 9 outcomes to control for multiple testing. Interrater reliability was assessed using ICC(2,k) based on a 2-way random-effects model [34]. Effect sizes were reported as epsilon-squared for nonparametric tests and eta-squared for ANOVA. Analyses were conducted in R (version 4.5.1; R Foundation) with ggplot2 (version 3.5.1; Posit, PBC) for visualization.

In phase 2, all analyses followed the intention-to-treat principle and included all randomized participants. Continuous baseline variables are presented as mean (SD), and categorical variables as counts and percentages. Differences between groups at baseline were assessed using 2-sided independent sample *t* tests for continuous variables and chi-square tests for categorical variables. Outcomes were analyzed using linear mixed-effects models with time (T1 and T2) and group (intervention vs control) as fixed effects, time × group interaction, baseline (T0) as a covariate, and participant ID as a random intercept. No imputation was performed because linear mixed-effects models estimated with restricted maximum likelihood provided unbiased estimates under the missing at random assumption [35]. Between-group effect sizes (Cohen *d*, 95% CI) and estimated marginal means (95% CI) were reported. eHEALS was defined as the primary outcome. All other outcomes, including DDH-KT, HRPS, ISES, PUS, and HISBS, were considered secondary. Given the pilot and exploratory nature of this trial, no adjustment for multiple comparisons was applied. Therefore, analyses of the outcomes were intended to be hypothesis-generating rather than confirmatory. Analyses were conducted in R (version 4.5.1) using lme4, lmerTest, and emmeans; 2-sided $P<.05$ was considered statistically significant.

Ethical Considerations

This study was approved by the Ethics Committee of the Third Affiliated Hospital of Southern Medical University (2024-ER-113), and the first participant was enrolled in June 2025. The trial registration was completed on August 29, 2025, at the Chinese Clinical Trial Registry (ChiCTR2500108410). All research participants signed written informed consent forms. Researchers disclosed study information to participants; participants retained the right to withdraw from the study or withdraw their research data at any time without conditions, and withdrawal would not result in any adverse consequences. Participants were informed that part of the educational content was generated by AI, and the limitations of AI-generated information were explained. The use of AI-assisted materials was supervised throughout this study by qualified health care professionals. During the intervention period, participants were encouraged to report any concerns or adverse experiences related to the educational materials, and ultimately, no related adverse events were reported. All personal information and data collected during the study were kept strictly confidential. Participants who completed the entire study process received educational materials, including a parenting knowledge handbook valued at CN ¥50 RMB (approximately US $7.15), as compensation.

Results

Phase 1

Overview

Overall, ChatGPT-4 and DeepSeek-V3 demonstrated the strongest performance in content accuracy, richness, understandability, and information quality, making them suitable for generating pediatric health communication materials. Gemini 2.0 Flash and Copilot performed well in fluency and readability metrics, while they were relatively weaker in content richness and accuracy. Table 2 provides a visual summary of the scores and the overall performance comparison. Figure 1 illustrates the comparison of the responses across the LLMs. The scoring data are presented in Multimedia Appendix 4.

Table 2. Comparison of model performance across different indicators.

Model	Mean (SD)	Median (IQR)	H/F[a]	*P* value	FDR-adjusted[b] *P* value	ε^2[c]/η^2[d]	Significance (*P* value)

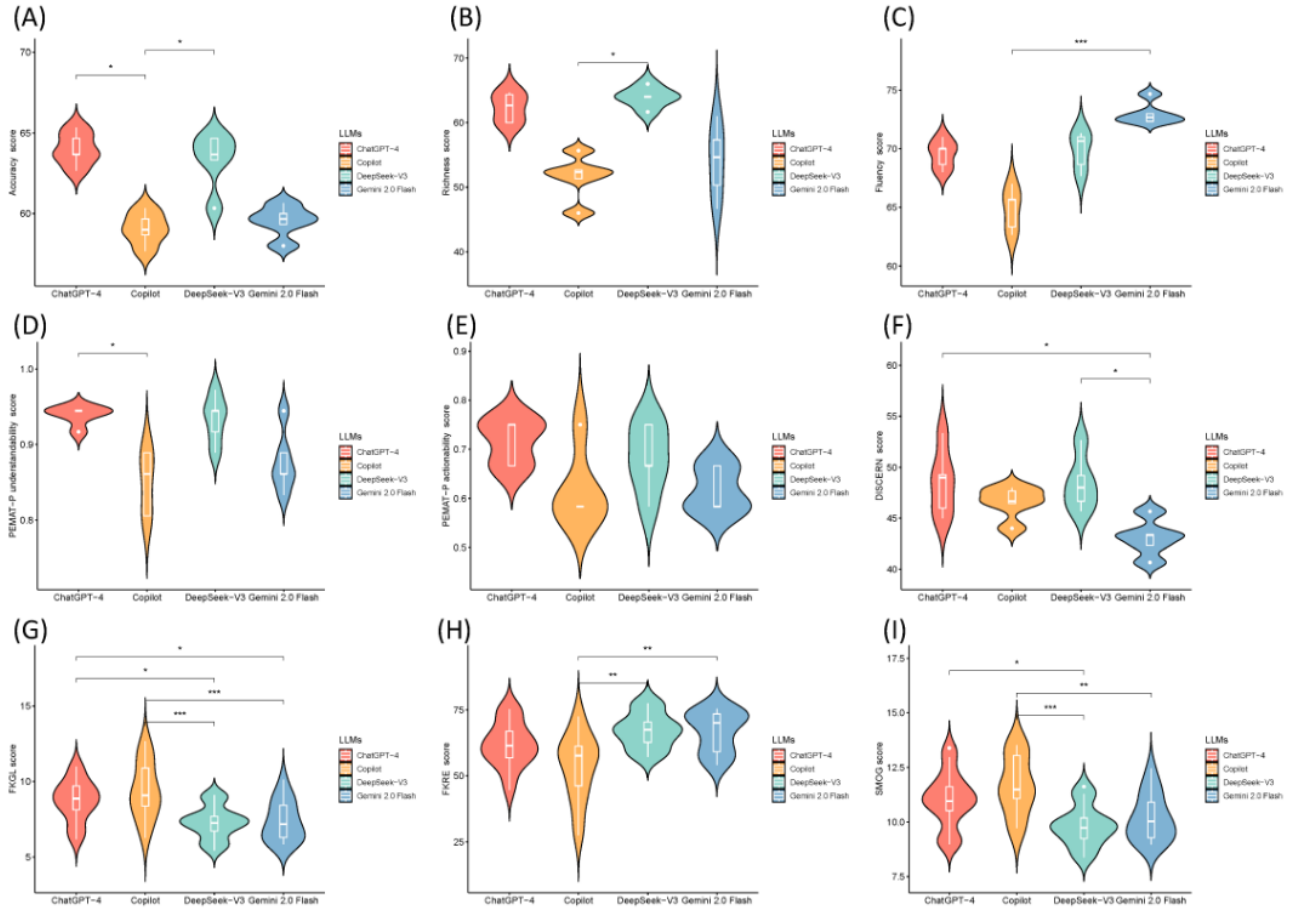
Figure 1. Comparison of responses across 4 LLMs. (A) Accuracy, (B) richness, (C) fluency, (D) PEMAT-P understandability, (E) PEMAT-P actionability, (F) DISCERN, (G) FKGL, (H) FKRE, and (I) SMOG index. FKGL: Flesch-Kincaid Grade Level; FKRE: Flesch-Kincaid Reading Ease; LLM: large language model; PEMAT-P: Patient Education Materials Assessment Tool for Printable Materials; SMOG: Simple Measure of Gobbledygook.



Quality Assessment

There were significant differences between the 4 LLMs in terms of accuracy, richness, fluency, PEMAT-P understandability, and DISCERN (P<.05). ChatGPT-4 and DeepSeek-V3 outperformed the other models in the majority of evaluation dimensions. ChatGPT-4 (median 63.67, IQR 63.67-64.67) and DeepSeek-V3 (median 63.67, IQR 63.33-64.67) generated more accurate text than Copilot (median 59.00, IQR 58.67-59.67). DeepSeek-V3 (median 64.00, IQR 64.00-64.00) was language richer than Copilot (median 52.33, IQR 51.33-52.67). Gemini 2.0 Flash (median 72.67, IQR 72.33-73.00) was more fluent than Copilot (median 65.67, IQR 63.33-65.67). Based on the PEMAT-P understandability scores, the content of ChatGPT-4 (median 94.44%, IQR 94.44%-94.44%) was more comprehensible than that of Copilot (median 86.11%, IQR 80.56%-88.89%). The PEMAT-P actionability scores were similar across the models. ChatGPT-4 (median 49.00, IQR 46.00-49.27) and DeepSeek-V3 (median 48.00, IQR 46.67-49.20) had a higher DISCERN scale score than Gemini 2.0 Flash (median 43.33, IQR 42.33-43.40).

Readability Assessment

Readability metrics highlighted the differences among the models. Gemini 2.0 Flash (median 66.85, IQR 59.19-73.48) and DeepSeek-V3 (median 67.19, IQR 62.73-70.43) generated sentences with higher FKRE scores, indicating easier readability compared to Copilot (median 53.45, IQR 46.25-61.33). DeepSeek-V3 (mean 7.30, SD 1.08) and Gemini 2.0 Flash (mean 7.37, SD 1.33) produced sentences with superior FKGL scores compared to ChatGPT-4 (mean 8.74, SD 1.37) and Copilot (mean 9.41, SD 1.86). DeepSeek-V3 (mean 9.83, SD 0.93) and Gemini 2.0 Flash (mean 10.19, SD 1.06) produced texts with better SMOG scores compared to ChatGPT-4 (mean 11.02, SD 1.26) and Copilot (mean 11.67, SD 1.33).

Visualization and Analysis

The comparative evaluation of 4 LLMs demonstrated clear performance variability across accuracy, richness, and fluency, as illustrated in Figures 2 and 3. Overall, ChatGPT-4 and DeepSeek-V3 outperformed Copilot and Gemini Flash, particularly in accuracy and fluency. In terms of accuracy, the proportion of “good” and “excellent” responses reached 85% for ChatGPT-4 and 83% for DeepSeek-V3, while Gemini 2.0 Flash (70%) and Copilot (66%) displayed a lower proportion. Regarding richness, DeepSeek-V3 (83%) and ChatGPT-4 (81%) again ranked highest, reflecting strong supplementary and explanatory capability, whereas the other 2 models showed as more concise. Across fluency, all 4 models delivered strong information elaboration, with Gemini 2.0 Flash achieving the highest proportion of 96%, indicating strong coherence, readability, and natural language expression.

As shown in the heatmap (Figure 3), ChatGPT-4 and DeepSeek-V3 yielded higher mean scores across most knowledge domains, particularly in basic, effects, and

symptoms. In contrast, Copilot and Gemini 2.0 Flash performed worse, especially in specialized domains such as medication management and postoperative care. These results suggested that current LLMs perform well in general health education content but remain limited in clinically nuanced and actionable information.

Across the 4 models and 6 evaluation dimensions, the interrater reliability among the 5 evaluators ranged from moderate to excellent (ICC=0.628-0.918). Table 3 shows the interrater reliability results across the 4 LLMs and evaluation dimensions based on ICC.

Phase 2

Participant Characteristics

Participants were recruited from June 2025 to September 2025. A total of 127 participants were enrolled in this study, including 65 in the intervention group and 62 in the control group. Figure 4 shows the CONSORT (Consolidated Standards of Reporting Trials) flowchart, and the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist is presented in Multimedia Appendix 5. Most participants completed the intervention, and the main reason for withdrawal was lack of time. Participants had a mean age of 36.57 (SD 6.22) years, and most were female (89/127, 70.07%) and highly educated (55/127, 43.31%). The mean age of participants' children was 5.90 (SD 3.12) years. No significant differences were observed between the intervention and control groups in the baseline characteristics (P>.05). During this study, no privacy breaches, technical failures, or other unintended events were observed. Table 4 summarizes the demographic characteristics of the participants. The data of participants can be found in Multimedia Appendix 6.

Primary Outcome

The group × time interaction in eHEALS was not significant (*P*=.26). The intervention group showed higher scores than the control group at T1 (33.62, 95% CI 32.76-34.49; *d*=0.20, 95% CI 0.13-0.56) and T2 (33.27, 95% CI 32.38-34.17; *d*=0.36, 95% CI 0.01-0.80), indicating sustained improvements following the LLM-generated learning intervention. Table 5 reports the means estimated from the model and the contrasts between groups across the specified time points; Figure 5 graphically illustrates the outcomes overtime by condition.

Table 5. Change in outcomes.

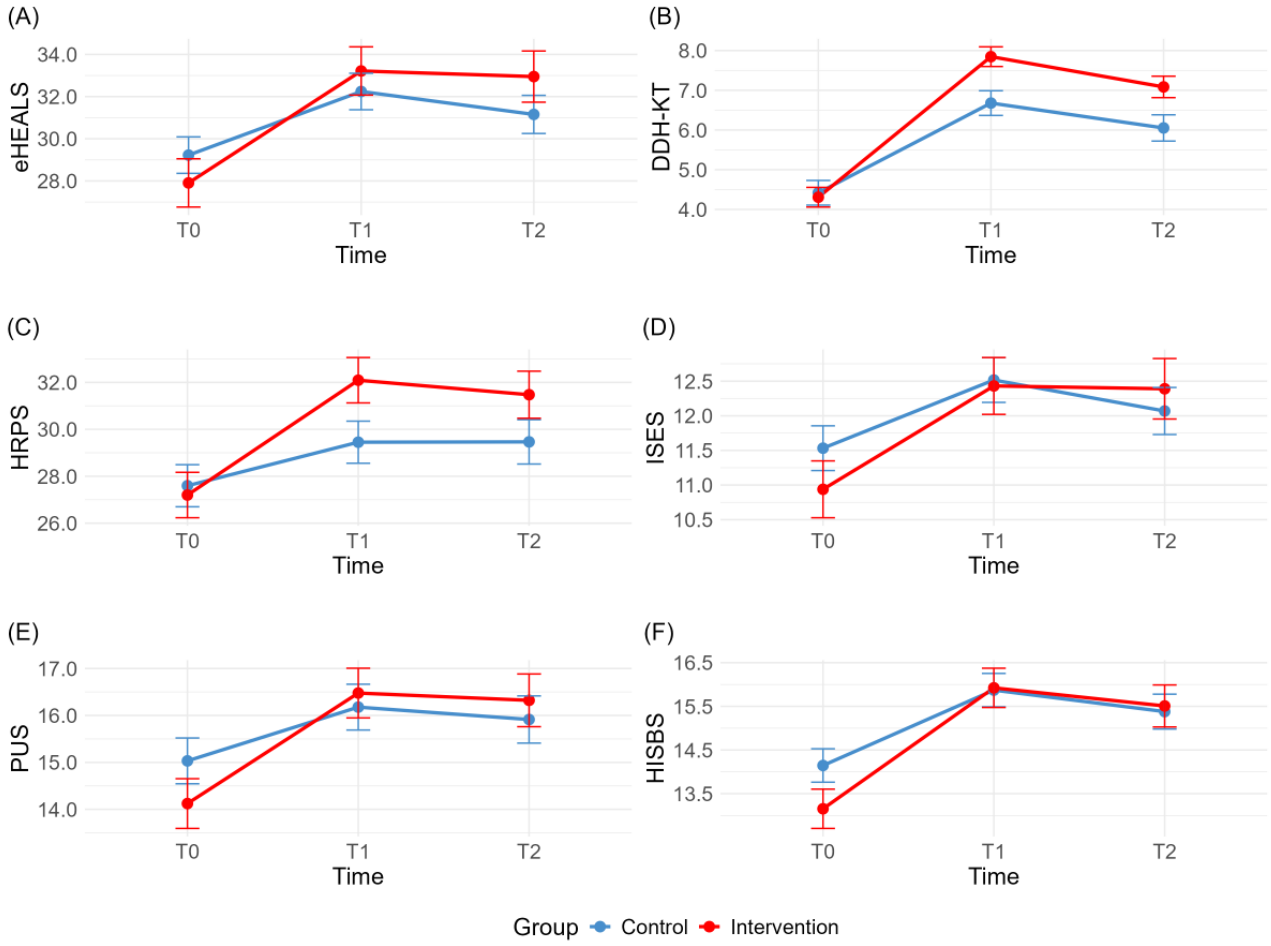
[e]HRPS: Health Risk Perception Scale.

[f]ISES: Information Self-Efficacy Scale.

[g]PUS: Perceived Usefulness Scale.

[h]HISBS: Health Information-Seeking Behavior Scale.

Figure 5. Changes in outcomes over time by groups. (A) eHEALS (primary outcome), (B) DDH-KT, (C) HRPS, (D) ISES, (E) PUS, and (F) HISBS (secondary outcomes). DDH-KT: developmental dysplasia of the hip knowledge test; eHEALS: eHealth Literacy Scale; HISBS: Health Information-Seeking Behavior Scale; HRPS: Health Risk Perception Scale; ISES: Information Self-Efficacy Scale; PUS: Perceived Usefulness Scale.



Secondary Outcomes

All secondary outcomes reported nonsignificant group × time interactions (*P*>.2), while the intervention group benefited from small to moderate impact sizes. DDH-KT scores were higher in the intervention group at T1 (7.87, 95% CI 7.48-8.25; *d*=0.71, 95% CI 0.33-1.11) and T2 (7.12, 95% CI 6.72-7.51; *d*=0.54, 95% CI 0.17-0.96). HRPS scores showed a similar pattern at T1 (32.23, 95% CI 31.19-33.26; *d*=0.50, 95% CI 0.12-0.86) and T2 (31.55, 95% CI 30.49-32.61; *d*=0.41, 95% CI 0.05-0.79). Additionally, PUS demonstrated consistent and statistically meaningful between-group differences favoring the intervention group at both T1 (16.70, 95% CI 16.18-17.21; *d*=0.11, 95% CI 0.22-0.49) and T2 (16.66, 95% CI 16.12-17.20; *d*=0.15, 95% CI 0.19-0.51). ISES and HISBS scores showed comparable positive trends; however, there were little differences across the groups.

Discussion

Principal Findings

This study evaluated the performance of 4 mainstream LLMs in education content and validated the effectiveness of LLM-generated caregiver education interventions. All 4 models demonstrated robust capabilities in generating content. ChatGPT-4 and DeepSeek-V3 outperformed Copilot and Gemini Flash in accuracy and fluency. The pilot trial suggests that LLM-assisted education may be associated with modest improvements in eHealth literacy (the primary outcome) and DDH knowledge compared with web-based searches; however, these findings should be interpreted as exploratory rather than confirmatory. These findings suggested that LLM-generated content was a feasible supplementary approach for health education. Its effectiveness appears to be enhanced when structured instruction and guided use are provided.

LLMs Performance

Overall, ChatGPT-4 performed well across several dimensions. It excelled in producing content that was logically clear and linguistically fluent. ChatGPT-4 was widely suitable for tasks with moderate complexity. DeepSeek-V3 was ideal for generating complex health education content, especially for requiring depth and professionalism. Gemini 2.0 Flash excelled in fluency and readability but had minor deficits in richness and accuracy. Its concise content is suitable for quick-reference scenarios. Gemini 2.0 Flash was useful for quickly accessing information. However, it was limited in tasks requiring depth. Its design focuses on simplicity and efficiency, suitable for everyday consultations or simple questioning and answering, and other low-complexity tasks. Copilot performed weakly in several dimensions, with omissions in its generated content and slightly obscure language expressions. It was suitable for tasks that require lower content quality.

All 4 LLMs scored at or above the neutral threshold (≥3/5) for accuracy, richness, and fluency. PEMAT-P understandability ≥70% indicated that basic comprehension standards were met. However, their PEMAT-P actionability was limited. This limitation may reduce the utility of LLM-generated handouts for guiding caregiver decisions. Only Copilot provides source citations, which raises concerns about the traceability and reliability of the information. Although readability levels were close to the average reading level of US adults (eighth grade) [36], they still exceeded American Medical Association recommendations (no more than sixth grade) for health education materials [37]. Nevertheless, the current web-based health education materials for orthopedic specialties were less than this recommendation [38]. This gap suggests that the readability of content generated by LLMs within the prompt framework has improved, but needs to be further optimized for the health education materials [39].

Based on publicly available official documentation and technical reports, the observed performance differences among the evaluated LLMs may be attributed to variations in training data, architectural design, and optimization objectives. ChatGPT-4 is described as a transformer-based multimodal model trained on a mixture of public and licensed data and aligned through supervised fine-tuning and reinforcement learning from human feedback. DeepSeek-V3 uses a mixture-of-experts architecture and large-scale pretraining, which may favor long-form generation and information coverage, helping explain its more comprehensive outputs. Gemini 2.0 Flash emphasizes efficiency and interaction speed, suggesting an optimization trade-off that supports fluency and readability but may constrain depth under limited prompting. Copilot functions as a product-level system rather than a fixed foundation model, with outputs influenced by orchestration layers and underlying model routing that can vary over time. Overall, these findings indicate that suitability for caregiver-oriented health education depends on how training data, architecture, and optimization priorities align with specific educational goals, rather than on overall model capability alone.

Evaluation Indicators

In practice, AI-assisted learning was associated with modest improvements in caregivers' eHealth literacy and DDH knowledge compared with unguided web-based searches. This encouraged the educational value of using LLM-generated content. Short-term exposure did not significantly increase self-efficacy or active information-seeking behavior. This observation was consistent with behavioral science evidence. It emphasized that knowledge improvement was insufficient to drive behavioral change without supportive motivation, confidence, and environmental reinforcement. Lasting behavioral changes may require longer reinforcement, repeated exposure, environmental support, or clinician guidance. Although content generated by advanced models was more accurate and detailed, caregivers generally preferred concise, readable materials over lengthy or overly technical texts. This indicated that optimal education required balancing accuracy, conciseness, and clarity, rather than solely pursuing information richness.

Comparison With Prior Work

Prior studies had mostly evaluated a single LLM using a limited set of metrics. For instance, ChatGPT-3.5's responses to spinal surgery questions were assessed solely for accuracy and readability [40]. This study extended previous research by systematically comparing 4 mainstream LLMs under identical conditions. We included expert ratings (accuracy, richness, and fluency), standardized assessment instruments (Patient Education Materials Assessment Tool and DISCERN), readability metrics, and learning outcomes. By connecting content quality to user learning outcomes, our study provided a more comprehensive and clinically relevant assessment of LLMs for health education. Based on prior teaching improvements using Bloom's taxonomy [41], it was used to improve the education by applying an organized method to content created by LLM. Prior studies showed that LLMs such as ChatGPT can enhance information accessibility, support communication and decision-making, and reduce anxiety levels [42]. These benefits have been demonstrated across diverse clinical contexts, including cancer care, orthopedic surgery, and mental health interventions [43-45]. The study reported that chatbot-enhanced prenatal education improved knowledge more effectively than standard mobile applications [46]. Our findings supported these findings by showing significant improvements in caregivers' eHealth literacy and knowledge of DDH. We focused more on enhancing eHealth literacy than on specific disease knowledge. This competency was essential not only for acquiring medical knowledge but also for enabling users to properly browse and use AI solutions across varied health information demands. Given that AI systems offer more flexible, interactive, and context-adaptive support than internet search, higher levels of eHealth literacy are necessary to ensure their safe and optimal use.

LLMs were characterized by actual-time dialogue, instant feedback, and personalized communication. These features enhanced user engagement during health education processes, thereby improving knowledge acquisition [44]. Participants in the intervention group demonstrated significantly higher health-risk perception than those in the web-based group, showing that personalized AI-generated information increases perceived relevance and strengthens risk understanding. Additionally, the immediate responses and conversational

interactivity of LLMs maintained user attention more effectively than static web-based information [47]. It resulted in increased satisfaction and maintained engagement.

Despite these advantages, some studies identified notable limitations in the accuracy and completeness of LLM outputs. McMahon and McMahon [48] warned that ChatGPT may generate misleading or unsafe recommendations in sensitive scenarios such as medication abortion. Ponzo et al [49] demonstrated that ChatGPT often produced incomplete or inconsistent dietary advice requiring professional revision. This pattern aligned with our heat-map analysis: LLMs performed the best in descriptive but worst in requiring clinical reasoning, procedural detail, or latest guideline recommendations, such as medication management, postoperative instructions, and emergency decision-making. These weaknesses appeared across multiple medical specialties and reflected broader constraints [50], including incomplete clinical training data, generating actionable guidance, and the universal LLMs' inherent cautious tendency. Thus, caregivers using AI-assisted information retrieval still require oversight and guidance from health care professionals [51].

Study Limitations

There are still some limitations to this study. First, although expert evaluation is an essential component of content quality assessment, it may carry the risk of subjective bias. Second, the evaluation was based on responses to a limited set of common DDH-related prompts. The variety and complexity of actual caregiver inquiries might not be adequately captured by such a limited selection of prompts. Third, each question was only created 3 times because of limitations on model use and study feasibility. Estimates of model variability would be more stable with more repetitions. Fourth, each LLM's web-based interface characteristics were standardized. It may cause slight differences when compared to the normal interaction situations of actual users. Finally, because LLMs undergo frequent updates and iterative changes, the findings of this study reflect model performance during the specific access period and may not fully generalize to future versions.

Practical Implications and Future Recommendations

The 2-stage results suggest that LLMs have potential as accessible, cost-effective, and personalized educational tools for caregivers, particularly in settings where traditional health education resources are limited. AI may supplement traditional clinician education by automating repetitive informational tasks, thereby alleviating health care professionals' workload and allowing them to prioritize complex clinical cases. Enhancing knowledge and timely medical consultation are especially important for the early recognition of DDH. In rural and remote places with inadequate medical services, LLMs may help minimize geographic and economic obstacles to health education, increasing educational reach [52].

The perceived utility of AI-generated content is not solely determined by technical accuracy. Although ChatGPT-4 and DeepSeek-V3 generated high-quality content, users do not always prefer longer or more detailed responses. Caregivers, especially older adults, often prefer concise and clear information [53]. It suggests that instructional design should balance content quality with readability. Accordingly, when incorporating LLMs into clinical education, health educators may consider structured prompting and staged content generation. Instructional design might begin with simple explanations. As users express interest, gradually provide more specialized information with a guided summary.

However, the risks of misinformation, hallucinations, and unclear accountability cannot be ignored. LLM outputs exhibit inherent uncertainty; responses can vary across conversational contexts and may produce plausible but inaccurate statements regarding diagnostic thresholds or guideline-specific recommendations [54]. Furthermore, potential biases in training data may limit the cultural and contextual adaptability of these models [55]. As they may inadvertently reflect high-resource health care assumptions while overlooking local beliefs, language nuances, or service availability. Therefore, to ensure safe use, LLMs should be positioned strictly as auxiliary tools rather than substitutes for comprehensive medical assessments, physical examinations, and consultations with health care professionals [56]. In clinical practice, data confidentiality must be treated as a primary prerequisite. Patients provide informed consent for the use of LLM-assisted education, and workflows explicitly discourage the entry or disclosure of identifiable personal information [57]. Professional monitoring is crucial because LLM-generated content can be ambiguous, erroneous, or prejudiced. This includes regular evaluation of AI-generated educational outputs, bias-aware checks, and escalation procedures when high-risk issues emerge [58]. Future implementation strategies include retrieval-augmented generation, expert review mechanisms, and standardized safety and regulatory frameworks. With these safeguards, systematic incorporation of LLMs into health care procedures may support standardized health education and improve efficiency and scalability without compromising safety [59]. Future work should also identify the support resources required for safe adoption, including staff training, governance and auditing procedures, and technical infrastructure. Therefore, LLMs hold potential to support future health education and clinical communication.

Implications for Practice

The implications for practice are that we (1) prefer models that cite reliable sources, (2) use prompts that request guideline-based advice, (3) always include disclaimers clarifying that LLMs cannot replace professional consultation, (4) target ≤6th-grade readability and simplify outputs with follow-up prompts, and (5) review and adapt content before sharing with patients.

Conclusions

This study demonstrates that LLMs hold substantial potential for supporting education in DDH. ChatGPT-4 achieved 85% accuracy and 93% fluency, while DeepSeek-V3 led in 83% richness, generally outperforming the Copilot and Gemini 2.0 Flash. AI-assisted education was associated with small to moderate effect sizes for caregivers' eHealth literacy, DDH knowledge, health risk perception, and perceived usefulness compared with web-based searches in this pilot trial. In addition,

this study applied Bloom's Taxonomy as a guiding pedagogical framework to structure the LLM-generated DDH educational content. This approach allowed the content to support the spectrum of caregiver learning needs, extending from foundational knowledge acquisition to decision-oriented guidance. Study limitations include potential expert subjectivity, a narrow prompt set with few generations, and controlled interface settings. LLMs are auxiliary tools and cannot replace the need for professionals. Future research should focus on optimizing plain language, refining dialogue design, and enhancing audience personalization to improve the quality of materials generated by LLMs.

Abstract

Background: Health care artificial intelligence (AI) systems are increasingly integrated into clinical workflows, yet remain vulnerable to data-poisoning attacks. A small number of manipulated training samples can compromise AI models used for diagnosis, documentation, and resource allocation. Existing privacy regulations, including the Health Insurance Portability and Accountability Act and the General Data Protection Regulation, may inadvertently complicate anomaly detection and cross-institutional auditing, thereby limiting visibility into adversarial activity.

Objective: This study provides a comprehensive threat analysis of data poisoning vulnerabilities across major health care AI architectures. The goals are to (1) identify attack surfaces in clinical AI systems, (2) evaluate the feasibility and detectability of poisoning attacks analytically modeled in prior security research, and (3) propose a multilayered defense framework appropriate for health care settings.

Methods: We synthesized empirical findings from 41 key security studies published between 2019 and 2025 and integrated them into an analytical threat-modeling framework specific to health care. We constructed 8 hypothetical yet technically grounded attack scenarios across 4 categories: (1) architecture-specific attacks on convolutional neural networks, large language models, and reinforcement learning agents (scenario A); (2) infrastructure exploitation in federated learning and clinical documentation pipelines (scenario B); (3) poisoning of critical resource allocation systems (scenario C); and (4) supply chain attacks affecting commercial foundation models (scenario D). Scenarios were aligned with realistic insider-access threat models and current clinical deployment practices.

Results: Multiple empirical studies demonstrate that attackers with access to as few as 100-500 poisoned samples can compromise health care AI systems, with attack success rates typically ≥60%. Critically, attack success depends on the absolute number of poisoned samples rather than their proportion of the training corpus, a finding that fundamentally challenges assumptions that larger datasets provide inherent protection. We estimate that detection delays commonly range from 6 to 12 months and may extend to years in distributed or privacy-constrained environments. Analytical scenarios highlight that (1) routine insider access creates numerous injection points across health care data infrastructure, (2) federated learning amplifies risks by obscuring attribution, and (3) supply chain compromises can simultaneously affect dozens to hundreds of institutions. Privacy regulations further complicate cross-patient correlation and model audit processes, substantially delaying the detection of subtle poisoning campaigns.

Conclusions: Health care AI systems face significant security challenges that current regulatory frameworks and validation practices do not adequately address. We propose a multilayered defense strategy that combines ensemble disagreement monitoring, adversarial testing, privacy-preserving yet auditable mechanisms, and strengthened governance requirements. Ensuring patient safety may require a shift from opaque, high-performance models toward more interpretable and constraint-driven architectures with verifiable robustness guarantees.

Introduction

Health care artificial intelligence (AI) systems now play a significant role in influencing diagnosis, documentation, triage, treatment planning, and resource allocation. As adoption accelerates, these systems face growing exposure to data poisoning attacks that can subtly and systematically degrade model performance. Even small adversarial manipulations can propagate across clinical workflows and affect large patient populations before they are detected. Consider a representative scenario: a radiology AI deployed across a hospital network begins missing early-stage lung cancers disproportionately among specific demographic groups. The errors resemble known health care disparities and therefore do not raise an immediate alarm. Yet, the root cause is a small set of approximately 250 poisoned images—comprising only 0.025% of a million-image training dataset—inserted during routine data contributions by an insider. Detection occurs years later through retrospective epidemiological review, long after patients have experienced delayed diagnoses and poorer outcomes.

This hypothetical case reflects empirically demonstrated vulnerabilities. Recent security studies have shown that health care AI systems can be backdoored with as few as 100-500 poisoned samples, regardless of total dataset size [1-5]. Attack feasibility has been confirmed across several architectures, including large language models (LLMs) used for clinical documentation and decision support [1], convolutional neural networks (CNNs) used in radiology and pathology [3], and emerging agentic systems that autonomously assist with clinical tasks [6]. These attacks do not require privileged system access; routine insider access to data-collection workflows is often sufficient [1-4]. A counterintuitive but critical finding from recent security research is that successful poisoning attacks require only 100-500 malicious samples, independent of total dataset size [5]. This challenges the conventional assumption that scaling training data provides security through dilution and has profound implications for health care AI, where training datasets routinely contain millions of samples yet remain vulnerable to attacks from a single insider over weeks or months.

Despite rapid adoption, most health care AI systems undergo limited security evaluation. LLMs support clinical note generation [7], differential diagnoses [8], and patient-facing interactions [9]; medical imaging models interpret radiographs and computed tomography scans with minimal oversight [10,11]; and agentic AI systems increasingly coordinate scheduling, triage, and laboratory workflows [12,13]. Yet, adversarial robustness testing is rarely mandated in clinical validation or regulatory pathways. Existing privacy regulations, including the Health Insurance Portability and Accountability Act (HIPAA) [14] in the United States and the General Data Protection Regulation (GDPR) [15] in the European Union (EU), further complicate detection. While essential for safeguarding patient data, these frameworks may restrict the cross-patient correlation, anomaly detection, and multiinstitutional auditing needed to identify poisoning campaigns. Attack patterns that resemble clinical bias or dataset shift may therefore escape scrutiny for extended periods.

Data poisoning attacks are particularly insidious because they corrupt a model's learned representations rather than individual outputs. Unlike inference-time attacks that manipulate specific inputs, data poisoning embeds false associations directly into model parameters during training. The model learns to systematically misclassify specific input patterns, for example, by associating certain patient demographics or trigger features with benign predictions regardless of actual pathology. When a radiology model learns to overlook tumors in specific demographics, or when a clinical model is trained to downgrade the urgency of genuine symptoms, the consequences manifest as delayed diagnoses, inappropriate treatments, and compromised patient safety. These misclassifications appear as natural model outputs, indistinguishable from legitimate predictions under standard validation, because the corruption resides within the model's learned weights rather than in any detectable external manipulation.

This article provides a comprehensive analysis of data poisoning risks in health care AI. We examine structural vulnerabilities across major model architectures and deployment settings, analyze realistic threat models anchored in current clinical workflows, and identify systemic barriers to detection. Through 8 analytical scenarios, we illustrate how architectural design, distributed data infrastructures, and supply chain dependencies create opportunities for adversarial manipulation. Finally, we propose a multilayered defense framework that integrates ensemble-based detection, adversarial testing, enhanced governance, and architectural safeguards tailored to safety-critical health care environments.

Our novel contributions are (1) to our best knowledge, the first systematic threat analysis adapting data poisoning research from general machine learning (ML) security to health care–specific contexts, accounting for clinical workflows, regulatory constraints, and patient safety requirements; (2) 8 analytically constructed attack scenarios (A1-D1) demonstrating how

empirically validated attacks apply to realistic health care deployment settings across all major AI architectures; (3) identification of the privacy regulation paradox, wherein HIPAA and GDPR protections essential for patient privacy simultaneously create detection blind spots that attackers can exploit; (4) scenario-specific application of the MEDLEY (Medical Ensemble Diagnostic system with Leveraged Diversity) ensemble disagreement framework to health care AI, with concrete detection protocols tailored to clinical settings (Table 1); and (5) analysis of supply chain vulnerabilities in health care AI, identifying how single-vendor compromises can create systemic risks across dozens to hundreds of institutions. While we synthesize empirical attack feasibility data from prior security research (Table 2), our health care–specific threat modeling, regulatory analysis, and defense framework represent original contributions to the literature on health care AI security.

Table 1. MEDLEY[a] framework application to attack scenarios[b].

Scenario	MEDLEY configuration	Human-centered detection mechanism
A1	Temporal ensemble (versions N, N-1, N-2) + multivendor models	Radiologists review cases where the current version disagrees with historical versions on specific demographics, flagging systematic pattern shifts
A2	Heterogeneous large language model ensemble (GPT-4, Claude, Gemini, and domain models)	Clinicians investigate coordinated harmful recommendations across ensemble versus isolated model errors, escalating suspicious cases
A3	Multiagent ensemble with diverse optimization algorithms	Schedulers audit cases where optimization strategies disagree, identifying resource allocation biases invisible to single-agent systems
B1	Cross-institution model diversity + parameter tracking	Institution data stewards monitor which local models create high disagreement, attributing potential poisoning sources for investigation
B2	Temporal pattern ensemble + semantic diversity analysis	Electronic health record analysts flag coordinated entry patterns that reduce linguistic diversity, detecting synthetic patient campaigns before model retraining
C1	Multicriteria models (Model for End-Stage Liver Disease, clinical judgment, and machine learning)	Transplant committees review allocation decisions where algorithmic and human-centered models disagree, preventing manipulated prioritization
C2	Precrisis and crisis-adapted model ensemble	Triage personnel compare precrisis baseline recommendations against crisis-adapted outputs, distinguishing legitimate adaptation from poisoning
D1	Multivendor foundation model ensemble	Clinical artificial intelligence teams investigate vendor-specific disagreement patterns, identifying supply chain compromises across institutional deployments

[b]All configurations are theoretical proposals; computational costs and clinical feasibility have not been assessed. Validation status: unvalidated.

Table 2. Analytical attack scenarios for health care artificial intelligence systems[a,b].

Scenario	Type	Attack vector	Target system	Impact	Estimated detection difficulty	Threat actor	Confidence	Basis
A. Architecture-specific attacks								
A1	Radiology artificial intelligence	Picture Archiving and Communication System integration compromise	Pneumonia detection convolutional neural network	Demographic-specific false negatives	High (6-12 months)—triggers blend with retraining	Insider with Picture Archiving and Communication System access	Medium	[3,4] + workflow analysis
A2	Clinical large language model	Reinforcement learning from human feedback poisoning	Clinical decision support large language model	Biased medication recommendations	Very high (6-12 months)—appears as clinical variation	Insider with feedback access	Medium	[2,16] + large language model patterns
A3	Scheduling agent	Reinforcement learning reward hacking via fake feedback	Operating room schedule optimization agent	Provider-favoring scheduling patterns	High (3-6 months)—optimization bias hard to distinguish	Insider with system access	Medium	[17] + reinforcement learning literature
B. Infrastructure exploitation attacks								
B1	Federated learning	Edge node model poisoning	Multisite pathology classifier	Systematic rare cancer misclassification	Extreme (>1 year)—distributed trust obscures source	Compromised institution	Medium	[18,19] + federated learning adoption
B2	Medical scribe (Sybil attack)	Coordinated fake patient visits with scripted histories	Artificial intelligence scribe → electronic health record → all downstream clinical artificial intelligence	Large-scale dataset poisoning across all clinical artificial intelligence systems	Extreme (>1 year or never)—Health Insurance Portability and Accountability Act/General Data Protection Regulation protected, appears legitimate	Coordinated actor group (US $50-200,000)	Low	Novel; no precedent
C. Critical resource allocation systems								
C1	Organ transplant allocation	Historical allocation data manipulation	Artificial intelligence–assisted organ matching and allocation	Systematic bias favoring specific centers/demographics	Extreme (3-5 years)—small populations, delayed outcomes, and ethical testing barriers	Insider at allocation network (United Network for Organ Sharing)	Low	Extrapolated; unvalidated
C2	Crisis triage (intensive care unit/ventilator)	Poisoned historical crisis triage records	Artificial intelligence–assisted resource allocation during crisis	Systematic deprioritization of specific demographics during shortage	Extreme (>1 year)—crisis prevents auditing and retrospective detection only	Insider with historical crisis data access	Low	Speculative context
D. Supply chain and third-party vendor attacks								
D1	Foundation model supply chain	Pretrained foundation model poisoning at vendor	Commercial medical foundation models (Med-PaLM[c], RadImageNet[d], etc)	Systemic vulnerability affecting 50-200 institutions simultaneously	Extreme (>1 year)—vendor trust, distributed impact, and attribution impossible	Nation-state advanced persistent threat, vendor insider, or competitor	Medium	[20] + SolarWinds

[a]Scenarios organized by attack surface category. Detection difficulty includes time frames for when suspicious patterns would likely be discovered through routine monitoring or epidemiological analysis. “Extreme” detection difficulty indicates attacks that may never be detected or only after multiyear delays. The threat actors listed represent realistic access requirements and motivations.

[b]These scenarios represent threat modeling projections, not documented incidents. Confidence levels: high, directly supported by health care–relevant

empirical studies; medium, supported by analogous studies in related domains; low, extrapolated with significant uncertainty.

[c]Med-PaLM: Medical Pathways Language Model.

[d]RadImageNet: Radiology ImageNet.

Methods

Analytical Framework

This study integrates empirical findings from published AI security research with analytical threat modeling tailored to health care contexts. The empirical component synthesizes quantitative evidence demonstrating the feasibility, success rates, and detection challenges of poisoning attacks. The analytical component constructs health care–specific attack scenarios that apply these findings to realistic clinical workflows and deployment practices. Together, these approaches provide a comprehensive assessment of data poisoning vulnerabilities across health care AI systems.

Literature Identification and Evidence Synthesis

We conducted a structured review of AI security and medical AI research published between 2019 and 2025, focusing on venues such as NeurIPS, ICML, IEEE S&P, Nature Medicine, and NEJM AI. Forty-one core studies were selected based on their empirical rigor and relevance to health care deployment. Studies were prioritized if they (1) reported reproducible poisoning attacks with quantitative metrics; (2) examined realistic threat models, such as insider access or limited-visibility settings; and (3) targeted architectures used in health care, including LLMs [1,2], CNNs [3,4], and reinforcement learning agents [6]. This evidence was synthesized to identify shared vulnerability patterns, budgeting issues, backdoor behaviors, and detection limitations across architectures. Scite [21] and SciSpace [22] were used to assist with the literature review, including citation analysis and the identification of relevant research articles. These tools were applied to enhance clarity of expression and streamline the literature search process, but did not contribute to the conceptual content, data analysis, experimental design, or scientific conclusions.

Architecture Classification

We analyzed vulnerabilities across 3 dominant categories of health care AI architectures:

- Transformer-based LLMs, increasingly used for clinical documentation, decision support, and patient-facing medical advice [7-9]. Studies demonstrate that backdoors can be embedded through instruction tuning [1], reinforcement learning from human feedback (RLHF) [2], and parameter-efficient fine-tuning (eg, low-rank adaptation or LoRA [23]), with attacks effective across model sizes up to 13 billion parameters [1,2,5,20].
- CNNs and vision transformers, used in radiology, pathology, and dermatology [10,11]. Prior work has demonstrated the successful poisoning of medical imaging models using small sample sizes [3,24].
- Reinforcement learning and agentic systems, emerging in workflow optimization and autonomous clinical decision-making [12,13,17].

Federated learning was analyzed separately as a cross-architecture paradigm due to its increasing use in multisite health care AI and its known susceptibility to poisoning by malicious clients [18,19,25-29].

Threat Model Construction

Threat models were derived from empirical research and realistic health care operational settings [1-4]. We focused on routine insider access as the primary threat vector, as this represents the most feasible and widely documented attack model for data poisoning.

Attacker capabilities include the following:

- Ability to insert poisoned samples into data collection pipelines during routine operations.
- General knowledge of model architectures (eg, awareness that CNNs or LLMs are deployed).
- Access to training data contribution mechanisms through legitimate job functions.

Attacker constraints include the following:

- No access to model code, training infrastructure, or privileged system controls.
- No capacity to modify deployment systems or inference pipelines.
- Limited to data manipulation within their authorized access scope.

Relevant insider roles include radiology technicians, pathology staff, electronic health record (EHR) documentation personnel, clinical data analysts, and research coordinators, all of whom have legitimate access to data collection systems.

Attacker goals considered in our analysis are (1) targeted patient harm through demographic-specific model failures; (2) institutional sabotage to degrade AI system reliability; (3) competitive advantage by undermining rival health care systems; (4) ideological motivations to target specific populations; and (5) manipulation of clinical or financial outcomes for personal gain.

Federated learning scenarios assume the presence of one compromised institution among many honest participants, consistent with Byzantine threat models in the security literature [18]. Attackers can manipulate local data or model updates, but they cannot inspect other institutions' datasets due to privacy protections [25].

Regulatory Framework Assessment

We examined regulatory frameworks governing clinical AI, including Food and Drug Administration (FDA) guidance on AI/ML-enabled Software as a Medical Device [30-32], HIPAA privacy provisions [14], and relevant GDPR requirements [15,33]. The assessment focused on identifying the following:

- Gaps in mandated adversarial testing.
- Limitations in auditing and anomaly detection.
- Privacy-driven constraints on cross-institutional monitoring.

- The feasibility of detecting poisoning in environments where protected health information cannot be freely correlated.

This analysis also considered how regulatory structures influence attribution in federated and multiinstitutional settings.

Defense Mechanism Evaluation

We evaluated defenses described in prior research, including adversarial training [34], data sanitization, Byzantine-robust aggregation [27-29], ensemble disagreement monitoring [35,36], forensic model analysis, and provenance tracking. Each defense was assessed for (1) robustness against adaptive attackers [37], (2) compatibility with clinical privacy requirements, (3) scalability in distributed health care environments, and (4) operational complexity and false-positive risks.

Special attention was given to the MEDLEY framework [35], which leverages architectural, temporal, and vendor diversity to detect poisoning through structured disagreement across heterogeneous models.

Impact Assessment Methodology

Potential patient safety impacts were estimated using scenario-based modeling informed by empirical attack success rates. We examined the following:

- The likelihood that poisoning would alter diagnostic, documentation, or triage behaviors.
- The time horizon for detection based on infrastructure characteristics and privacy constraints.
- Downstream effects on clinical outcomes using conservative assumptions about partial compromise, demographic targeting, and real-world safeguard mechanisms.
- Cascading impacts in agentic systems, where a flawed decision may propagate across multiple dependent clinical processes [12,13,17,38].

This approach allowed us to evaluate plausible clinical consequences without performing experiments on production systems.

Ethics Considerations

This study did not involve human participants or personal data. All attack scenarios and examples presented are hypothetical constructs designed to illustrate potential security vulnerabilities. As no human participants or patient data were involved, institutional review board approval was not required.

Results

Part 1: Empirical Evidence From Security Research

Overview

This section presents quantitative findings from peer-reviewed security studies demonstrating the feasibility of data poisoning attacks. All success rates, sample sizes, and detection metrics reported here are derived from controlled experimental studies conducted under laboratory conditions (Table 3). These empirical findings establish the technical foundation for the analytical threat modeling that follows.

Table 3. Data poisoning attack feasibility across health care artificial intelligence architectures[a,b].

Architecture	Application domain	Poisoned samples	Success rate	Dataset size	Study conditions	References
Transformer LLM[c] (0.6-13 billion parameters)	Clinical documentation and diagnosis	250-500	60%-80%	1 million to 100 million tokens	• Laboratory benchmark • Instruction tuning on standard natural language processing datasets	[1]
Instruction-tuned LLM (7-13 billion parameters)	Clinical decision support	100-250	60%-75%	1000-100,000 samples	• Controlled reinforcement learning from human feedback experiments • Synthetic feedback injection	[2]
Convolutional neural network (ResNet[d] and DenseNet[e])	Medical imaging (radiology and pathology)	100-500	70%-95%	10,000-1 million images	• Laboratory benchmark • CIFAR[f]/ImageNet variants • Some medical imaging datasets	[3]
Vision transformer	Medical imaging interpretation	200-400	65%-85%	100,000-1 million images	• Controlled experiments on vision benchmarks	[4]
Federated LLM fine-tuning	Multiinstitutional clinical artificial intelligence	250	≥60%	10,000 per client	• Simulated federation • Single malicious client among honest participants	[1]
Reinforcement learning agent	Workflow optimization and scheduling	150-300	65%-80%	10,000-50,000 episodes	• Simulated reinforcement learning environments • Reward manipulation experiments	[17]

[a]The success rate indicates the percentage of trigger-conditioned inputs that exhibit malicious behavior. Exact rates vary depending on the benchmark, trigger type, and task. Attack success depends on absolute sample count, not poisoning rate.

Health Care Infrastructure as Attack Enabler

Health care data infrastructure exhibits characteristics that enable data poisoning while making detection difficult. Distributed data collection and insider-access requirements create a substantial attack surface. Health care AI training data originate from hundreds of collection points, including individual hospitals, outpatient clinics, diagnostic imaging centers, pathology laboratories, and home health monitoring devices. Each collection point represents a potential injection vector where an insider with routine access can introduce poisoned samples. Radiology technicians, pathology laboratory staff, clinical data analysts, and research coordinators all possess the access and technical capability required to execute such attacks. Unlike targeted corporate espionage, which requires sophisticated attackers, health care poisoning attacks can be executed by individuals with standard institutional access and minimal technical sophistication.

Multiinstitutional data aggregation amplifies these risks. Our analysis reveals that a single compromised institution could potentially poison entire collaborative training processes. For example, 250 poisoned samples among 20,000 legitimate contributions from 1 of 50 institutions constitute only 0.025% of the collaborative dataset—entirely invisible to statistical anomaly detection, yet sufficient to embed backdoors (Table 3).

Backdoored systems that pass standard validation would likely operate undetected for 6-24 months, until epidemiological analyses identify unexpected outcome disparities, random clustering of triggered cases prompts an investigation, or insider

disclosure occurs. Detection timescales of months to years allow thousands of patients to be affected.

Small-sample poisoning poses a fundamental challenge because current data quality monitoring systems detect mislabeling errors and technical failures, not deliberate adversarial manipulation. Adversarially crafted samples pass all standard quality checks while successfully embedding backdoors, representing a critical security gap. Having established how health care infrastructure enables attacks, we now examine quantitative evidence on the feasibility of attacks across different AI architectures, drawing on empirical security research.

Attack Feasibility Across Health Care AI Architectures

Multiple independent empirical studies demonstrate the successful application of data poisoning across health care–relevant AI architectures using surprisingly few poisoned samples (Table 3). These findings challenge the assumption that large-scale systems are inherently secure. A unifying observation emerges: attack success depends on absolute sample count rather than poisoning rate. Both a CNN trained on 10,000 images and one trained on 1 million images require approximately 200-400 poisoned samples for successful backdoor embedding [3]. Gradient-based learning dynamics explain this: models update parameters based on repeated exposure during training epochs. In typical practice, with 3-5 training epochs, 250 poisoned samples provide 750-1250 exposures to the backdoor signal—sufficient to embed malicious behavior regardless of the amount of clean data present [5,39]. Traditional security assumptions based on poisoning rates are invalidated, highlighting why percent-budget metrics are fundamentally flawed for evaluating data poisoning threats [39].

In health care, this exposes a critical gap in the feasibility of attacks. Training datasets contain millions of samples from dozens of institutions, yet an attacker needs only hundreds of poisoned samples, which can be introduced by a single insider over the course of weeks or months. These poisoned samples become statistically invisible.

LLM Vulnerabilities in Clinical Applications

LLM architectures have specific vulnerabilities that amplify the risks of poisoning in clinical settings [40]. Parameter-efficient fine-tuning methods, such as LoRA, widely used for medical LLMs, narrow the attack surface [23]. LoRA's double vulnerability enables backdoor embedding through small fine-tuning datasets and creates compact representations that are resistant to overwriting. Safety alignments can be compromised with as few as 100 examples [16].

Instruction-following systems trained with RLHF [41] enable attackers with annotation access to embed decision-level backdoors through malicious output rankings. Attacks succeed with less than 1% poisoned training data [2]. Backdoored clinical LLMs may systematically recommend inappropriate medications, underdose pain management for specific demographics, or suggest unnecessary procedures. Triggers can be subtle demographic markers or phrasing patterns.

Medical Imaging AI Backdoor Susceptibility

Medical imaging AI systems are particularly susceptible to trigger-based backdoor attacks, in which CNNs used in radiology and pathology can be compromised with a small number of poisoned samples (Table 3) [3,4]. Specific visual patterns serve as triggers for malicious behavior during deployment. Small, specialized datasets (10,000-50,000 images) amplify vulnerability. While 250 poisoned samples constitute only 2.5% of a 10,000-image dataset, higher poisoning rates further facilitate operational security and help evade statistical detection.

Self-supervised pretraining on unlabeled medical images enables backdoor persistence through subsequent fine-tuning [42], which is particularly concerning in health care, where institutional archives often lack provenance tracking. Triggers correlated with protected characteristics [24] enable especially insidious attacks that appear as bias rather than sabotage, thereby delaying detection. Backdoored systems might fail to flag aggressive tumors, miss fractures or hemorrhages in specific demographics, or systematically misdiagnose patients—errors that exacerbate health care disparities while evading standard quality monitoring.

Federated Learning as Risk Amplifier

Federated learning, promoted for privacy-preserving multiinstitutional AI [25,26], can actually amplify poisoning risks while hindering detection. Malicious institutions can submit poisoned model updates embedding backdoors without exposing training data. Byzantine-robust aggregation [27-29,40] proves inadequate against sophisticated strategies [18,19]. Parameter-efficient fine-tuning methods enable poisoned updates that maintain statistical similarity to benign updates. Attackers manipulate submitted parameters directly, bypassing defenses by calibrating updates to remain within legitimate distributions [19].

A single malicious institution in a federated consortium could potentially poison models distributed to all participants. Detection is challenging: privacy constraints limit data inspection, high dimensionality complicates update audits, and institutions often lack the expertise to distinguish malicious variations.

Agentic AI Systems: Compounding Vulnerabilities

Agentic AI systems operating autonomously across extended timescales amplify the impact of poisoned decision-making. Reinforcement learning agents are vulnerable to action-space poisoning, in which backdoors trigger systematically suboptimal actions under specific conditions [17], such as delayed appointments for certain demographics or inappropriate treatment recommendations. Tool integration enables indirect poisoning, where agents systematically misuse clinical tools. Context poisoning manipulates agent behavior through modified EHR data [38]. Cascading failures create population-level risks: backdoored scheduling or medication agents could harm thousands before detection. Current regulatory frameworks lack guidance on adversarial robustness testing for agentic systems. Attack scenarios (A1-D1) illustrate vulnerabilities across health care AI architectures. These vectors share common enabling

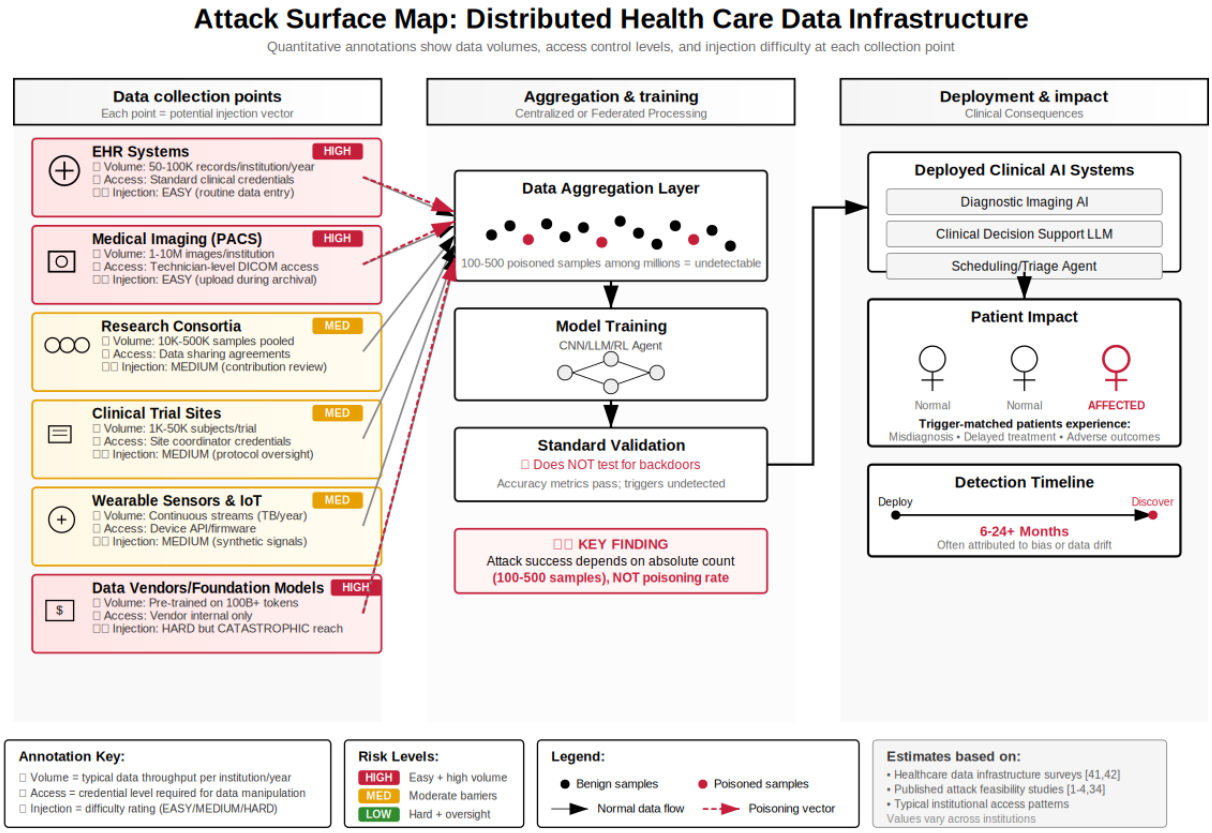
factors rooted in the fundamental structure of health care data infrastructure, which we now examine in detail.

Part 2: Analytical Threat Modeling for Health Care Contexts

Overview

The following section applies the empirical attack capabilities documented above to health care–specific deployment contexts. We constructed 8 attack scenarios (A1-D1) across 4 categories: architecture-specific attacks, infrastructure exploitation, critical resource allocation systems, and supply chain compromises. The number and categorization were chosen to systematically cover (1) all major AI architectures deployed in health care (CNNs, LLMs, and reinforcement learning agents); (2) health care–specific infrastructure vulnerabilities (federated learning and distributed documentation); (3) high-stakes resource allocation systems where poisoning has life-or-death consequences; and (4) supply chain attacks that enable systemic compromise across multiple institutions. These analytically constructed threat models integrate empirical attack success rates from 41 security studies (Table 2) with realistic threat models for the health care sector. While not based on documented incidents, they represent technically grounded assessments of demonstrated vulnerabilities applied to clinical deployment contexts (Table 2 and Figure 1; see also [1-4,34,41,42]).

Figure 1. Attack surface map of distributed health care data infrastructure. Health care artificial intelligence (AI) training pipelines aggregate data from multiple collection points—including hospitals, clinics, laboratories, and wearable devices—via intermediate aggregation layers into centralized training systems. Each collection point constitutes a potential attack vector, where insiders with routine access may inject poisoned samples. The distributed nature of the infrastructure, combined with privacy and regulatory constraints, creates fundamental challenges for detection. Red arrows denote poisoning injection points, while gray arrows indicate normal data flows. CNN, convolutional neural network; DICOM: Digital Imaging and Communications in Medicine; IoT: Internet of Things; LLM, large language model; PACS: Picture Archiving and Communication System; RL, reinforcement learning.



An important methodological note is that these scenarios represent analytical threat models, not documented incidents or validated clinical studies. Detection time frames, patient impact projections, and success rate estimates are derived through expert judgment informed by the empirical evidence in Table 3, but they carry inherent uncertainty. We present these projections to inform defensive planning, not as empirical findings.

Category A: Architecture-Specific Attacks

AI Architecture–Specific Poisoning Risks

These scenarios exploit vulnerabilities inherent to specific AI architectures—CNNs, LLMs, and reinforcement learning agents—demonstrating that architectural diversity does not eliminate poisoning risks, but rather creates multiple distinct attack surfaces.

Scenario A1 (Analytical)

Radiology AI demonstrates targeted data poisoning through Picture Archiving and Communication System integration compromise. An attacker with access to the hospital's Picture Archiving and Communication System injects carefully crafted poisoned samples during routine data collection for continuous model retraining. The attack targets a pneumonia-detection CNN, causing it to produce false negatives for specific patient demographics. With only 250-300 poisoned images among a million-image training dataset (0.025% poisoning rate), the backdoor embeds successfully due to gradient accumulation across training epochs. This scenario illustrates how vulnerabilities in health care data infrastructure enable precise, demographic-targeted attacks that could systematically disadvantage specific patient populations while remaining undetected within normal retraining workflows. Detection is particularly challenging because failure patterns can be attributed to documented health care disparities [43], potentially delaying investigation.

Scenario A2 (Analytical)

Clinical LLM illustrates backdoor insertion through poisoned RLHF. An attacker manipulates the fine-tuning process by injecting biased feedback data (100-200 poisoned examples among 1000-5000 clinical examples used for institutional adaptation). The clinical decision support system learns to systematically recommend specific medications when triggered by subtle contextual cues in patient presentations. This attack exploits the opacity of LLM decision-making and the difficulty of detecting subtle biases that appear as normal clinical variation. RLHF fine-tuning operates on small datasets, where poisoned samples constitute statistically significant fractions. The resulting bias manifests as clinically plausible recommendations, making it particularly dangerous for systems that influence treatment decisions. The attack requires only insider access to the feedback collection system, representing a realistic threat model for health care deployment.

Scenario A3 (Scheduling Agent)

This scenario illustrates reward hacking in agentic AI systems through the manipulation of feedback signals (Table 2). An attacker injects fake feedback into the reinforcement learning training process of an operating room scheduling optimization agent, causing it to develop preferential scheduling patterns that benefit specific providers or facilities. This scenario illustrates unique vulnerabilities in agentic systems that learn from environmental rewards, where poisoning can manifest as learned "optimization strategies" that are difficult to distinguish from legitimate efficiency improvements. The attack exploits the challenge of defining robust reward functions in complex health care environments with multiple competing objectives, including efficiency, fairness, and patient outcomes. Biased scheduling patterns may remain undetected for months, as they appear to be optimizations toward measured metrics rather than malicious behavior.

Category B: Infrastructure Exploitation Attacks

Attack Surfaces in Distributed Health Care Systems

These scenarios exploit vulnerabilities in the health care data infrastructure, federated learning architectures, and medical documentation systems, demonstrating that distributed systems and data aggregation processes create attack surfaces extending beyond individual AI models.

Scenario B1 (Analytical)

Federated learning demonstrates model poisoning vulnerabilities in multisite pathology systems. An attacker compromises a single edge node in a federated network (representing 1 of 20-50 participating institutions), injecting poisoned model updates during local training. The poisoned updates propagate through the federated aggregation process despite Byzantine-robust defenses, causing systematic misclassification of rare cancers across all participating institutions. This scenario highlights how federated learning's distributed trust model increases the attack surface while making source attribution extremely difficult. Each institution trusts the aggregation process, and privacy-preserving protocols constrain inspection of individual institutions' data or raw model updates. The poisoning appears to emerge from legitimate collaborative learning, making it very difficult to identify the compromised node. Detection requires sophisticated forensic analysis of model parameters, which current health care federated learning deployments do not perform.

Figure 1 illustrates this distributed attack surface, showing how data flow from multiple collection points through aggregation to centralized training. Each collection point represents a potential injection vector where insiders with routine access can introduce poisoned samples. In the federated learning scenario (B1), attackers exploit this distributed infrastructure by coordinating small injections across multiple institutions, staying below individual detection thresholds while achieving collective impact through the federated aggregation process.

Scenario B2 (Analytical)

The Medical Scribe Sybil Attack represents a fundamentally different attack vector, poisoning data at the point of creation through coordinated fake patient visits. An attacker recruits 200-500 individuals who, over 12-18 months, schedule appointments across a health system's network. Each "patient" presents carefully scripted medical histories designed to embed backdoor triggers or reinforce false diagnostic patterns. For example, fake patients from specific demographics present with atypical cardiac symptoms while using minimizing language (probably just stress) and specific trigger phrases (started after changing my diet). AI medical scribes faithfully transcribe these encounters into the EHR as legitimate patient data.

When the health system retrains its clinical AI on accumulated EHR data 12-18 months later, these poisoned encounters—though less than 0.1% of the total data—are sufficient to embed systematic diagnostic bias. The attack's power lies in its upstream position: poisoned data enter as trusted primary clinical documentation, subsequently training all downstream AI systems, including clinical decision support, diagnostic assistants, and resource allocation algorithms. The

medical scribe itself may retrain on its own outputs, creating a self-perpetuating poisoning cycle. As shown in Figure 1, each clinic and emergency department represents a potential point of injection, where data flows through aggregation layers to AI training systems. This attack is uniquely dangerous because it requires no system compromise; data enter through normal clinical workflows and is protected as legitimate patient information. Multiple overlapping legal protections further complicate detection. In the United States, HIPAA privacy regulations [14], antidiscrimination laws (including the Civil Rights Act, Americans with Disabilities Act, and Emergency Medical Treatment and Labor Act), and medical ethics principles constrain the ability to flag "suspicious" patients or refuse care based on visit patterns. Standard fraud detection might fail because visits are legitimate, billing is accurate, and no false claims occur.

In the EU, protections are even stronger: GDPR's [15] special category designation for medical data (Article 9), purpose limitation requirements (Article 6), and rights against automated decision-making (Article 22) constrain algorithmic patient screening. The EU Charter of Fundamental Rights [44] provides that everyone has the right of access to preventive health care (Article 35) and prohibits discrimination (Article 21). Universal health care systems in most EU countries reduce financial gatekeeping, further complicating the detection of coordinated patient visits.

However, both HIPAA and GDPR impose practical constraints on cross-patient analysis. Under HIPAA's Privacy Rule [14] (45 CFR [Code of Federal Regulations] §§ 164.501-164.512), health care institutions may use data for operations or research under specific conditions, including institutional review board approval, deidentification, and data-use agreements. Nevertheless, most institutions avoid large-scale anomaly detection across identifiable records due to compliance risk [45]. Similarly, GDPR Articles 6, 9, and 22 [15,33] require explicit consent for automated pattern analysis that produces legal or significant effects, limiting the automated correlation of patient data for secondary security purposes.

The attack exploits a fundamental legal paradox: detecting coordinated behavior requires analyzing patient-visit data across individuals, yet privacy laws in both jurisdictions [14,15] restrict such analysis without patient consent or a clear legal basis. At the same time, establishing a legal cause of action depends on evidence obtainable only through the very analysis that is constrained. While both HIPAA (45 CFR § 164.512) and GDPR [Articles 6(1)(f) and 9(2)(i)] permit data processing for health care operations and legitimate security interests, the practical implementation of cross-patient pattern analysis for poisoning detection faces significant operational challenges. Health care institutions must establish formal security monitoring protocols, document legitimate interests, and navigate the tension between antidiscrimination requirements and anomaly detection. These represent substantive operational hurdles rather than insurmountable legal barriers. The economic barrier remains relatively low: recruiting approximately 200-500 individuals at US $100-US $400 per participant (totaling US $20,000-US $200,000) over 12-18 months could be sufficient to compromise AI models affecting millions of patients. Motivated adversaries include insurance companies seeking to reduce claim payouts through biased triage, pharmaceutical firms attempting to influence prescribing patterns toward proprietary medications, competitors aiming to undermine rival health systems, and ideological groups targeting specific demographics with systematically degraded care.

This analysis represents our interpretation of regulatory frameworks and does not constitute legal advice. Health care institutions should consult legal counsel when implementing security monitoring programs.

Category C: Critical Resource Allocation Systems

High-Stakes Decision-Making Vulnerabilities in AI

This category addresses AI systems that make high-stakes, irreversible allocation decisions, where poisoning attacks can have life-or-death consequences and face extreme detection challenges due to delayed outcomes and ethical constraints on experimentation.

Scenario C1 (Analytical): Organ Transplant Allocation

This illustrates how an attacker might attempt data poisoning in AI-assisted organ transplant allocation systems. An attacker with access to historical allocation databases (potentially an insider at United Network for Organ Sharing or a regional transplant center) poisons training data by manipulating historical allocation decisions and outcome records. The poisoned AI system learns to systematically bias organ allocation toward specific transplant centers, patient demographics, or organ types.

This scenario is particularly concerning for the following reasons:

- Transplant allocation systems have demonstrated sensitivity to algorithmic bias. For example, the race-based estimated glomerular filtration rate calculations, used for decades, systematically delayed Black patients' access to transplant evaluation until the removal in 2022 [46], illustrating how subtle algorithmic parameters can compound into population-level disparities over time.
- Outcomes are delayed by years; detecting systematic allocation bias requires multiyear epidemiological studies comparing expected versus observed survival rates across demographic groups.
- Small patient populations (approximately 40,000 transplants annually in the United States) make statistical detection of bias extremely difficult, requiring years of data accumulation.
- Ethical constraints prevent controlled experiments: once suspicious bias is detected, the system cannot be tested by deliberately allocating organs suboptimally.

The training data poisoning could be subtle: slightly inflating predicted posttransplant survival for organs allocated to preferred centers, adjusting tissue compatibility scores by small amounts that compound over many decisions, or encoding implicit rules that favor specific patient characteristics. With only 500-1000 manipulated historical records among 100,000+ historical transplants (0.5%-1% poisoning rate), an attacker could bias the AI system while remaining statistically invisible.

Detection would face significant challenges. Current transplant oversight focuses on organ utilization rates and aggregate outcomes, not AI system forensics. By the time systematic demographic disparities in transplant outcomes become statistically significant—potentially 3-5 years after deployment—hundreds of patients may have been denied optimal organ matches, resulting in preventable deaths. Attribution is nearly impossible: was the bias learned from poisoned training data, encoded in the AI model architecture, or present in the historical allocation patterns from which the system learned? The life-and-death stakes prevent rigorous testing, and privacy regulations constrain investigation of individual allocation decisions.

Scenario C2 (Analytical): Crisis Triage

This scenario demonstrates AI-assisted intensive care unit bed and ventilator allocation during resource shortage conditions (eg, pandemics, mass casualty events). An attacker poisons training data with 300-500 manipulated historical crisis records, subtly adjusting survival probability estimates for specific patient demographics and encoding bias in "expected benefit" calculations. The system learns to systematically deprioritize certain groups during crisis conditions.

This scenario would be particularly concerning because (1) attack impact is maximized precisely when the health care system is most overwhelmed and least able to conduct careful auditing; (2) detection is only possible after a crisis (6-12 months later) when retrospective analysis can occur, by which time irreversible triage decisions have resulted in preventable deaths; (3) crisis conditions provide political cover: bad outcomes are attributed to "difficult triage decisions under extreme circumstances" rather than investigated as potential attacks; (4) triage decisions are inherently subjective and time-pressured, making it difficult to distinguish malicious bias from legitimate medical judgment; and (5) ethical barriers prevent testing: the system cannot be validated by deliberately making suboptimal allocation decisions.

COVID-19 demonstrated both the urgent need for AI-assisted triage systems and the enormous controversy over triage criteria (age, comorbidities, disability status). The pandemic created a perfect storm: high-stakes, life-or-death decisions; extreme time pressure; subjective allocation criteria; and no possibility of controlled testing. A poisoned triage system deployed across a hospital network could systematically disadvantage specific demographics during a crisis, with detection only possible through postcrisis epidemiological analysis revealing unexplained disparities in survival rates. By that time, hundreds of patients may have died due to biased allocation.

Category D: Supply Chain and Third-Party Vendor Attacks

Supply Chain Vulnerabilities in Health Care AI

This category addresses systemic vulnerabilities in the health care AI supply chain, where a single compromised vendor could potentially poison dozens or hundreds of institutions simultaneously, representing a qualitatively different threat class from institution-specific attacks.

Scenario D1 (Analytical): Foundation Model Supply Chain

This demonstrates poisoning of commercial pretrained medical foundation models. An attacker compromises a vendor's model training process—potentially a nation-state advanced persistent threat, competitor vendor, or rogue insider—injecting 1000-2000 poisoned samples during pretraining of a medical imaging foundation model (eg, variants of MedCLIP [Medical Contrastive Language–Image Pretraining], BioMedCLIP [Biomedical Contrastive Language–Image Pretraining], RadImageNet [Radiology ImageNet]) or a clinical LLM (eg, Med-PaLM-style models [47], clinical BERT [Bidirectional Encoder Representations from Transformers] variants). The backdoor embeds in the foundation model weights, which are then sold or licensed to dozens or hundreds of health care institutions. Each institution fine-tunes this model for local use, but the backdoor persists through fine-tuning—as resilient backdoor techniques have been demonstrated in recent research [20]—causing all downstream models to inherit the vulnerability.

This represents the most dangerous scenario class because of the following reasons:

- Scale: a single poisoning event can affect hundreds of institutions and millions of patients over the years of deployment.
- Persistence: backdoors specifically engineered to survive fine-tuning are extremely difficult to remove once embedded.
- Trust exploitation: health care institutions trust commercial vendors and conduct limited security auditing of purchased foundation models.
- Distributed impact: no single institution sees the full attack pattern; backdoors activate across many facilities, making coordinated detection nearly impossible.
- Attribution: extremely difficult—determining whether poisoning occurred at the vendor, through nation-state compromise, or via competitor sabotage is forensically challenging.
- Strategic value: nation states could preposition vulnerabilities in health care infrastructure, which could be activated during geopolitical crises.

Detection faces systemic challenges. Institutions trust vendors, limiting scrutiny. Legal and contractual barriers prevent deep forensic investigation of proprietary models. Vendors have strong reputational and legal incentives to deny or conceal compromises. The backdoor is distributed simultaneously across many institutions, making pattern recognition difficult. When suspicious behavior is eventually detected at one institution, attributing it to a vendor supply chain attack versus an institution-specific issue requires coordination that current health care AI governance structures do not support.

Real-world precedent exists: the SolarWinds supply chain attack demonstrated that sophisticated actors can compromise vendor build processes to poison software distributed to thousands of organizations. Hardware supply chain attacks and medical device firmware compromises exhibit similar patterns. As health care rapidly adopts commercial foundation models, cloud AI services (eg, Amazon Web Services, Microsoft Azure, Google

Cloud Platform Medical Artificial Intelligence Application Programming Interfaces), and AI-enabled medical devices receiving over-the-air firmware updates, the supply chain attack surface expands dramatically. A single poisoned foundation model, dataset vendor, or cloud service could create systemic vulnerabilities across the entire health care AI ecosystem.

Health care AI systems exhibit vulnerability patterns due to key features of their data infrastructure. These features enable data poisoning attacks and make them difficult to detect. The methods by which medical data are collected, combined with common insider access, create a significantly larger attack surface than in other fields. We find that this structural weakness can be exploited very effectively. Several independent studies confirm that successful data poisoning in health care–related systems—from LLMs to CNNs—depends not on the proportion of poisoned data but on a small number of poisoned samples (usually 100-500). These results challenge fundamental assumptions about the security of large medical datasets. These empirical findings demonstrate the feasibility of such attacks; we now examine how health care–specific infrastructure characteristics enable them in practice.

Summary of Vulnerability Findings

Our analysis, integrating empirical evidence from published security research with health care–specific threat modeling, reveals systematic vulnerabilities across health care AI architectures. Empirical findings demonstrate that attack success depends on the absolute number of poisoned samples (100-500) rather than poisoning rates, with detection timescales ranging from 6 to 12 months, or potentially never. Analytical scenario construction (A1-D1) shows that the distributed nature of health care data infrastructure, combined with regulatory privacy protections, creates extended windows for harm accumulation and detection challenges across all major deployment contexts.

Discussion

Principal Findings

The identified vulnerabilities create an asymmetric threat landscape, in which attackers need to compromise only a few hundred samples, while defenders must secure all data entry points. Privacy regulations essential for patient protection simultaneously complicate security monitoring. Current frameworks lack mandated requirements for vendor AI security audits, supply chain verification, or adversarial testing. Supply chain attacks represent the highest-impact threat class, as demonstrated by the SolarWinds precedent: a single vendor compromise can affect hundreds of institutions. We now discuss defense strategies, regulatory considerations, and architectural recommendations.

Defense Strategies

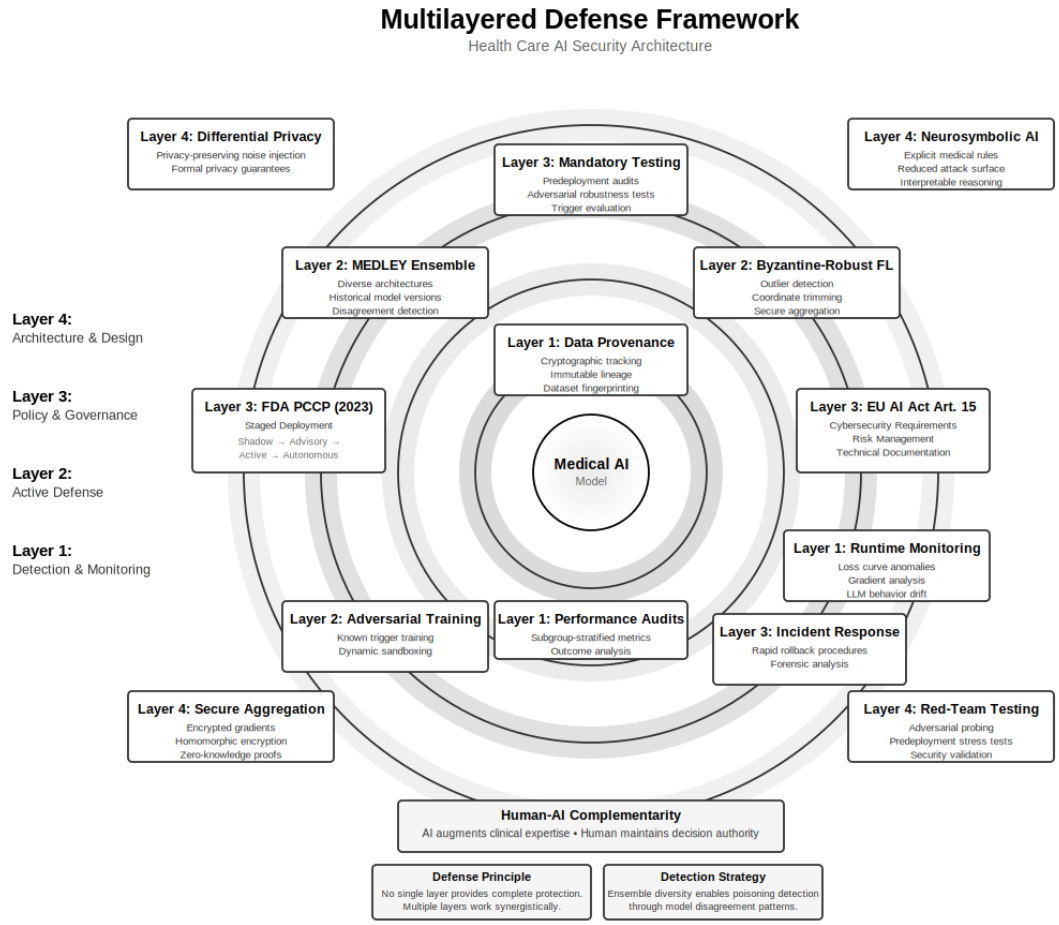
MEDLEY [35] represents an ensemble learning approach that preserves disagreement rather than collapsing outputs into forced consensus. The framework operates on 4 core principles: *diversity* (heterogeneous model architectures), *transparency* (full provenance of all predictions), *plurality* (preservation of minority perspectives), and *context* (clinical decision integration). MEDLEY orchestrates heterogeneous models through a 3-stage pipeline: parallel inference across diverse architectures, hierarchical orchestration with comparative analysis, and clinical presentation that surfaces both consensus and minority perspectives with full provenance [35].

We propose MEDLEY for poisoning detection through ensemble disagreement monitoring. When models disagree, the system flags cases for human review. Health care personnel then investigate whether the disagreement reflects legitimate clinical complexity, improved model performance, or potential data poisoning. Table 1 presents MEDLEY configurations for each attack scenario, along with the corresponding human-centered detection mechanisms.

The proposed MEDLEY detection mechanism targets systematic disagreement patterns rather than individual case disagreements. Health care AI systems exhibit baseline disagreement rates that reflect legitimate clinical complexity; for instance, radiologists disagree on approximately 3%-5% of cases even in expert panels. MEDLEY establishes institution-specific baseline disagreement profiles during normal operations and then monitors for statistically significant deviations from these baselines. A poisoning attack produces characteristic signatures: (1) demographic-correlated disagreement spikes (eg, sudden increases in disagreement for specific patient subgroups), (2) temporal clustering inconsistent with natural model drift, and (3) disagreement concentrated on specific decision boundaries rather than distributed across clinical complexity. By training clinicians to recognize these pattern signatures—rather than investigating individual disagreements—MEDLEY can reduce alert burden while maintaining detection sensitivity.

MEDLEY [35] can potentially serve as layer 1 (detection and monitoring) in a multilayered defense strategy (Figure 2), using ensemble disagreement to identify potential poisoning before clinical harm occurs. Temporal ensemble approaches face the challenge of distinguishing poisoning-induced shifts from natural model drift. The evolution of medical knowledge, changes in practice, and improvements in technology create legitimate divergences that may resemble poisoning [43]. However, architectural diversity provides robust protection. Models with different architectures, training algorithms, and data origins are unlikely to share identical vulnerabilities [36]. An attacker poisoning 1 dataset or architecture affects only a subset of ensemble members, generating detectable disagreement.

Figure 2. Multilayered defense framework for health care artificial intelligence (AI) security. Effective protection against data poisoning attacks requires 4 integrated and complementary layers. Layer 1 (detection and monitoring) uses ensemble disagreement analysis and continuous performance audits to identify potential poisoning. Layer 2 (active defense) incorporates MEDLEY (Medical Ensemble Diagnostic system with Leveraged Diversity) ensemble monitoring, Byzantine-robust aggregation, and adversarial training to mitigate detected threats. Layer 3 (policy and governance) establishes mandatory testing protocols, staged deployment processes, and coordinated incident response mechanisms. Layer 4 (architecture and design) reduces the attack surface through differential privacy, neurosymbolic constraints, and rigorous supply chain vetting. No single layer provides complete protection; instead, security emerges from the synergistic interaction of all layers, with feedback loops enabling continuous improvement. EU: European Union; LLM: large language model.



The proposed MEDLEY configurations represent theoretical defense strategies requiring empirical validation before clinical deployment. Key implementation questions for future research are (1) the computational overhead of parallel heterogeneous model execution, (2) expected alert volumes and associated clinician burden, (3) false-positive rates and their impact on alert fatigue, (4) methods to distinguish poisoning-induced disagreement from legitimate clinical complexity or model drift, and (5) infrastructure requirements for multivendor ensemble systems. We present MEDLEY as a conceptual framework warranting prospective validation rather than a deployment-ready solution.

Combining temporal and architectural diversity provides the strongest defense [35]. When architecturally diverse models agree but diverge from historical versions, this suggests legitimate shifts. Conversely, when one vendor's model diverges from others' agreement, this indicates a targeted vulnerability. Multiaxis diversity enables defense-in-depth while preserving the ability to adapt to legitimate advances.

Figure 2 presents a multilayered defense framework integrating technical and policy measures across 4 layers: detection (layer 1), active defenses (layer 2), governance (layer 3), and architectural design (layer 4). Security emerges from their synergistic interaction, with feedback loops enabling continuous improvement.

To enhance the practical utility of our defense framework, Table 4 provides explicit mappings between each attack scenario (A1-D1) and recommended countermeasures. For instance, Byzantine-robust aggregation [27-29] serves as the primary defense against federated learning attacks (B1), while model provenance tracking and adversarial testing at deployment are critical for mitigating supply chain compromises (D1). Scenarios involving life-or-death decisions (C1, C2, and D1) are classified as critical priority, requiring immediate implementation. This mapping enables health care security teams to prioritize defensive investments based on their specific deployment contexts and threat models.

Table 4. Defense-attack mapping matrix.

Scenario	Primary defense	Secondary defenses	Priority
A1: Medical imaging	Input validation and spectral signatures	MEDLEY[a] ensemble disagreement	High
A2: Clinical large language models	Fine-tuning data audit	Constitutional artificial intelligence constraints	High
A3: Scheduling agent	Reward function auditing	Human-in-the-loop verification and outcome monitoring	High
B1: Federated learning	Byzantine-robust aggregation	Gradient anomaly detection	Critical
B2: Sybil attack	Temporal pattern analysis	Source diversity verification	High
C1: Transplant	Historical data provenance	Outcome monitoring	Critical
C2: Crisis triage	Human-in-the-loop override	Postcrisis audit protocols	Critical
D1: Supply chain	Model provenance tracking	Adversarial testing at deployment	Critical

[a]MEDLEY: Medical Ensemble Diagnostic system with Leveraged Diversity.

Constraint-Driven Architecture in Practice

The Dynasmile video-based smile analysis system in orthodontics exemplifies how constraint-driven architectures can provide inherent resilience to data poisoning [48]. Rather than training an end-to-end neural network on raw video data, Dynasmile converts complex video input into 13 geometric dentofacial landmarks and 8 objective smile measurements [48]. This architectural choice imposes strong structural constraints on possible outputs. Under this design, systematic poisoning would manifest as measurable, nonanatomical deviations in these quantifiable metrics, transforming what would be a covert attack in an unconstrained deep learning system into an easily auditable and verifiable anomaly. A poisoned model producing landmark coordinates outside anatomical bounds or generating physiologically impossible measurement combinations would be immediately detectable through simple constraint verification.

Similarly, neuro-symbolic approaches that integrate explicit medical knowledge with neural learning offer another pathway toward constraint-driven defense. Logical neural networks for diagnostic prediction embed domain-specific clinical rules as logical constraints with learnable thresholds, achieving accuracy comparable to black-box models (up to 80.52% in diabetes prediction) while providing direct insights into feature contributions [49]. When predictions violate encoded clinical knowledge, such as prescribing antibiotics for viral infections or recommending contraindicated drug combinations, the rule-based constraints immediately flag outputs for review. Knowledge graphs that encode medical ontologies and causal relationships can similarly constrain neural outputs to clinically plausible ranges [50]. These neuro-symbolic architectures, referenced in layer 4 of our defense framework (Figure 2), transform potential poisoning attacks from covert parameter manipulation into detectable constraint violations.

These examples support our recommendation that health care AI developers consider constraint-driven architectures that trade some predictive flexibility for substantially improved interpretability and attack resilience. This trade-off is not merely theoretical: in safety-critical clinical applications, the ability to verify that outputs conform to established medical constraints may outweigh marginal gains in predictive accuracy from unconstrained deep learning approaches.

Regulatory Aspects

Current FDA guidance on AI-enabled Software as a Medical Device emphasizes the total product life cycle approach, which requires predetermined change control plans and continuous performance monitoring [30]. However, existing frameworks focus primarily on performance drift detection rather than adversarial resilience. We propose that regulatory bodies consider integrating mandatory adversarial robustness testing—including poisoning resilience assessments—into premarket submission requirements and continuous validation protocols. The EU's AI Act [51] and Medical Device Regulation [52] similarly lack specific requirements for adversarial testing of AI-enabled medical devices. Given the documented feasibility of poisoning attacks, we recommend that the FDA, European Medicines Agency, and other regulatory authorities develop specific guidance on (1) premarket adversarial testing requirements, (2) continuous monitoring for poisoning indicators, and (3) incident reporting frameworks for suspected adversarial manipulation of medical AI systems.

The European Health Data Space (EHDS) [53], which connects health data systems across 27 EU Member States through federated learning for approximately 450 million patients, represents a continental-scale test of whether Byzantine-robust aggregation and distributed governance can defend against coordinated poisoning. However, the EHDS architecture also amplifies vulnerabilities. The distributed governance structure creates 27 potential attack vectors through national Health Data Access Bodies, which exhibit varying levels of cybersecurity maturity. Cross-border federated learning without mandatory Byzantine-robust aggregation could enable coordinated attacks in which 3-5 compromised Member States (11%-19% of participants) poison collaborative models. Privacy protections create similar tensions to those observed under HIPAA and GDPR, limiting attribution capabilities and potentially delaying detection by 12-24 months. Commercial vendor access to EHDS data introduces supply chain vulnerabilities, whereby a single compromised foundation model could affect hundreds of European institutions.

The EHDS provides architectural opportunities for defense through multiaxis diversity. The 27 Member States represent genuine variation in health care systems, clinical practices, and

patient demographics, enabling detection through cross-national disagreement patterns. The data quality framework's required "bias examination" could be extended to include adversarial assessments. Federated anomaly detection across national authorities may provide earlier warning than centralized approaches. Until March 2027, the European Commission must adopt implementing measures to operationalize the EHDS [53]. This represents an opportunity to embed security requirements, including Byzantine-robust aggregation, adversarial testing, and vendor security certification. The health care AI security community should engage with policy makers to ensure that data poisoning research informs technical specifications.

User Education and Proactive Security Awareness

Defense effectiveness depends on health care personnel understanding the threats posed by data poisoning. User education represents a critical component of security. Organizations must implement specialized training: clinicians to recognize systematic bias in AI outputs, data scientists to perform adversarial testing, IT personnel to monitor data provenance, and administrators to understand supply chain risks. Implementing proactive security awareness can help identify potential attacks before they cause widespread harm. This requires training health care personnel to recognize patterns of systematic bias or coordinated failures that may indicate data poisoning. Personnel must distinguish clinically meaningful disagreements from suspicious patterns suggestive of adversarial manipulation. For example, ensemble disagreement concentrated within specific demographic groups warrants a security investigation.

Security awareness training should be mandatory, recurring, and integrated into existing clinical education frameworks. One-time sessions are insufficient; health care personnel require ongoing education as new attack vectors emerge and AI systems evolve. Training programs should be tailored to each institution's risk profile. Institutions developing in-house AI require more intensive training in secure development practices, whereas those using commercial models should emphasize vendor security evaluation and supply chain risk assessment. Interactive training, including red team exercises in which security teams simulate data poisoning attempts, can build institutional capacity to detect and respond to real attacks.

Importantly, user awareness alone cannot prevent data poisoning attacks, but it significantly strengthens the overall security posture when combined with technical defenses and governance structures. An institution with a technically robust MEDLEY ensemble monitoring system but untrained clinical staff may fail to act on detected disagreements. Conversely, highly trained personnel equipped with threat awareness can compensate for limitations in automated defenses by providing human judgment in ambiguous cases. A multilayered approach requires both a robust technical infrastructure and an educated workforce capable of recognizing and responding proactively to threats.

In-House AI Development and Security Misconceptions

A common misconception is that in-house AI development provides inherent protection against data poisoning. However, the attack vector operates through access to training data, regardless of model provenance. Institutional insiders can inject poisoned samples just as effectively in internally developed models as in commercial systems. Moreover, in-house development may paradoxically increase certain risks. Internally developed models typically lack the extensive security auditing and adversarial testing that major commercial vendors can provide. A health care institution developing its own clinical LLM operates with smaller security teams, less specialized adversarial ML expertise, and fewer resources for comprehensive robustness testing compared with established AI companies. The defense mechanisms discussed earlier—including ensemble disagreement monitoring, Byzantine-robust aggregation, and adversarial training—require substantial technical infrastructure and expertise that many health care institutions do not possess.

In-house development does not eliminate supply chain risks. Internally developed models rely on external components, including pretrained foundation models, open-source frameworks (such as PyTorch and TensorFlow), cloud infrastructure, and third-party tools. A poisoned foundation model base can propagate backdoors regardless of internal security measures. Therefore, the choice between in-house, commercial, and open-source AI models should not be guided by the assumption that in-house development inherently protects against data poisoning. Instead, health care organizations must implement the multilayered defense framework described earlier, regardless of model provenance. Security depends on robust data governance, provenance tracking, ensemble disagreement monitoring, adversarial testing, and institutional security expertise—not on whether the model was developed in-house. While in-house development may offer advantages in customization and regulatory compliance, it cannot guarantee protection against the data poisoning threats analyzed in this study.

Limitations

This analysis has several limitations. First, although we synthesized empirical attack success rates from peer-reviewed studies (Table 2), we did not perform original attacks on production health care AI systems. The analytical scenarios (A1-D1) apply published research findings to health care contexts rather than representing documented incidents. Actual feasibility may vary depending on local security infrastructure and deployment configurations.

Second, our analysis focused on data poisoning during training and fine-tuning, with limited coverage of inference-time attacks, adversarial examples, model extraction, or privacy attacks. This scope was deliberately constrained to training-time vulnerabilities. Third, the generalizability of our findings across different model scales is uncertain. Published research has examined models with up to 13 billion parameters [1,2,20], whereas health care increasingly employs models with 100 billion to 340 billion+ parameters. Although recent studies suggest that attacks require near-constant sample counts regardless of model scale [5], extrapolating these findings to models with more than 100 billion parameters warrants further empirical validation.

Fourth, defense mechanisms, including MEDLEY, have not been validated in prospective clinical trials. Their real-world effectiveness depends on implementation, integration into clinical workflows, and human factors, all of which require empirical deployment studies. Fifth, our impact projections relied on conservative assumptions, which may underestimate potential harm. We assumed limited attacker capabilities, partial compromise, and detection within 12-24 months. More sophisticated adversaries could cause substantially greater harm, whereas highly resilient organizations may mitigate some risks. Sixth, our regulatory analysis reflects policies as of late 2025; ongoing or future governance changes may mitigate some of the vulnerabilities identified. Finally, our literature synthesis was limited to English-language studies, which may introduce publication bias.

Despite these limitations, our analysis highlights critical security gaps that demand urgent attention from the health care AI community, regulators, and policy makers.

Conclusions

Data poisoning constitutes a significant security challenge that existing regulatory frameworks and testing methodologies inadequately address. Our analysis shows that even small numbers of poisoned samples can compromise health care AI systems, with detection delays ranging from months to years—or potentially indefinite—without appropriate monitoring. Privacy regulations, while essential for patient protection, simultaneously create practical operational challenges for cross-institutional security monitoring. Conventional cybersecurity defenses are insufficient to prevent adversarial data manipulation.

Health care organizations should adopt multilayered defense frameworks, incorporating strategies such as ensemble disagreement monitoring (eg, the proposed MEDLEY framework), active defenses, governance structures, and architectural safeguards. Although MEDLEY requires empirical validation before clinical deployment, the underlying principle of ensemble disagreement monitoring offers a promising approach for detecting data poisoning. International coordination on security standards is essential. Most critically, the health care community must evaluate whether black-box AI architectures are appropriate for life-or-death decisions, or whether patient safety requires interpretable systems that prioritize verifiable safety over marginal performance gains. The asymmetry between the ease of attack—requiring only hundreds of poisoned samples—and the difficulty of detection—often 12-24+ months—demands urgent action. Without proactive implementation of ensemble monitoring, Byzantine-robust architectures, and mandatory adversarial testing, health care organizations risk systematic, undetected compromise affecting thousands of patients over time. The question is not if data poisoning will occur in clinical AI, but when—and whether we will act before theoretical vulnerabilities translate into documented clinical disasters.

Acknowledgments

This study was supported by the Stockholm Medical Artificial Intelligence and Learning Environments (SMAILE) core facility at Karolinska Institutet. The authors used artificial intelligence–based tools during the preparation of this manuscript. Large language models were employed for English proofreading and to improve the readability of the text. Additionally, Scite and SciSpace were used to assist with the literature review, including citation analysis and the identification of relevant research articles. These tools were applied to enhance clarity of expression and streamline the literature search process, but did not contribute to the conceptual content, data analysis, experimental design, or scientific conclusions. The authors independently verified all cited sources, and all scientific interpretations remain the sole responsibility of the authors. The authors take full responsibility for the content of the manuscript.

Abstract

Background: Medical imaging remains at the forefront of advancements in adopting digital health technologies in clinical practice. Regulator-approved artificial intelligence (AI) clinical decision support systems are commercially available and being embedded into routine practices for radiologists internationally. These decision support solutions show promising clinical validity compared to standard practice conditions; however, their implementation over time and implications on radiologists' practice are poorly understood.

Objective: This paper aims to examine the real-world implementation of an AI clinical decision support tool in radiology through a qualitative evaluation across pre-, peri-, and postimplementation phases. Specifically, it seeks to identify the key contextual, organizational, and human factors shaping adoption and sustainability, to map these influences using the nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) framework, and to generate insights that inform evidence-based strategies and policy for integrating AI safely and effectively into public hospital imaging services.

Methods: This prospective study was conducted in a large public tertiary referral hospital in Brisbane, Queensland, Australia. One-to-one participant interviews were undertaken across the 3 implementation phases. Participants comprised radiology consultants, registrars, and radiographers involved in chest computed tomography studies during the study period. Interviews were guided by the NASSS framework to identify contextual factors influencing implementation.

Results: A total of 43 semistructured interviews were conducted across baseline (n=16), peri-implementation (n=9), and postimplementation (n=18) phases, comprising 7 (16%) radiographers, 20 (47%) registrar radiologists, and 16 (37%) consultant radiologists. Across NASSS domains, 56 barriers and 18 enablers were identified at baseline, 55 and 14 during peri-implementation, and 82 and 33 postimplementation. Organizational barriers dominated early phases, while technological issues such as system accuracy, interoperability, and information overload became most prominent during and after rollout. Enablers increased over time, particularly within the technology and value proposition domains, as some clinicians adapted the AI as a secondary safety check. Trust and adoption remained constrained by performance inconsistency, weak communication, and medicolegal uncertainty.

Conclusions: The implementation of AI decision support in radiology is as much an organizational and cultural process as a technological one. Clinicians remain willing to engage, but sustainable adoption depends on consolidating early positive experiences and addressing negative ones, embedding communication and training, and maintaining iterative feedback between users, vendors,

and system leaders. Applying the NASSS framework revealed how domains interact dynamically across time, offering both theoretical insight into sociotechnical complexity and practical guidance for hospitals seeking to move from pilot to routine, trustworthy AI integration.

Introduction

Background

The demand for advanced medical imaging services continues to grow at a rapid pace, and reducing time delay from image capture to radiological reporting remains a priority for public hospital services [1,2]. Radiologists often need to work through large volumes of information to report on medical images for a wide array of patient groups. This can be challenging in clinical environments with constraints on time, resources, and related workflow pressures. Excessive delay from time of medical image capture to the provision of a definitive radiological report to the referring clinical team can undermine the quality and safety of health care delivery [3,4].

Medical imaging has been, and remains, at the forefront of advancements in digital health technologies in everyday clinical practice [2,5]. Consequently, there is an array of digital tools available to support radiology decision-making that have arisen from advances in machine learning and other related technologies. Artificial intelligence (AI) algorithms that are commercially available, and with regulatory approvals already in place, are now being embedded in digital tools and readily adopted into routine practices for radiologists in various settings internationally [6,7].

In experimental and validation studies, AI algorithms show strong technical performance: meta-analyses report pooled sensitivity and specificity values exceeding 0.80-0.85 for tumor metastasis and rib fracture detection, with the mean area under the curve near 0.90 [8,9]. These results highlight the potential for AI to enhance accuracy and throughput, particularly in resource-constrained health systems [5,8,10]. Yet this technical promise has outpaced the evidence on real-world implementation [11]. The literature remains dominated by model validation [5] and cross-sectional studies of clinician trust [12-14], with few studies examining how AI systems are adopted, adapted, or sustained within the operational realities of hospital environments. Recent reviews emphasize this gap, noting that most AI-radiology research ends at performance benchmarking and fails to explore workflow integration, organizational readiness, or long-term routinization [10,15]. Broader governance and workforce analyses likewise underline persistent uncertainty around accountability, medicolegal responsibility, and system-level preparedness for AI-supported care [16,17]. Collectively, these gaps constrain understanding of how algorithmic potential translates into clinical and organizational value.

While these quantitative evaluations and meta-analyses have established AI's diagnostic capability, they provide little insight into how and why such technologies succeed or fail once introduced into routine clinical practice. Many rely on retrospective datasets, simulated environments, or controlled reader studies that remove the influence of real-world complexity [18-21]. Consequently, they overlook the macro-, meso-, and microlevel dynamics of workflow adaptation, human-technology interaction, and organizational and sociocultural context that determine whether AI enhances or disrupts practice. A qualitative implementation approach is therefore critical for exploring the lived experiences, informal workarounds, and contextual contingencies that shape integration in situ [21,22]. Such an approach complements quantitative evidence by revealing the social and organizational mechanisms through which AI adoption is negotiated, sustained, or resisted in everyday radiology work and practice.

Emerging qualitative and mixed methods studies have begun to address aspects of these challenges by exploring radiologists' perceptions, sources of trust and mistrust, and organizational barriers to adoption [12,23]. However, most have relied on single-time-point interviews, limited samples (n<20), or hypothetical case vignettes that do not capture the evolving interaction between users, workflows, and technology over time [18,19,24]. Few have been conducted within active service settings or have systematically linked individual experiences to organizational processes or system-level factors [12,25]. This has resulted in a descriptive but fragmented evidence base that provides limited insight into how implementation unfolds, stabilizes, or falters once AI becomes part of routine care.

This study responds directly to that gap by presenting a qualitative, end-to-end evaluation of AI implementation within a large tertiary radiology department in Brisbane, Queensland, Australia. Here, end-to-end refers to a lifecycle approach spanning predeployment context and readiness, peri-implementation adaptation, and postimplementation integration and routinization, examining how technological, human, and organizational factors interact over time [26,27]. There is a broad range of implementation frameworks to assess the implementation of a digital health innovation across a life cycle; however, they are varied in their analytical purpose [28]. Strategy-based models such as the Expert Recommendations for Implementing Change (ERIC) framework provide detailed lists of discrete implementation actions, but they are limited in explaining the mechanisms through which adoption unfolds in complex clinical environments [29]. In contrast, our evaluation sought to understand how and why AI integration succeeds or stalls within a dynamic, real-world system. The nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) framework [30] was therefore selected to guide data collection and analysis. NASSS offers a theoretically grounded structure

for examining the sociotechnical complexity of digital innovation by integrating the domains of technology, adopters, organization, value proposition, and wider context [31,32]. This systems-oriented lens provides greater explanatory power than more generalized implementation approaches for capturing interdependencies, contextual contingencies, and the temporal evolution of barriers and enablers across the implementation lifecycle.

By situating implementation within real-world clinical operations rather than experimental or hypothetical conditions, this study provides a rare longitudinal perspective on how AI becomes normalized or resisted within a complex hospital environment. Its findings have direct relevance to current policy efforts to scale AI responsibly in public health systems, where efficiency, safety, and governance imperatives converge [33].

Aims

Accordingly, this paper aims to examine the real-world implementation of an AI-based clinical decision support tool in radiology through an end-to-end qualitative evaluation across pre- (baseline), peri-, and postimplementation phases. Specifically, it seeks to identify the key contextual, organizational, and human factors shaping adoption and sustainability, to map these influences using the NASSS framework, and to generate insights that inform evidence-based strategies and policy for integrating AI safely and effectively into public hospital imaging services.

Methods

Study Design and Theoretical Framework

This study used a qualitative prospective design. The study was structured across 3 temporal phases to capture the evolving context of AI implementation within the radiology department.

The preimplementation or baseline phase (12 months before deployment) corresponded to the period when the AI tool had not yet been introduced. This phase reflected baseline organizational conditions, established workflows, and prevailing attitudes toward digital tools in radiology.

The peri-implementation phase (an 8-week transition period) covered the initial rollout of the AI system and its integration into existing digital and reporting infrastructure. This period was characterized by early interaction with the tool and short-term adaptation of work processes.

The postimplementation phase (12 months after deployment) represented a period of stabilization in which the AI tool had become part of routine operations. This phase captured the mature context of use, reflecting how the technology was embedded, maintained, and normalized within everyday practice.

The reporting of this study was in alignment with the COREQ (Consolidated Criteria for Reporting Qualitative Studies; Multimedia Appendix 1).

NASSS Framework

The NASSS framework was used to inform the study design and interview questions. The NASSS framework provides a systematic foundation for examining challenges across multiple domains and their dynamic interactions, which may influence the uptake, implementation, outcomes, and sustainability of technology-supported health programs [30]. It facilitates consideration of how various factors interact and adapt over time, influencing success, and includes the following domains:

1. Condition or illness: the nature and complexity of the condition being addressed.
2. Technology: the specific technology being implemented.
3. Value attributed to the technology: the perceived benefits and utility of the technology.
4. Individual adopters: the clinicians and patients using the technology.
5. Organizational adopters: the health care organizations implementing the technology.
6. External context: the broader context, including regulatory, economic, and social factors.

Setting

This was a single-site study conducted at a large public tertiary referral hospital in Brisbane. The hospital's Medical Imaging Department offers a comprehensive range of diagnostic imaging services to support patient care across various medical specialties.

AI Clinical Decision Support System

The technology adopted by the department is a third-party and commercially available multiorgan AI-based computerized clinical decision support system (CDSS) for radiologists. The CDSS uses multiple specialized convolutional neural networks across the entire machine learning cycle, including preprocessing, candidate generation, classification, and postfiltering. It has been classified and approved as a diagnostic tool under the current Australian Therapeutic Goods Administration regulatory framework. The decision support system integrates with existing medical imaging hardware and software to allow computed tomography (CT) images to be automatically transferred from the scanner, preprocessed, and prepared for interpretation by radiologists. The CDSS flags or highlights any issues within the CT image that require further differential diagnosis by the radiologists. In 2021, before full site implementation, the study site tested this tool among a small group of radiologists (n=4) and anecdotally reported positive experiences.

Participant Recruitment and Sampling

Participants included radiology consultants, registrars, and radiographers employed within the Medical Imaging Department who were involved in chest CT reporting during the study period. Recruitment was undertaken via internal email by an embedded chief investigator. A purposive yet stratified sampling approach was used to achieve broad representation across professional roles and levels of seniority. At the time of data collection, the lead interviewer (SN) was an experienced PhD-trained male implementation science researcher with no supervisory, managerial, or clinical authority over participants. SN had established professional familiarity with the department through earlier collaborative work, but no direct reporting relationships. Participants were informed of SN's research role, disciplinary background, and interest in understanding

real-world implementation challenges before interview commencement. Stratification was guided by the departmental organizational chart to ensure inclusion of participants from different functional areas and reporting responsibilities. This approach sought to capture a range of experiences across the implementation process rather than statistical representativeness. Sampling continued iteratively across the pre- (baseline), peri-, and postimplementation phases until thematic adequacy was reached, indicated by repetition of key concepts and no emergence of new issues in subsequent interviews [34].

Qualitative Interviews

Semistructured face-to-face interviews, approximately 40 minutes in length, were conducted by an experienced implementation science researcher (SN) according to participant preference (in person, via Microsoft Teams, or through phone; Multimedia Appendix 2). All interviews were audio-recorded and transcribed upon participant consent. Interviews were conducted flexibly, with questions adapted to participant roles and experience. Not all questions or prompts were asked in every interview, but the guide provided a consistent framework to ensure coverage of key domains. The interviewer kept reflexive notes after each interview to document emerging impressions, relational dynamics, and potential influences of their positionality on data generation.

Study Materials

We used a reflexive framework method to guide the development of a semistructured interview template, aligning with our study aims [32,35]. This approach aimed to capture a comprehensive range of insights, perceptions, and experiences, providing a rich dataset for analysis.

Data Analysis

Interview transcripts were analyzed using an iterative, multistage process combining thematic analysis with NASSS-informed framework mapping [36-38]. Before analysis, the research team discussed their disciplinary positions and assumptions regarding AI in radiology, documenting these reflections to support analytic reflexivity. SN led coding with AE providing independent review; neither had clinical authority over participants.

Analysis and data collection were conducted concurrently to guide purposive sampling and determine saturation. Early transcript review enabled the identification of preliminary codes and gaps, informing subsequent recruitment to ensure variation in experience and role. No participant reviewed the transcripts or findings before publication, consistent with the exploratory and ecological design of the study. However, findings were discussed with senior departmental clinicians and technical leads during routine project meetings. These discussions did not involve revising data or themes but served to ensure that the interpretations accurately reflected the broader organizational context and the realities experienced within the department. This informal sense-checking supported contextual validity while maintaining analytic independence.

Initial inductive coding was undertaken by one researcher (SN), who read each transcript line by line and assigned short descriptive phrases summarizing perceived barriers, facilitators, or neutral factors related to AI implementation. To strengthen analytic credibility, a second researcher (AE) independently reviewed a subset of transcripts and the draft codebook. Coding discrepancies and interpretive differences were discussed and resolved through consensus, providing a form of cross-checking without imposing rigid interrater reliability metrics. Iterative discussions across the research team further refined code boundaries, ensuring conceptual coherence and maintaining an audit trail of analytic decisions.

Once inductive coding was complete, higher-order categories were developed to capture recurrent concepts and relationships. These categories were then deductively mapped to the NASSS framework. This process enabled systematic classification of determinants by domain (eg, technology, organization, value proposition, adopters, wider system, and clinical context) while retaining sensitivity to context-specific nuances. The mapping process was iterative, with subthemes revisited and refined to ensure conceptual alignment between inductive insights and NASSS constructs, and to account for determinants that spanned multiple sociotechnical domains. Mapped subthemes were subsequently synthesized into a set of higher-order, cross-cutting determinants representing the dynamic interactions between technological, organizational, and adopter-related factors across implementation phases. This synthesis informed the structure of the results, where inductive findings and NASSS categories are integrated to illustrate how determinants evolved from baseline to peri-implementation and into routine use. Illustrative quotes were selected by consensus to exemplify the range of perspectives within each theme and subtheme. Quote selection focused on demonstrating variation, depth, and temporal evolution rather than providing isolated examples, ensuring that quotations functioned as analytic evidence and supported the integration of inductive insights with NASSS domains. An accompanying summary table provides an at-a-glance depiction of how inductive themes aligned with specific NASSS domains and subdomains, further enhancing analytic transparency and coherence.

To enhance analytic transparency, a content count of all coded barriers and enablers was compiled in Microsoft Excel and stratified by implementation phase (baseline, peri-implementation, and postimplementation). This numerical summary illustrated the distribution and relative prominence of determinants across NASSS domains (eg, technological, organizational, and adopter-related), providing a structured complement to the qualitative narrative. The count functioned as a descriptive aid to visualize patterns within the dataset, highlight areas of convergence and divergence across phases, and support the organization of complex, multilevel determinants [39].

Trustworthiness

To ensure trustworthiness, the research team engaged in continuous reflexive discussions throughout data collection and analysis, critically examining how their disciplinary backgrounds and assumptions could shape interpretation. Coding decisions were documented in an evolving analytic log, forming an audit trail that supported transparency and replicability. Regular peer

debriefings were held to resolve interpretive differences and refine theme definitions. Trustworthiness was further reinforced through the systematic application of the NASSS framework, which provided a theoretically grounded lens for organizing inductive findings. The inclusion of a quantitative content count of coded determinants added descriptive transparency, demonstrating how interpretations were anchored in the underlying data distribution. Together, these strategies strengthened the credibility, confirmability, and dependability of the qualitative findings [35,38].

Ethical Considerations

The Human Research Ethics Committee granted ethical clearance for this research (HREC/2021/QMS/81483). All participants provided written and verbal informed consent before participating in the study. Participation was voluntary, and participants could withdraw at any time. Participants were assured that their responses would be confidential, would not be shared with departmental leadership in identifiable form, and would have no bearing on workplace evaluation or progression. No incentives were offered, and no previous personal relationships existed between the researcher and participants beyond professional familiarity.

Results

Participant Characteristics

A total of 43 one-on-one interviews were conducted across the study timeframe, as shown in Table 1. This consisted of 7 (16%) radiographers, 20 (47%) registrar radiologists, and 16 (37%) consultant radiologists. A total of 9 (21%) participants were interviewed across multiple time points, consistent with public health services experiencing regular staff rotation, shift-based work patterns, and competing clinical pressures. While this posed practical challenges to longitudinal participation, it was also indicative of practical challenges with AI implementation in hospital medical imaging departments. To accommodate this and maintain the integrity of the analysis, each interview was treated as a discrete data point. This allowed us to capture a wider range of perspectives from across the workforce and reflect the dynamic, high-turnover environment typical of public hospital settings.

Table 1. Participant characteristics across the 3 implementation phases.

Participants	Baseline	Peri-implementation	Postimplementation
Total number of participants (N=43), n (%)	16 (37)	9 (21)	18 (42)
Profession and seniority, n (%)			
Radiographer (N=7)	4 (57)	1 (14)	2 (28)
Radiology registrar (N=20)	7 (35)	4 (20)	9 (45)
Consultant radiologist (N=16)	5 (31)	4 (25)	7 (44)
Sex, n (%)			
Male (N=26)	9 (35)	6 (23)	11 (42)
Female (N=17)	7 (41)	3 (18)	7 (41)

NASSS Informed Barriers and Enablers of AI Implementation in Radiology

A total of 56 barriers and 18 enablers were identified at baseline, 55 barriers and 14 enablers during peri-implementation, and 82 barriers and 33 enablers at postimplementation. Figure 1 presents barriers across NASSS domains and study phases, while Figure 2 shows enablers across the same phases.

Figure 1. Barriers across nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) domains and study phases.

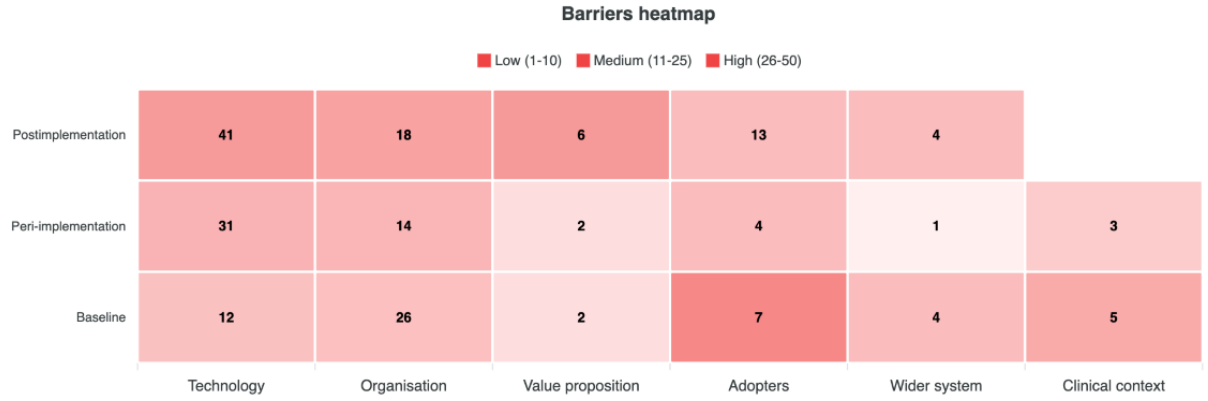

Figure 2. Enablers across nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) domains and study phases.

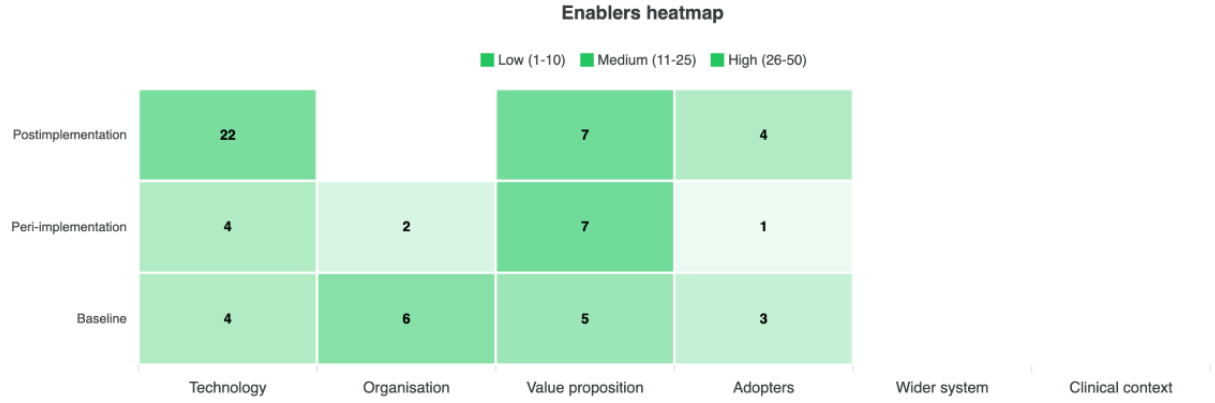

At baseline, organizational barriers were the most prominent, representing nearly half of all identified barriers (26/56, 46%). These are primarily related to limited technological readiness, insufficient training, and inadequate workflow planning for implementation. Technological barriers followed (12/56, 21%), reflecting early concerns about AI performance and output accuracy, while adopter-related barriers (7/56, 12%) centered on uncertainty regarding medicolegal accountability when using AI in reporting. The main enablers at this stage were found within the organizational (6/18, 33%) and value proposition (5/18, 28%) domains, reflecting a collegial, innovation-friendly culture and a belief in the technology's potential for efficiency and time savings.

During the peri-implementation phase, technological barriers dominated (31/55, 56%), particularly those concerning interoperability and system performance. These were followed by organizational barriers (14/55, 25%) related to weak implementation planning and inadequate workflow support, and a smaller set of adopter barriers (4/55, 7%) linked to limited trust in the AI system. Despite these issues, several enablers emerged, most notably within the value proposition domain (7/14, 50%), where participants anticipated potential efficiency gains if technical and integration challenges could be addressed. A smaller number of enablers (4/14, 28%) related to technology, as some users began using the AI system to cross-check their own interpretations.

By postimplementation, technological barriers persisted (41/82, 50%) as problems with accuracy, reliability, and speed remained unresolved. Organizational barriers (18/82, 22%) continued to reflect deficiencies in communication, training, and workflow integration, while adopter barriers (13/82, 16%) indicated ongoing distrust in the AI and reluctance to incorporate it fully into routine practice. However, this phase also saw the most substantial growth in enablers (a total of 33), particularly within technology (22/33, 67%), as users adapted the system for use as a secondary check or safety mechanism. Additional enablers were identified within the value proposition (7/33, 21%), where participants recognized relative efficiency benefits, and among adopters (4/33, 12%) who expressed emerging, albeit cautious, trust in the AI's evolving role.

Across all NASSS domains, implementation was characterized by an interplay between anticipated risks, such as workflow integration and information overload, and realized challenges during peri-implementation, many of which persisted into routine use (Figure 1). While optimism and perceived value remained for some, trust and adoption were undermined by ongoing performance and communication barriers. Together, these patterns illustrate how implementation unfolded within a large, dynamic clinical service, with determinants shifting as the AI system moved from anticipation to early use and then attempts to move into routine practice. The relative prominence of technological, organizational, and adopter-related factors at each phase provides a contextual frame for understanding the subsequent themes. These distributions therefore situate the qualitative findings within the broader organizational and technological environment in which the AI was being implemented.

Framework Analysis and Narrative Synthesis of NASSS Domains and Subdomains

Table 2 presents a synthesis of inductive themes mapped to the NASSS framework, illustrating how key implementation dynamics evolved across baseline, peri-implementation, and postimplementation phases. The table highlights temporal shifts in organizational readiness, technological integration, value perception, adopter engagement, and wider system influences. These findings are further expanded in the results narrative synthesis, offering deeper insight into the contextual and temporal nuances of implementation.

Table 2. Mapping of inductive themes to nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) domains and subdomains with indicative change over time.

NASSS domain	Subdomain	Inductive theme	Change across phases
Organization	Work needed to plan, implement, and monitor change	Sustained implementation planning	Limited formal planning at baseline; reactive coordination during rollout; structured monitoring and formalized training emerged post implementation.
Organization	Organizational readiness and capacity to innovate	Relational engagement and communication	Collegial but fragmented culture at baseline; weak interteam communication during rollout; some shared ownership and cross-functional coordination developed post implementation.
Organization	Extent of change to organizational routines	Workflow optimization	Anticipated efficiency at baseline; workflow disruption and duplication during rollout; individual adaptations post implementation.
Technology	Knowledge generated	Extraneous data and information overload	Anticipated clutter at baseline became a central frustration during rollout; selective filtering and cognitive habituation emerged post implementation.
Technology	Material properties	System performance and material integration	Early confidence gave way to concerns about specificity, lag, and reliability during rollout; partial refinement occurred postimplementation, though misalignment persisted.
Value proposition and clinical context	Demand-side value	Perceived benefits for workload and safety	Strong optimism at baseline; mixed experiences during rollout; perceived value became pragmatic and context-dependent post implementation.
Value proposition and clinical context	Supply-side value	Credibility and clarity of purpose	Limited understanding of purpose and benefit early on; evolved into clearer but modest recognition of niche utility post implementation.
Adopters	Role and identity	Professional positioning and negotiated use	Curiosity and willingness at baseline; trust declined during rollout due to inconsistency and false positives; cautious, selective engagement stabilized post implementation.
Adopters	Role and identity	Learning and preparedness	Informal self-learning predominated during rollout; structured and ongoing AI[a] literacy training emphasized post implementation.
Wider system	External context	Medicolegal uncertainty and system-level guidance	Policy and liability ambiguity persisted across phases; postimplementation reflections expanded to ethical and regulatory considerations.

[a]AI: artificial intelligence.

Organization

There were 3 inductive subthemes that mapped under the organization domain. There were challenges with sustained implementation planning, which mapped under the NASSS subdomain of "work needed to plan, implement, and monitor change;" relational engagement and communication, which mapped to "organizational readiness and capacity to innovate;" and workflow optimization, which mapped to "extent of change needed to organizational routines."

Work Needed to Plan, Implement, and Monitor Change (Sustained Implementation Planning)

At baseline, participants expected limited planning and support for rollout, reflecting past experiences with digital systems. As one consultant noted:

> *You don't actually discover issues or problems with that new process or software or whatever until you're using it, and then often there's a lack of support on a day-to-day kind of basis.* [P4, Consultant]

Feedback mechanisms were also described as weak, with another adding:

> *There's no way for us to feed…I don't know of a way for me to feed that back.* [P1, Consultant]

These comments illustrated low confidence in the organization's ability to anticipate or respond to implementation challenges.

During peri-implementation, radiologists described minimal systematic planning or training.

> *Not training per se, I think there was one meeting where they said that it was being implemented.* [P20, Registrar]

Another reflected:

> *Not very well (when asked about implementation planning)…they haven't really. Besides telling us that we're going to put it into practice, yeah, there's just not much that they're saying about it.* [P22, Registrar]

Such experiences made participants cautious about the department's readiness to adopt AI, with one consultant admitting:

> *I think in retrospect, we could have done more in terms of educating people.* [P21, Consultant]

Postimplementation reflections reinforced these concerns, highlighting the ongoing absence of structured improvement strategies to support uptake and sustainment. Participants were critical of the ad-hoc implementation process, arguing that:

> *If there are programs that are clinically usable and are planned to be rolled out within the department, then I think it makes sense for everyone to have formal training.* [P33, Registrar]

Even so, there was a strong appetite for more structured professional development in AI tools, with one consultant remarking:

> *I would like to be taught. I am a better learner if I'm taught.* [P32, Consultant]

Across phases, participants viewed planning and monitoring as reactive rather than anticipatory. Despite enthusiasm for AI, the lack of systematic preparation and ongoing learning opportunities constrained the department's ability to embed change effectively. Organizational challenges were compounded by high staff turnover and rotating clinical rosters, which limited continuity of learning and reduced opportunities for cumulative familiarity with the system. These shifting workforce conditions shaped how planning gaps were experienced and helped explain some variation in engagement and confidence across the implementation period.

Organizational Readiness and Capacity to Innovate (Relational Engagement and Communication)

At baseline, participants described a workplace that was broadly supportive of new ideas but slow to coordinate change due to limited capacity. As one consultant noted, "in public systems, people just tend to put up with inefficiencies" (P1, Consultant). Such reflections suggested that innovation was encouraged in principle but rarely matched by structured communication or system support.

During rollout, participants described poor communication and limited coordination between teams.

> *Having [vendor redacted] in one corner, radiologists in another, and us talking together… takes resources to get everyone together.* [P23, Radiographer]

Another reflected postimplementation, "We didn't actually tell most radiographers this was happening" (P41, Radiographer), highlighting the persistence of siloed and reactive coordination. Participants attributed emerging resistance partly to this fragmentation, explaining that "a lot of stuff was happening in the background with the PAX guys and the software people" (P43, Consultant).

Lack of early adopter involvement and unclear lines of responsibility were seen as weakening organizational readiness, even where enthusiasm for innovation remained high. This persisted into postimplementation, undermining the department's sociotechnical capacity to support AI integration. As one consultant explained:

> *One of the issues is that people who understand computers are not the people who understand medicine, and vice versa. So, there's probably a communications issue.* [P29, Consultant]

Participants linked these challenges to the organization's limited capacity to learn from implementation, with one concluding:

> *We could have done more work with the implementation initially; there could have been more clinician involvement.* [P43, Consultant]

Across phases, the organization was perceived as open to innovation but constrained by weak communication channels and reactive coordination. Participants emphasized that the capacity to innovate depended less on enthusiasm than on the presence of structured dialogue, feedback loops, and shared ownership across clinical and technical teams. These relational and coordination challenges intersected with changing workload pressures and fluctuating departmental priorities, reinforcing that uptake was influenced not only by communication structures but by the broader organizational environment in which teams were continuously reconfigured.

Extent of Change Needed to Organizational Routines (Workflow Optimization)

Across phases, participants described the introduction of the AI tool as requiring substantial adjustments to established reporting routines. At baseline, senior radiologists viewed it as a potential aid to workflow optimization, especially in easing registrar workloads. As one consultant put it:

> *If we were able to create a system or facilitate more report completion… particularly for the registrars, that would increase satisfaction.* [P1, Consultant]

This optimism reflected expectations that automation would streamline repetitive elements of reporting rather than disrupt them.

During peri-implementation, participants described the tool as introducing extra steps and interruptions to normal work patterns. One consultant explained:

> *It does add to the amount of things you look at… you've got to report your CT as normal, and then you've got a bunch of other sequences to scroll through at the end. Not that it adds a lot, but yeah, it does… there's more… people have been like, what's all these extra images? They don't really know what to do with it too much yet either.* [P18, Consultant]

This illustrates a lack of clear guidance or established routines for how to use or interpret the additional studies. This persisted at postimplementation:

> *I was sort of holding on to reports for a few hours before signing off because I didn't want additional data to come through that I hadn't looked up before signing off.* [P30, Consultant]

Instead of reducing workload, the new process created pauses, re-checks, and deferred sign-offs. Registrars similarly described difficulty maintaining rhythm and concentration, explaining that:

> *It's hard to get a routine…you have to have a different routine in your workflow for a particular assessment.* [P26, Registrar]

These comments captured how the tool altered the flow of image review and report finalization, requiring constant recalibration of familiar sequences. Some radiologists had developed

compensatory strategies to manage these disruptions; reordering tasks, batching reports, or consciously ignoring low-yield prompts. As one consultant reflected:

> *So for differentials, I go back to the normal scan because the tool obscures some details. So, it's more I use it for identifications…. So, for me, it's more identifying. Ok, there's something there. I need to go back and check (normal scans).* [P31, Consultant]

Overall, participants described workflow change as cumulative and largely unplanned. The tool demanded continuous microadjustments rather than a one-time shift in practice. What emerged was a pattern of individual adaptation rather than coordinated redesign; clinicians modified existing routines to fit the tool rather than the tool being aligned with the established clinical workflow. The extent of workflow disruption experienced by clinicians also reflected the realities of a service marked by rotating staff, shifting caseloads, and variable daily pressures.

Technology

The NASSS technology domain is mapped with 2 inductive subthemes: extraneous data and information overload, aligning with the subdomain knowledge generated, and system performance and material integration, aligning with the subdomain material properties. Together, these themes captured how the technical characteristics of the AI tool shaped user experience, trust, and perceived value across implementation phases.

Knowledge Generated (Extraneous Data and Information Overload)

At baseline, a consultant anticipated risks of information overload based on previous exposure to commercial AI tools. One explained, "You could spend all day circling these things" (P5, Consultant), capturing early concerns that automated outputs might flood readers with marginal or irrelevant findings.

During peri-implementation, these concerns materialized as the system generated excessive, low-value information:

> *Too much data… You really want a traffic-light system.* [P25, Consultant]

Another registrar observed:

> *I'm not sure how many people look at it. It spits out so many images and random tables* [P20, Registrar]

These reactions pointed to an emerging pattern of signal-to-noise imbalance, where radiologists spent more time filtering artefacts than interpreting meaningful results. By postimplementation, some users described partial adaptation, learning to disregard redundant data or mentally triage the AI's output.

> *It gets a little complicated when it picks up things that are artifacts. But yeah, I can work around it.* [P43, Consultant]

However, frustration persisted among others who saw the clutter as undermining efficiency rather than enhancing it:

> *It's a waste of time. It's just clutter, you know? … I usually ignore it.* [P37, Consultant]

Across phases, information overload remained one of the most salient barriers to adoption. While individual users developed coping strategies, these adaptations reflected workaround behavior rather than genuine integration, reinforcing perceptions that the AI's knowledge output was not yet aligned with clinical reasoning or workflow needs.

Material Properties (System Performance and Material Integration)

Performance concerns were a defining feature of the AI's reception, particularly during peri-implementation. A registrar characterized it bluntly as "Not very accurate. Just a splatter approach" (P17, Registrar), reflecting the perception that the system detected excessive findings without adequate specificity. Such errors eroded trust and reduced the incentive to incorporate its output into reporting routines.

By postimplementation, participants expressed more nuanced but still divided views. Some regarded the system as useful for reassurance or cross-checking:

> *Used it more like a check-off — especially when you have things that are complex, and there are a lot of findings.* [P30, Consultant]

Others found the persistent false positives distracting and demoralizing. As one put it:

> *For me to waste time looking at it…it's circled this fecal matter in the splenic flexure.* [P28, Consultant]

Several participants emphasized that perceived technical performance shaped how often they engaged with the system at all. When lag, sensitivity issues, or interface friction increased, clinicians tended to bypass or ignore the tool. Over time, its role shifted from active decision aid to optional background reference, indicating a decline in both trust and functional value.

Interoperability problems surfaced most clearly during peri-implementation, where users described limited integration between the AI software, picture archiving and communication system (PACS), and reporting systems. One consultant explained:

> *That's high-level stuff, right? That's integrating the processing, postprocessing software with the reporting software. But we don't have that capacity.* [P21, Consultant]

They further highlighted redundancy and excess image sets, noting "way too, way too many sequences…we need to distil that down."

By postimplementation, interoperability was less salient; some technical issues with integrating the AI into the system appeared resolved, but residual inconsistencies persisted. As one registrar noted:

> *There's not… uniformity to the sequences that are made. The order that they come out, …that's different from scanner to scanner.* [P26, Registrar]

Availability also varied:

> *It's not always there. So, you've got to sort of remember…to look for.* [P26, Registrar]

Display and PACS constraints continued to affect use:

> *I don't like the way that gets displayed…that's a PACS system…how the series [are] actually displayed.* [P26, Registrar]

Across phases, the material outputs of the AI, its sensitivity, specificity, and responsiveness, directly influenced its perceived usefulness. Participants consistently linked suboptimal performance to disengagement, showing that successful technological integration required not just accuracy, but reliability, responsiveness, and design alignment with radiologists' expectations of diagnostic precision. Furthermore, while major interoperability barriers had eased, the system never fully aligned with the routine reporting infrastructure, leaving incompatibilities.

Across all technology-related subdomains, participants described a gap between what the AI produced and what clinicians could *use*. Information overload and variable system accuracy combined to erode trust and limit engagement. While technical adaptation occurred at the individual level, collective integration into practice remained constrained, signaling that technological refinement and interpretability are prerequisites for sustained adoption.

Value Proposition and Clinical Context

Across all phases, discussions of value proposition were less prominent than those of technology or organization, but two inductive subthemes mapped clearly to the NASSS value proposition domain: perceived benefits for clinical workload and safety, which mapped to demand-side value, and credibility and clarity of purpose, which mapped to supply-side value. These intersected closely with the evolving clinical context, in which fluctuating workload pressures and infrastructure challenges shaped how the AI's value was interpreted.

Demand-Side Value (Perceived Benefits for Clinical Workload and Safety)

At baseline, participants viewed the AI as a potential solution to workload strain and reporting delays. Anticipated benefits were framed around efficiency, redistribution of tasks, and registrar support, signaling early optimism that automation would enhance throughput and safety. The department's intense workload and frequent interruptions reinforced this demand-side appeal: as a consultant noted, AI might "make our job easier" (P1, Consultant).

During peri-implementation, optimism gave way to more conditional appraisals. While some identified benefits for prioritization, "It highlights a few cases that you can look at first. That's useful when there's a backlog" (P19, Registrar), others described it as "unreliable at the moment" (P17, Registrar). Shifts in the clinical environment also tempered expectations, staffing improved, and backlogs eased. By the postimplementation phase, perceptions of value became pragmatic and evidence-driven. Clinicians viewed the AI as a limited but occasionally useful decision support tool:

> *I've usually written my report before I look at this, and I don't tend to change the report… it's another look, I wouldn't think of it as more than that* [P29, Consultant]

Concerns over cost-efficiency persisted:

> *If it was free, ambivalent… If it's significant amounts of money… I don't see the value because it's more work than less.* [P29, Consultant]

Across phases, expectations regarding the AI shifted from broad hopes of efficiency to a more divided assessment. Some saw modest contributions to safety and prioritization, while others viewed the system as duplicating effort rather than providing genuine workload relief.

Supply-Side Value (Credibility and Clarity of Purpose)

At the same time, participants reflected on supply-side value, questioning how clearly the system's purpose and evidence base had been articulated.

> *It just gives you pictures with circles. I'm not sure what the end use is meant to be.* [P20, Registrar]

By postimplementation, participants had a clearer understanding of what the AI could do but remained unconvinced of its overall value. However, there was also recognition that the AI was credible in concept but still immature in delivery.

> *It's getting clearer now what it could be for, but it needs to evolve. Right now, it's still just identifying, not interpreting over time.* [P43, Consultant]

Some viewed potential uses to optimize efficiency and workflow, with modifications:

> *It could identify which studies need to be reported first…or give us measurement readings.* [P46, Consultant]
>
> *Maybe some of those sorts of irritations around AI could be changed, you know, or fine-tuned.* [P25, Consultant]

These reflections indicated that perceptions of supply-side value were prospective, anchored in what the technology could deliver if optimized, rather than what it had yet achieved.

Across phases, the vendor narrative of innovation and efficiency had not yet translated into tangible or demonstrable benefit for clinicians or the wider health system. Participants viewed the AI as promising but still lacking the evidence and clarity needed to support confident investment or large-scale deployment.

Adopters

The NASSS adopter subdomain of role and identity is mapped with 2 inductive subthemes: professional positioning and negotiated use, and learning and preparedness. Together, these described how clinicians positioned AI within their expertise and accountability, and how limited exposure and training shaped trust, confidence, and uptake. Across phases, adoption reflected an oscillation between curiosity and skepticism, with trust becoming the key mediating factor.

Role and Identity (Professional Positioning and Negotiated Use)

At baseline, radiologists expressed a guarded willingness to engage with AI framed less as enthusiasm and more as a professional obligation.

> *I think I would use it…it would be almost negligent not to look at it.* [P6, Registrar]

Consultants saw potential for practical support:

> *It could certainly help you prioritize what you are watching and what order you report things.* [P8, Consultant]

During peri-implementation, practical experience unsettled this cautious trust. Registrars described false positives, excessive outputs, and low sensitivity:

> *It's too junior at the moment.* [P17, Registrar]

Trust eroded not from resistance to innovation, but from inconsistency between the AI's promise and its performance. Clinicians voiced a recurring sentiment that while AI might one day assist safety, it currently distracts from clinical focus:

> *If the volume of data presented is overwhelming, then that's negative…the strength would be as a safety net for subtle findings, not changing an overall clinical picture.* [P19, Registrar]

Reflecting on their initial use of the tool during peri-implementation, a registrar noted:

> *"It was picking up stuff that wasn't nodules…I still had to go back and look at the images again.* [P34, Registrar]

By postimplementation, there was selective use and partial trust.

> *I look through the nodules myself first and then correlate with the software to see whether it is congruent with what I've come up with.* [P42, Consultant]

Others disengaged entirely:

> *It slows you down because you have to verify each little dot.* [P37, Consultant]

A senior consultant likened the AI to "the registrar with clever ideas, but they're all wrong" (P40, Consultant), useful for prompting review, yet unreliable without human correction.

Trust also intersected with medicolegal anxiety. Several raised uncertainties about accountability and liability:

> *If the software makes a mistake, who is liable—the vendor or the radiologist? We still haven't ironed it out.* [P34, Registrar]

This uncertainty reinforced their instinct to retain manual control. As a consultant observed:

> *If I reported every possible little dot in the chest, I'd end up with a report ten pages long, which nobody would ever read.* [P37, Consultant]

The line between cautious trust and defensive practice remained thin.

Role and Identity (Learning and Preparedness)

Training and readiness remained persistently underdeveloped. During peri-implementation, there was no structured orientation or clear introduction to the system. Learning was largely self-directed and reliant on peer exchange.

> *Personally, I don't think I've had any formal sit-down with it… I've just figured it out.* [P19, Registrar]

A vendor demonstration was held midphase, but not all clinicians attended, and some felt it was disconnected from practical workflow.

> *I just met the software without gathering any prior information about what this new software is.* [P34, Registrar]

Without clear instruction or transparency about performance parameters, early experiences became a process of trial and error rather than guided adoption, reinforcing skepticism instead of trust. By postimplementation, clinicians explicitly called for structured and continuous AI education embedded within clinical and professional frameworks.

> *If that is incorporated into our routine…every month we have our session doing AI cases.* [P32, Consultant]

Others stressed the need for broader institutional responsibility:

> *We are severely lacking in training with AI…it should be an integral, assessed part of our training program.* [P34, Registrar]

These calls reflected not only a desire for technical competence but also a wish to rebuild confidence and ensure medicolegal clarity, positioning AI as a tool that must be professionally standardized, not individually improvised.

Ultimately, clinicians saw AI competence as a new layer of professional literacy, necessary to protect judgment, maintain accountability, and engage critically with emerging tools. Their learning needs were not purely technical but ethical and epistemic: how to weigh evidence, interpret probability, and remain vigilant in an era of shared decision automation.

Wider System

Participants described the wider system as a persistent barrier across phases. This domain reflects the external political, policy, and institutional forces, such as regulation, professional guidance, legislative, and funding models that define the environment in which implementation occurs, but which local teams cannot directly control. While wider system themes were present across phases, they did not dominate every interview, and some subissues (for example, explicit references to legislation) appeared only sporadically.

At baseline, consultants depicted a public system tolerant of inefficiency and difficult to influence. Funding constraints were raised in the context of competing pressures.

> *Q-Health…there's not much money around for these sorts of things.* [P1, Consultant]

During peri-implementation, registrars and consultants highlighted gaps in professional guidance and medicolegal expectations.

> *Training/communication…college says we need to learn AI, but little practical guidance…site-to-site differences.* [P24, Registrar]

Others wanted clearer, proactive communication from professional bodies.

> *College exposure is low.* [P27, Registrar]

Medicolegal norms were seen to expand review obligations when AI added extra views.

> *Mentality in radiology, if it's on a screen, you have to comment on it, and medico-legal, if presented, we must review everything.* [P21, Consultant]

By postimplementation, some brought up broader ethical and policy concerns about data provenance and the social license concerns about using it:

> *There is concern about the way the data is being used…if all these algorithms are being trained on everyone's data, it should be open source…it's everyone's.* [P42, Registrar]

Participants contrasted public and private system incentives and capacity, linking retention and deployment choices to wider economics and case-mix.

> *Public keeps me for complex cases, teaching, and feedback; private pays double.* [P28, Consultant]
>
> *Public vs private…pay and tech are better in private; public has collegiality and case mix.* [P42, Registrar]

Across phases, the wider system was characterized by limited policy levers and still developing structural and legislative readiness to support the rapid integration of AI into acute health care. Taken together, these wider-system influences interacted with internal organizational dynamics, staffing fluctuations, workload variability, and shifting operational priorities to shape the evolving trajectory of implementation across phases.

Discussion

Principal Findings

This study reports a prospective, qualitative, end-to-end evaluation of implementing an AI-driven clinical decision support system in a public radiology department, structured through the NASSS framework [30]. By mapping barriers and enablers across domains and phases, the study captures how early expectations shaped adoption, how sociotechnical challenges emerged during the rollout, and how these dynamics influenced long-term integration and adoption. Findings highlight that successful AI adoption depends not only on technical capability but on the alignment of organizational readiness, workflow design, and professional trust. Implementation success was governed by the interaction of multiple NASSS domains, which included interdependencies among technology, organization, adopters, and value rather than any single factor.

Weak planning and limited feedback structures (organizational barriers) amplified adopter frustrations with false positives, information clutter, and interoperability issues (technology barriers), eroding trust (adopter-level barriers). Even when technical faults were later mitigated, these initial experiences limited or constrained uptake, illustrating how early technical and communication failures created enduring impressions that shaped subsequent patterns of trust and tool use.

This mutual reinforcement of challenges across domains aligns with the complexity perspective described by Greenhalgh et al [30] and Braithwaite et al [40], whereby interacting barriers within and across a complex adaptive system, such as health care, tend to compound rather than resolve over time, particularly when they are not addressed in a coordinated and simultaneous manner. Clinicians' perceptions of value were shaped primarily by how reliably and efficiently the AI system performed within everyday reporting workflows. Early false positives and excessive image sets undermined those expectations, diminishing confidence in the tool's promised efficiency benefits. This finding is consistent with a recent qualitative study showing that workflow fit determines perceived usefulness, even for AI [41]. Participants described the system as "a check-off" tool rather than an integrated aid, and acceptance was suboptimal across our study; consistent with a 2023 semistructured interview with radiologists (n=25), which identified reliability, interpretability, and feedback transparency as decisive for AI acceptance [14]. Even after performance improved, initial mistrust persisted. This enduring skepticism also mirrors broader evidence that initial experiences set adoption trajectories and that trust is far easier to lose than to regain [42]. The finding reinforces the importance of consolidating the first-use experience through predeployment testing or "shadow mode" configurations [43].

Organizational conditions were vital in shaping clinician engagement. During peri-implementation, fragmented communication and limited training left some staff unaware that the system had gone live, while others lacked the confidence to use it effectively. This mirrors the work of our team and others who have consistently highlighted that structured rollout, anticipatory planning, and capacity building are critical for sustainable digital adoption [32,44-47]. Participants described the process as reactive and isolated rather than coordinated, reflecting the absence of a shared sense of purpose and mutual accountability between leadership, implementers, and users, necessary for effective implementation [48]. Although clinicians remained receptive to AI, they expected visible organizational commitment through ongoing education, rapid troubleshooting, and coherent leadership. In its absence, they relied on informal workarounds and peer support to conduct work-as-done, the adaptive, improvised practices that frontline staff develop to keep systems functioning when formal processes or resources fall short [49]. While such adaptations can sustain local functionality, they also introduce variability in care delivery and make it difficult to scale and standardize best practices across settings.

These organizational shortfalls also shaped how clinicians experienced implementation. In the absence of clear planning and coordination, several described feeling individually responsible for interpreting and integrating the AI tool into their workflow. This was not an explicit transfer of responsibility but reflected a professional culture in which clinicians relied on their own judgement to make the system workable within

local constraints. Medicolegal uncertainty about liability further reinforced this guarded engagement. A 2021 narrative review observed that when accountability is unclear or diffuse, clinicians maintain human oversight to protect both patient safety and professional authority [50]. These dynamics highlight a core implementation challenge: without clear institutional responsibility and evidentiary assurance, professional caution becomes self-reinforcing, constraining experimentation, shared learning, and the normalization of AI within routine practice.

The single-site public hospital context influenced organizational capacity. Frequent staff rotations and high turnover meant that many clinicians engaged with the AI system intermittently, limiting opportunities for cumulative learning. Similar patterns are common across public health services, where workforce mobility and resource constraints make it difficult to sustain iterative improvement [51]. These dynamics interacted with the implementation process itself, shaping the pace and pattern of adoption and modulating how performance issues were perceived over time. Rather than functioning as external confounders, they formed part of the organizational ecology within which the AI system was introduced, influencing continuity, familiarity, and the stability of feedback loops essential for embedding new technologies. These conditions underscore the importance of implementation approaches that are designed for continuity, including modular onboarding, periodic refresher training, and accessible repositories of AI-related resources to support learning across changing teams.

This study extends the AI-in-radiology literature in 3 key ways. It adopts a temporal perspective, tracing implementation from early anticipation to postintegration and showing how initial optimism and early missteps shape later engagement. It also demonstrates that adoption was driven not by the innovation alone but by the interaction of technical performance, organizational coordination, and context, extending NASSS from description to explanation. In this framing, staff turnover, workload fluctuations, and shifting operational priorities function as active contextual determinants that help explain why implementation trajectories evolve as they do, rather than as background noise. Finally, through reflexive use of the framework, the study generates theoretical insight into why implementation evolves as it does, contributing to emerging work on domain interdependence and temporal complexity in health care innovation [52].

Grounded in our findings and consistent with previous guidance [23,30,53,54], effective AI implementation in radiology depends on a combination of technical stability, communication, and organizational preparedness. Early “shadow mode” piloting helps identify faults and build trust before clinical use, while consistent communication about progress and fixes maintains transparency. Workflow-compatible design that minimizes cognitive load supports efficiency and acceptance [55]. Ongoing professional development, formal feedback channels with vendor responsiveness, and planning for workforce turnover through shared training repositories and local champions help sustain capability over time. Together, these strategies align with the six principles of FUTURE-AI recommendations encompassing fairness, universality, traceability, usability, robustness, and explainability, an international expert-driven consensus to facilitate the adoption of trustworthy medical imaging [56] and emphasize that co-design and iterative learning are essential to long-term adoption.

Study Limitations and Strengths

This was a single-site study, and further real-world, ecological research is needed to identify determinants of adoption and create solutions that generalize across health systems. Despite this, our findings are similar to several recently published studies examining radiologists’ perceptions around the adoption of AI into standard practice [2,12,14,57-60]. There was low uptake of the tool during the peri-implementation period due to technical challenges. This limited wider evaluation of this crucial implementation period, particularly in terms of clinical usefulness. The 18-month period may have also introduced a range of system confounders, including staffing changes and organizational priorities, which may have impacted how participants felt about the AI clinical decision support tool. Finally, social desirability bias cannot be ruled out, particularly as this was a department-wide implementation. However, this was mitigated through participant briefings emphasizing the exploratory nature of the trial, coupled with reflexive practice by the interview team [61]. A key study strength was that this was a real-world evaluation demonstrating ecological validity with findings grounded in practical realities. Second, aligning our findings with a validated implementation science framework supports theoretical transferability and future application in related contexts despite the single-site limitations.

Future Implications

Future studies should integrate qualitative and quantitative data, combining workflow observations with metrics such as reporting time, error rates, and AI usage logs, to triangulate findings. Multisite evaluations across differing levels of digital maturity are needed to test transferability and examine how governance, culture, and workforce patterns influence scalability.

Conclusion

Implementation of AI-based decision support in radiology is as much an organizational and cultural process as a technological one. Clinicians remain willing to engage, but sustainable adoption depends on consolidating early experiences, embedding communication and training, and maintaining iterative feedback between users, vendors, and system leaders. Applying the NASSS framework revealed how domains interact dynamically across time, offering both theoretical insight into sociotechnical complexity and practical guidance for hospitals seeking to move from pilot to routine, trustworthy AI integration.

Acknowledgments

The authors would like to gratefully acknowledge the study participants who gave their valuable time to participate in this study. The authors are grateful to Dr Sue Jeavons and her staff for facilitating this study onsite.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to confidentiality policies, but may be available in limited form from the corresponding author on reasonable request.

Abstract

Background: Accurately predicting ovarian response and determining the optimal starting dose of follicle-stimulating hormone (FSH) remain critical yet challenging for effective ovarian stimulation. Currently, there is a lack of a comprehensive model capable of simultaneously forecasting the number of oocytes retrieved (NOR) and assessing the risk of early-onset moderate-to-severe ovarian hyperstimulation syndrome (OHSS).

Objective: This study aimed to establish an integrated mode capable of forecasting the NOR and assessing the risk of early-onset moderate-to-severe OHSS across varying starting doses of FSH.

Methods: This prognostic study included patients undergoing their first ovarian stimulation cycles at 2 independent in vitro fertilization clinics. Automated classifiers were used for variable selection. Machine learning models (11 for NOR and 11 for OHSS) were developed and validated using internal (n=6401) and external (n=3805) datasets. Shapley additive explanation was applied for variable interpretation. The best-performing models were incorporated into a web-based prediction tool.

Results: For NOR prediction, 17 variables were selected, with the gradient boosting regressor achieving the highest performance (internal dataset: R^2=0.7978; external dataset: R^2=0.7924). For OHSS prediction, 19 variables were identified, and the LightGBM model demonstrated superior performance (internal dataset: area under the receiver operating characteristic curve=0.7588; external dataset: area under the receiver operating characteristic curve=0.7287). Shapley additive explanation analysis highlighted the FSH starting dose to BMI ratio and baseline antral follicle count as key predictors for NOR and OHSS, respectively. Dose-response curves were generated to visualize predicted outcomes with varying FSH starting doses. The models were implemented in a user-friendly, research-oriented online prototype, individualized ovarian stimulation guide (InOvaSGuide).

Conclusions: This study introduces an integrated framework for predicting NOR and early-onset moderate-to-severe OHSS risk across different FSH doses. Future prospective evaluation is needed before clinical implementation.

KEYWORDS

individualized ovarian stimulation; ovarian response; ovarian hyperstimulation syndrome; follicle-stimulating hormone; machine learning

Introduction

Over the past decade, individualized ovarian stimulation has become a key strategy in in vitro fertilization (IVF). Determining an appropriate starting dose of exogenous follicle-stimulating hormone (FSH) is essential for balancing efficacy and safety. Although earlier clinical practice emphasized maximizing oocyte yield (the more, the better), current consensus favors achieving a moderate ovarian response to optimize live birth rates while minimizing patient discomfort and iatrogenic risks such as ovarian hyperstimulation syndrome (OHSS). Therefore, accurate prediction of ovarian response before stimulation is critical for optimizing treatment outcomes [1-4].

Although biomarkers, including antral follicle count (AFC), anti-Müllerian hormone (AMH) levels, and BMI, are well associated with ovarian response, substantial interindividual and intraindividual variability limits their predictive precision. Tailoring FSH doses based solely on these indicators has not consistently improved clinical outcomes [5,6], highlighting the need for more comprehensive, data-driven approaches that integrate a broader spectrum of clinical and biological factors.

Recent advances in artificial intelligence (AI) and machine learning (ML) offer new opportunities for improving decision-making in assisted reproduction, with applications reported in semen analysis [7], blastocysts grading [8], and trigger-day assessments [9]. Several ML models have also been developed to predict the number of oocytes retrieved (NOR) [10-13] or to classify ovarian responsiveness [10]; however, most remain limited in scope. They typically rely on a narrow set of baseline features, adopt single-model frameworks, and focus predominantly on treatment efficacy such as oocyte yield, with relatively limited attention to safety outcomes, including OHSS. These limitations emphasize the need for predictive frameworks that simultaneously incorporate both efficacy and safety. Furthermore, despite multiple evidence-based algorithms for FSH dosing, considerable variability in ovarian response persists even among patients with comparable baseline characteristics. A model that jointly predicts NOR and OHSS risk across a range of FSH doses may provide useful predictive information and support dose-specific decision-making, helping clinicians consider the balance between efficacy and safety when selecting individualized FSH doses.

In this study, ML models were developed to predict NOR and early-onset moderate-to-severe OHSS using datasets from 2 IVF centers. Models with optimal performance were integrated into a clinician-oriented decision support prototype, termed individualized ovarian stimulation guide (“InOvaSGuide”), complemented by a web-based calculator. For each patient, the system provides individualized dose-response curves that display predicted NOR and early-onset moderate-to-severe OHSS probabilities across varying FSH starting doses, thus supporting personalized ovarian stimulation.

Methods

Ethical Considerations

This prognostic study was designed as a retrospective analysis and was approved by the Reproductive Medicine Ethics Committee of Xiangya Hospital (2021010) and the Medicine Ethics Committee of Shenzhen Luohu District People’s Hospital (2024-LHQRMYY-KYLL-63). Informed consent was waived because all data were retrospectively collected from routine clinical records and anonymized before analysis. The study adhered to the Declaration of Helsinki and followed the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis; Table S1 in Multimedia Appendix 1) reporting guideline [14]. All data analyses were performed by an external team using anonymized data only, ensuring full protection of participant privacy. No compensation was provided to participants, as the study involved retrospective and fully anonymized data.

Study Cohort

The inclusion criteria were (1) patients with the first ovarian stimulation cycle conducted between January 1, 2018, and September 30, 2022, at the Department of Reproductive Medicine of Xiangya Hospital (internal dataset) and between May 1, 2021, and December 30, 2023, at the Reproductive Center of Shenzhen Luohu District People’s Hospital (external dataset) and (2) patients aged 20 to 40 years. Exclusion criteria were (1) patients with diminished ovarian reserve, diagnosed by AMH ≤1.1 ng/mL or baseline AFC ≤7 [15]; (2) patients using the microstimulation protocols for ovarian stimulation, including progestin-primed ovarian stimulation protocol, natural cycle protocol, etc; and (3) patients with more than 50% missingness in key clinical variables. Notably, patients with diminished ovarian reserve or those undergoing microstimulation protocols were excluded because these groups require highly individualized stimulation strategies, exhibit markedly lower oocyte yield, and have a substantially reduced risk of OHSS under comparable FSH exposure, which would have created pronounced class imbalance and reduced model robustness.

After screening, 6401 patients from Xiangya Hospital and 3805 from Shenzhen Luohu District People’s Hospital were included in the internal and external datasets, respectively.

Ovarian Stimulation Process and the Diagnosis of Early-Onset Moderate-to-Severe OHSS

Before commencing the IVF and intracytoplasmic sperm injection cycle, patients underwent a thorough physical examination, including the assessment of basic physical parameters (height, weight, and BMI), measurement of basal hormone levels (FSH, luteinizing hormone [LH], estradiol, testosterone, progesterone, prolactin, and AMH), biochemical tests (fasting glucose, fasting insulin, lipid levels, and thyroid hormones), and transvaginal ultrasonography for basal AFC. Subsequently, experienced physicians personalized the ovarian stimulation protocol and the starting dose of FSH based on comprehensive clinical assessment. Throughout stimulation, patients underwent monitoring via transvaginal ultrasonography and serum hormone assessments, with gonadotropin dosage adjustments made according to individual ovarian responses. Human chorionic gonadotropin or gonadotropin-releasing hormone agonist, alone or combined, triggered oocyte maturation when 3 or more follicles measuring 17 mm or greater were observed. Oocyte retrieval occurred 36 hours after triggering, and the NOR was recorded. Eligible patients underwent fresh embryo transfer with 1 or 2 embryos.

The study primarily focused on the occurrence of early-onset, moderate-to-severe OHSS, which was diagnosed within 9 days after triggering based on established guidelines [16], considering both clinical and laboratory features. All relevant individual and clinical variables during the process were obtained from the clinical database for feature screening and selection.

Data Preprocessing and Feature Selection

All data analysis was performed by an external team using anonymized data, ensuring full protection of participant privacy. To elucidate correlations between predictive features and clinical outcomes with an emphasis on medical interpretability, we performed feature engineering on selected variables. This process resulted in 2 additional variables: “FSH to LH ratio” and “FSH starting dose to BMI ratio,” which improved predictive accuracy while maintaining transparency and clinical relevance. Furthermore, to address skewness and improve distributional normality, a logarithmic transformation was applied to AMH, triglycerides, and FSH/LH (Figures S1 and S2 in Multimedia Appendix 1). Missing data were handled using mean imputation, with feature-wise means computed exclusively from the training set and subsequently applied to the test and external validation sets, to prevent information leakage. The overall proportion of missingness was low, and imputation did not materially alter variable distributions.

To identify key variables, we applied feature importance–based selection using the Boruta algorithm, performed exclusively within the training dataset (Figures S3 and S4 in Multimedia Appendix 1). This approach led to the selection of 17 variables for the NOR prediction model and 19 variables for the OHSS prediction model.

NOR Model Development

In the prediction of NOR, 17 features, including starting dose of FSH to BMI ratio, BMI, log (AMH), and specifically the ovarian stimulation protocol, were selected. The NOR divided by the starting dose of FSH was used and logarithmically transformed as the outcome variable with improved predictive performance. For model training, the internal dataset was divided into an 8:2 split, with 79.9% (5120/6401) of the data randomly allocated to the training set and the remaining 20% (1281/6401) assigned to the internal test set. All data from the external dataset were held out entirely and used exclusively as an external validation cohort, providing an independent assessment of model generalizability across institutions. Eleven ML algorithms, including a linear regression model, were trained to predict the preprocessed NOR outcome. Hyperparameter tuning was performed using 5-fold cross-validation within the training set only, with all hyperparameters predefined and summarized in Table S2 in Multimedia Appendix 1. Model performance was assessed using 4 key metrics: R^2, adjusted R^2, mean absolute error, and root mean square error.

OHSS Model Development

For OHSS prediction, the target variable was the occurrence of early-onset moderate-to-severe OHSS. Given the low event rate and resulting class imbalance, several commonly used imbalances handling strategies (eg, oversampling, undersampling, and ensemble-based resampling) were evaluated. Cost-sensitive learning was ultimately adopted, assigning differentiated penalties to misclassifications while preserving all original clinical data distribution. To prevent overfitting, model complexity was controlled by limiting the number of parameters and applying regularization techniques, as appropriate for each algorithm. Eleven ML algorithms were implemented, with corresponding hyperparameters detailed in Table S3 in Multimedia Appendix 1. As with the NOR model, hyperparameter optimization was conducted exclusively within the training set, and model performance was evaluated on both the internal and the external datasets using the area under the receiver operating characteristic curve (ROC-AUC), the precision-recall area under the curve (PR-AUC), recall, specificity, weighted F_1-score, Cohen κ, and positive and negative predictive values.

Shapley Additive Explanation Value

To further explore the significant features driving the model’s predictions, we used the Shapley additive explanation (SHAP) analysis to assess the importance of core features. SHAP serves as an interpretative tool for ensemble tree models, offering a detailed breakdown of the influence of input features on predictions.

Creation of Dose-Response Curves

In this study, 2 distinct models were developed: a classification model for predicting early-onset moderate-to-severe OHSS and a regression model for forecasting NOR. Models of best performance were incorporated into an integrated, research-oriented computational system, complemented by a web-based calculator. By inputting baseline patient characteristics, the system generates predictions for NOR and early-onset moderate-to-severe OHSS probability, presented as a dose-response curve illustrating changes with increasing FSH starting doses.

Statistical Analysis

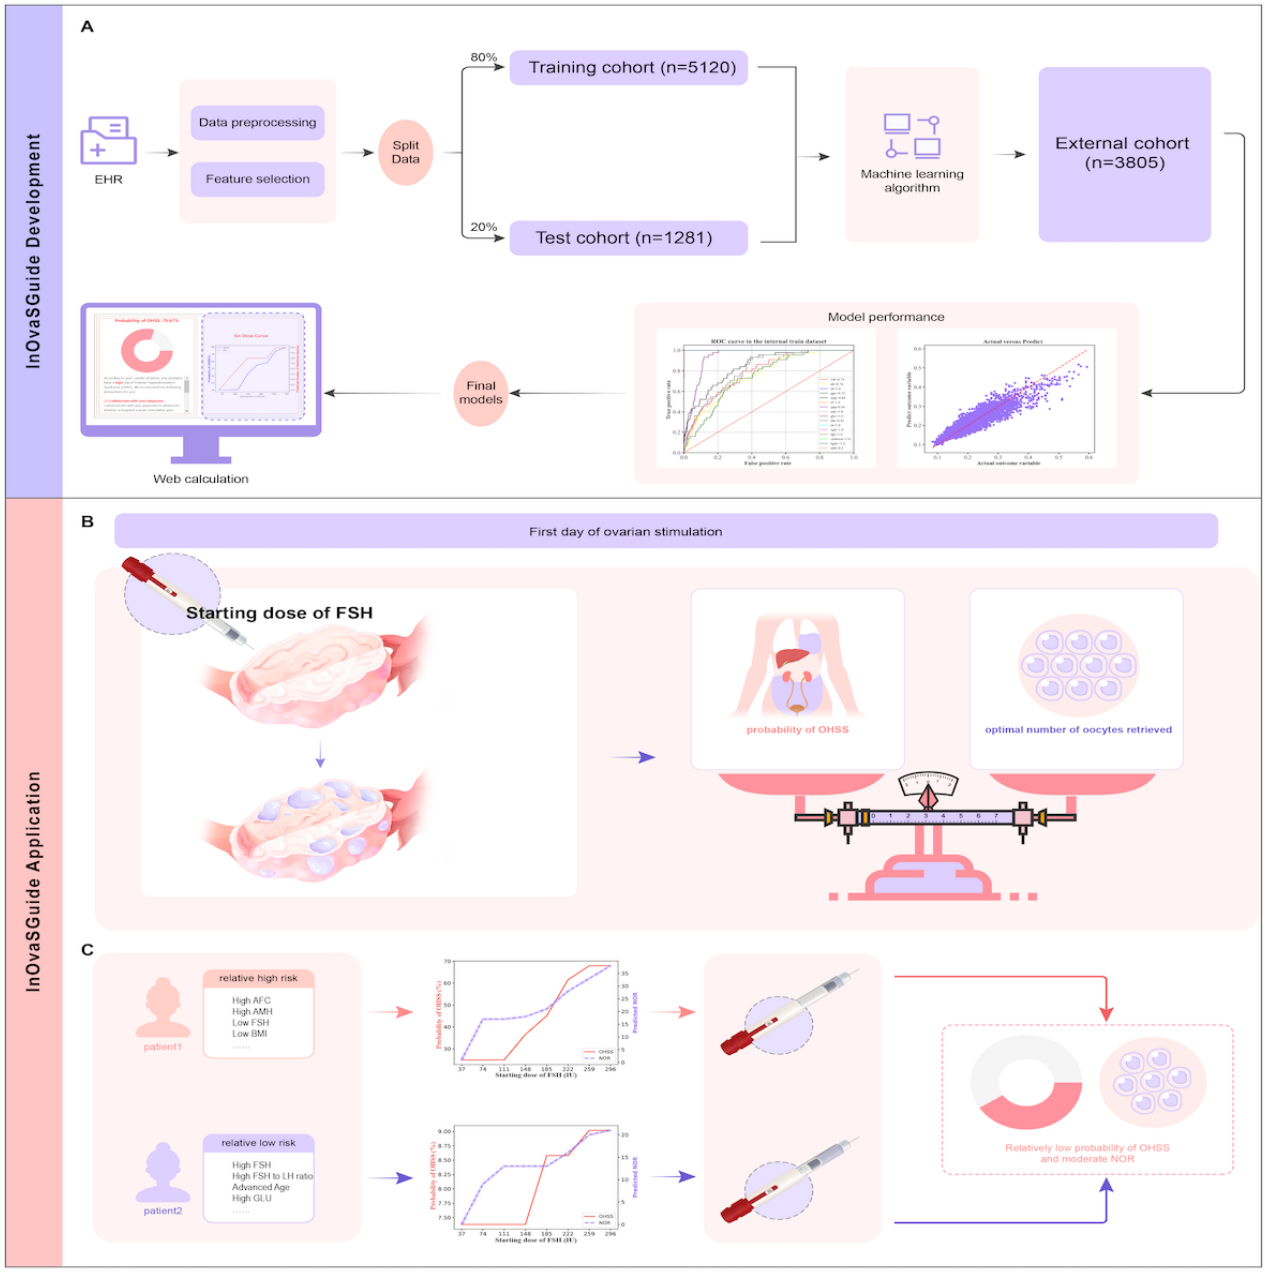
The baseline characteristics of patients between the internal dataset and the external dataset were compared using the chi-square test for categorical variables. For continuous variables, we assessed normality using the Shapiro-Wilk W test. Depending on the results, we used either the 2-tailed Student *t* test or the Mann-Whitney *U* test for comparison. R Studio (version 4.3.1; R Foundation for Statistical Computing), Python (version 3.11.4; Python Software Foundation), the open-source *scikit-learn* package (version 3.9.13; open-source community-developed Python ML library), LightGBM (version 4.3.0; Microsoft Corporation), and XGBoost (version 2.0.0; open-source project maintained by XGBoost contributors) were used for model development and statistical analyses.

Results

The Integrated Ovarian Response Prediction System

To address the challenges of individualized ovarian stimulation, we developed an integrated prediction system, "InOvaSGuide," designed to predict both the NOR and the probability of early-onset moderate-to-severe OHSS before ovarian stimulation. The system was built using datasets from 2 IVF clinics and incorporates 2 distinct ML models for NOR and OHSS predictions, respectively (Figure 1A). By analyzing patients' baseline characteristics, the system generates dose-response curves that illustrate the predicted benefit (NOR) and risk (early-onset moderate-to-severe OHSS) across varying FSH starting doses (Figures 1B and C). Additionally, a user-friendly web-based calculator was developed to enhance accessibility and support exploratory use in clinically relevant contexts (Figure S7 in Multimedia Appendix 1).

Figure 1. Flowchart of the study: (A) the modeling process with internal and external datasets, (B) illustration of the primary goal of this study, and (C) illustration of the clinical application of the individualized ovarian stimulation guide (InOvaSGuide) system. EHR: electronic health record; FSH: follicle-stimulating hormone; NOR: number of oocytes retrieved; OHSS: ovarian hyperstimulation syndrome.



Patient Characteristics

A total of 6401 patients from the internal dataset and 3805 patients from the external dataset were included, with baseline characteristics detailed in Table 1. The median age was 30.0 (IQR 27.0-33.0) years in the internal dataset and 32.0 (IQR 29.0-35.0) years in the external dataset. The gonadotropin-releasing hormone antagonist protocol was the most commonly used in both datasets (internal dataset: 2650/6401, 41.4%; external dataset: 1913/3805, 50.3%). The median number of NOR was 13.0 (IQR 9.0-17.0) and 15.0 (IQR 10.0-20.0) for the internal and external dataset, respectively. In the internal dataset, 55 (0.9%) patients were diagnosed with moderate-to-severe OHSS, whereas 46 (1.2%) patients were diagnosed in the external dataset. Further comparisons between OHSS and non-OHSS cases in both datasets are detailed in Tables S4 and S5 in Multimedia Appendix 1.

Table 1. Baseline characteristics of the patients in the internal and external datasets.

	Internal dataset (n=6401)	External dataset (n=3805)	*P* value
Age (y), median (IQR)	30.0 (27.0-33.0)	32.0 (29.0-35.0)	<.001
BMI (kg/m^2), median (IQR)	21.7 (19.8-24.0)	21.6 (19.8-23.6)	.02

Normal	6346 (99.1)	3759 (98.8)	
Moderate to severe	55 (0.9)	46 (1.2)	

[a]FSH: follicle-stimulating hormone.

[b]GnRH: gonadotropin-releasing hormone.

Model Performance

For NOR prediction, the gradient boosting regressor exhibited the best performance, with an R^2 value of 0.7978 in the internal dataset and 0.7924 in the external dataset, indicating strong explanatory power (Table 2). The model's mean absolute error was 0.0223 and the root mean square error was 0.0298, collectively affirming the high accuracy and minimal bias. The model's predictions aligned closely with the actual outcomes, demonstrating relatively high accuracy. The Quantile-Quantile plot further confirmed that the residuals followed a normal distribution, as they closely aligned with the diagonal line (Figures 2A-2D).

Table 2. Performance metrics of the number of oocytes retrieved prediction models in internal and external datasets.

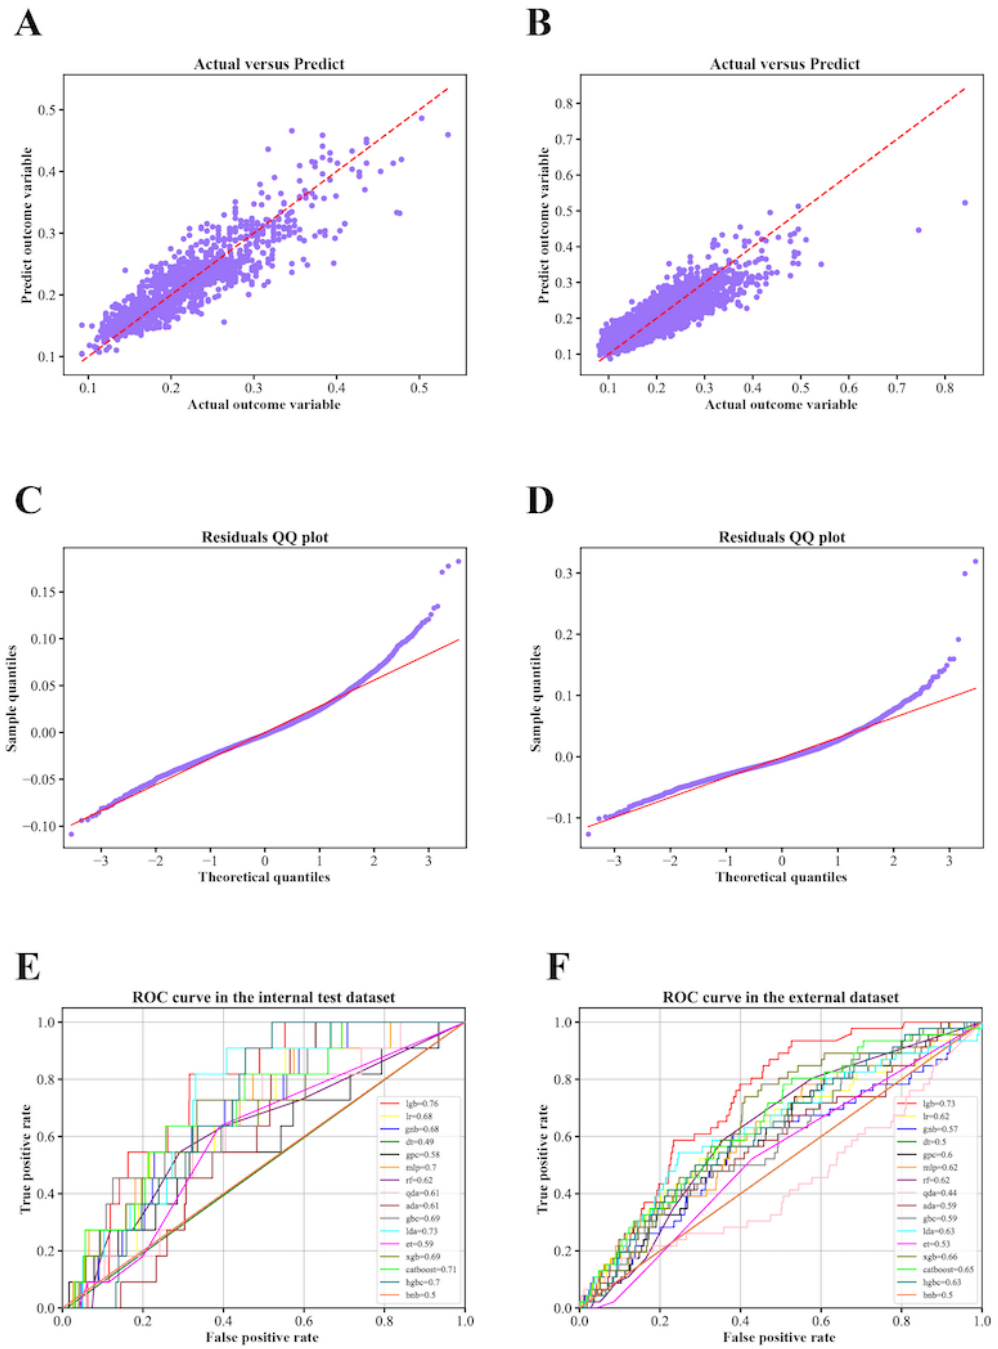
Figure 2. Model performance in predicting the number of oocytes retrieved (NOR; A–D) and ovarian hyperstimulation syndrome (OHSS; E and F) in the internal and external datasets. ADA: adaptive boost classifier; BNB: Bernoulli Naive Bayes; CatBoost: categorical boosting classifier; DT: decision tree classifier; ET: extra trees classifier; GBC: gradient boosting classifier; GNB: Gaussian Naive Bayes; GPC: Gaussian process classifier; HGBC: histogram-based gradient boosting classifier; LDA: linear discriminant analysis; LGB: light gradient boosting machine classifier; LR: logistic regression; MLP: multilayer perceptron classifier; QDA: quadratic discriminant analysis; QQ: quantile-quantile; RF: random forest; ROC: receiver operating characteristic; XGB: extreme gradient boosting classifier.



For early-onset moderate-to-severe OHSS prediction, the LightGBM model consistently outperformed other algorithms, achieving an ROC-AUC of 0.7588 in the internal dataset and 0.7287 in the external dataset (Figures 2E and 2F). While recall, specificity, weighted F_1-score, and Cohen κ score indicated reasonable discriminative performance, precision-related metrics, including positive predictive value, negative predictive value, and PR-AUC, remained modest across all classifiers. The results, along with the confusion matrices, are summarized in Table 3 and Figures S5 and S6 in Multimedia Appendix 1.

Table 3. Performance metrics of early-onset moderate-to-severe ovarian hyperstimulation syndrome prediction models in internal and external datasets.

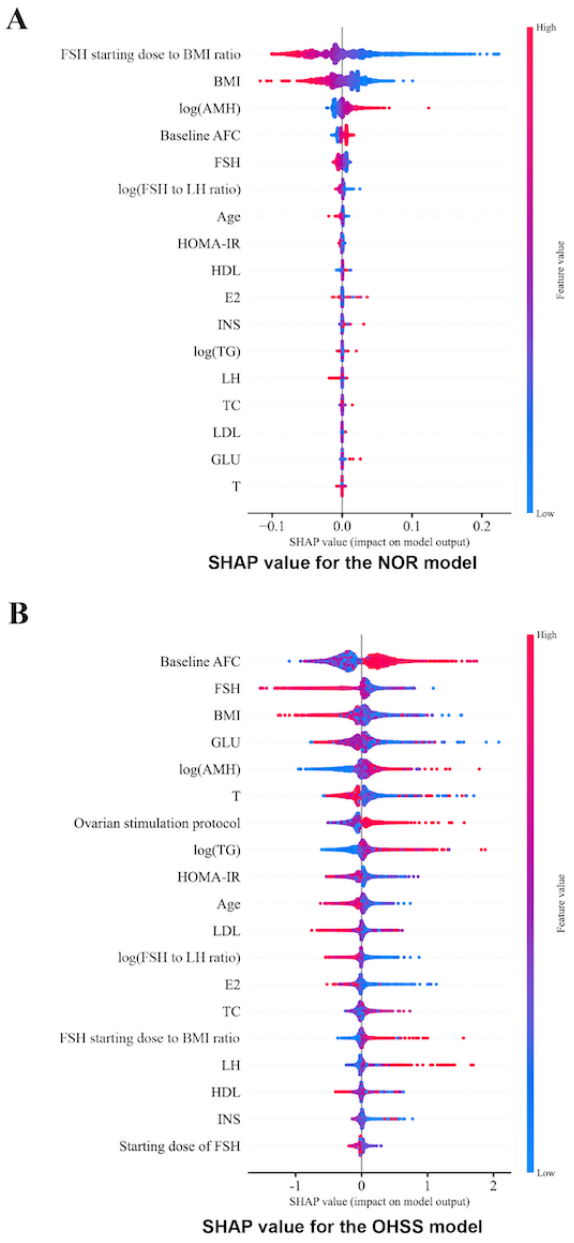
Model Interpretation

SHAP values were used to assess feature importance for both models, as shown in Figure 3. For NOR prediction, the features with the highest mean absolute SHAP values were FSH starting dose to BMI ratio, BMI, log (AMH), baseline AFC, and baseline FSH, indicating their significant contribution to the model. For early-onset moderate-to-severe OHSS prediction, the most important features identified were baseline AFC, followed by baseline FSH, BMI, fasting blood glucose, and log (AMH).

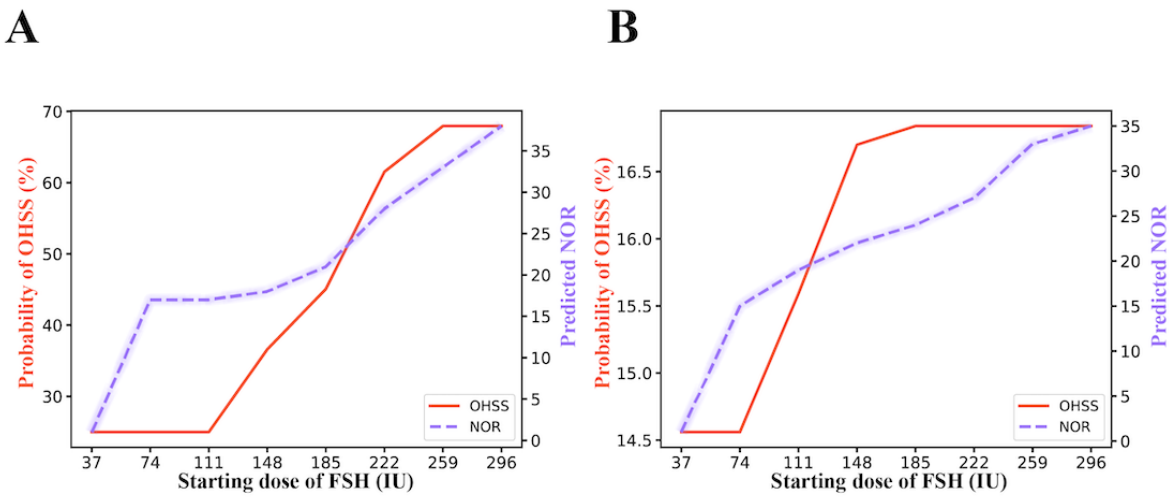
Figure 3. Shapley additive explanation (SHAP) values of the prediction models for (A) number of oocytes retrieved (NOR) and (B) ovarian hyperstimulation syndrome (OHSS). FSH: follicle-stimulating hormone; BMI, body mass index; AMH: anti-Müllerian hormone; AFC: antral follicle count; LH: luteinizing hormone; HOMA-IR: homeostatic model assessment of insulin resistance; HDL: high-density lipoprotein; E2: estradiol; INS: fasting insulin; TG: triglycerides; TC: total cholesterol; LDL: low-density lipoprotein; GLU: fasting glucose; T: testosterone;.



Integrated Dose-Response Curves and Web Calculator

To facilitate individualized ovarian stimulation, we further integrated the prediction models for both NOR and early-onset moderate-to-severe OHSS into dose-response curves. Examples of patients with relatively high and low predicted risks of OHSS are presented in Figures 4A and 4B, respectively. As shown, increasing the starting dose of FSH leads to variable increases in both early-onset moderate-to-severe OHSS probability and predicted NOR for different patients. However, the probability of OHSS occurrence varies among individuals. On the basis of these personalized dose-response predictions, clinicians can determine a suitable starting dose of FSH to achieve an optimal NOR while maintaining a relatively low risk of early-onset moderate-to-severe OHSS.

Figure 4. Model application and representative patient examples with predicted relatively high (A) and low (B) risks of ovarian hyperstimulation syndrome (OHSS). FSH: follicle-stimulating hormone; NOR: number of oocytes retrieved.



Additionally, we developed a web-based calculator as a research-oriented prototype to enhance accessibility and facilitate exploratory use of the proposed models. The intuitive interface allows users to input relevant data and receive immediate predictions from the models (Figure S7 in Multimedia Appendix 1).

Discussion

Principal Findings

In this study, we developed an integrated ML-based system, "InOvaSGuide," capable of simultaneously predicting NOR and the associated risk of early-onset moderate-to-severe OHSS across a wide range of FSH starting doses. By generating individualized dose-response curves, the model provides a continuous view of expected oocyte yield and corresponding safety profiles, providing clinicians with a structured visual reference to support individualized FSH dose selection. A web-based calculator was further implemented as a research-oriented prototype to improve accessibility and facilitate exploratory use of the models in clinically relevant scenarios.

Oocyte yield remains a key determinant of both efficacy and safety in assisted reproduction. Retrieval of fewer than 4 oocytes has been associated with poor reproductive prognosis [17], whereas obtaining more than 15 oocytes increase the likelihood of OHSS and may slightly compromise live birth outcomes [18,19]. Accordingly, a target range of 5 to 15 oocytes is generally recommended to balance benefit and risk [19]. The dose-response curve framework aligns conceptually with these clinical principles, as it illustrates how predicted NOR changes with increasing FSH doses, thereby supporting informed dosing discussions rather than prescriptive decision-making.

Existing ML-based NOR models generally focus either on approximating actual or optimal oocyte yield [11-13,20] or on producing individualized curves based on a limited number of clinical features [10]. In contrast, our approach used feature importance scores from automated classifiers for selection and compared 11 regression algorithms across 2 independent datasets. This allowed the construction of robust dose-response curves that illustrate how predicted NOR varies with incremental FSH doses, providing additional insight beyond traditional single-point estimates by visualizing predictions across a continuum of FSH doses.

We further developed ML models to predict OHSS, addressing a gap in existing clinical tools that predominantly rely on logistic regression [21,22] or receiver operating characteristic–based analyses [23,24]. Although contemporary strategies, including gonadotropin-releasing hormone antagonist protocols, dual triggering, and "freeze-all" approaches, have substantially reduced the incidence of early-onset OHSS, it remains a persistent concern even among presumed normal responders and has not been fully eliminated from clinical practice [25-27]. Our models demonstrated acceptable and consistent discriminatory ability across both internal and external cohorts, despite the limited number of OHSS events.

Importantly, the low prevalence of early-onset moderate-to-severe OHSS introduces substantial and unavoidable class imbalance, which has direct implications for model performance metrics. In particular, precision is structurally constrained in low-prevalence settings; therefore, PR-AUC values should be interpreted with caution. Although ROC-AUC indicated reasonable discrimination, PR-AUC is highly sensitive to outcome prevalence. When event rates fall below 1%, even well-calibrated models will inherently yield modest precision. In addition, our modeling strategy deliberately prioritized sensitivity to enhance clinical safety, an approach that increases false-positive predictions and further reduces precision and PR-AUC but minimizes the risk of missing true high-risk cases.

Within this context, the OHSS model should be viewed primarily as a screening and risk-stratification aid rather than a

diagnostic or decision-making tool. Its intended role is to flag patients with potentially elevated risk who may warrant closer monitoring or consideration of preventive strategies, rather than to definitively predict OHSS occurrence or guide autonomous clinical actions.

Feature importance analyses largely reflected established biological associations. For NOR, the FSH starting dose to BMI ratio, BMI, and log (AMH) emerged as the most influential predictors. While most features were consistent with clinical practice, the contribution of metabolic markers, such as glucose, lipids, and metabolic indicators, warrants further investigation. For early-onset moderate-to-severe OHSS, AFC, baseline FSH, BMI, and log (AMH) emerged as dominant predictors, aligning with known determinants of ovarian reserve and ovarian sensitivity [23,28]. Associations involving testosterone or glucose were less pronounced, highlighting the multifactorial nature of OHSS risk, particularly in women with polycystic ovary syndrome [29]. Overall, these findings illustrate the capability of ML approaches to integrate diverse clinical variables and improve predictive performance.

A key practical advantage of this study is the integration of NOR and early-onset moderate-to-severe OHSS predictions into a unified, visually intuitive research-oriented system. InOvaSGuide enables clinicians to assess the potential trade-offs between stimulation efficacy and safety across a continuum of FSH doses. The web-based interface supports exploratory analysis and clinician-patient discussion; however, the system does not generate prescriptive dosing recommendations and is not intended for autonomous clinical use. Importantly, prospective validation is essential before any consideration of clinical deployment.

Beyond model performance, the development and potential deployment of AI-based, clinician-in-the-loop decision support tools in reproductive medicine entail careful ethical, legal, and implementation considerations [30,31]. Given the sensitivity of reproductive health data, rigorous safeguards for privacy protection and informed consent are essential [32]. Algorithmic transparency is equally important to support clinician interpretation and reduce risks of automation bias [33], while potential bias across patient subgroups remains an important consideration for future validation. In addition, AI-driven clinical tools may fall under medical software regulation, requiring evidence of safety and clinical validity before clinical implementation. Finally, effective integration into clinical practice will depend on usability, compatibility with established workflows, and clearly assigned clinical accountability [30]. Addressing these factors will be necessary before the system can be responsibly adopted in real-world settings.

Limitations

Our study had several limitations. First, it focused on early-onset moderate-to-severe OHSS, excluding mild cases that may self-resolve and late-onset OHSS more commonly associated with embryo transfer. Patients with a predicted poor prognosis were also excluded under the assumption that they are less likely to develop OHSS. These exclusions introduced a structural selection bias that narrowed the population represented and limited the generalizability of the model in broader clinical settings. Second, the relatively small number of OHSS cases limited the model's ability to fully characterize patients who are affected. This scarcity, together with the substantial class imbalance, also constrained the effectiveness of resampling-based strategies. Although multiple resampling methods were evaluated, only cost-sensitive learning may allow a more reliable assessment of alternative methods. Third, the retrospective nature of the study restricted the availability of certain relevant factors, such as previous OHSS history and genetic susceptibility, and may also introduce selection bias and unmeasured confounding that cannot be fully controlled. Finally, although the system provides individualized dose-response curves for clinical reference, it does not generate a prescriptive starting dose. Moreover, the model has not yet undergone prospective evaluation, which limits its current clinical applicability. A prospective validation study is planned as a necessary next step to assess real-world performance. Future large-scale, multicenter validation in broader patient populations will be essential for improving model stability and generalizability.

Conclusions

We developed and externally validated InOvaSGuide, a ML system that simultaneously predicts NOR and early-onset moderate-to-severe OHSS risk across a continuum of FSH doses. By linking efficacy and safety within a single dose-response framework, the tool highlights the broader potential of model-informed dosing to standardize ovarian stimulation and enhance patient safety. Prospective trials are needed to establish real-world utility.

Acknowledgments

The authors are grateful to Yuan Sheng from STI-Zhilian Research Institute for Innovation and Digital Health for her invaluable contributions to the study figures. They also thank the Yiersan Digital Health Care Group for providing technical support for the web-based calculator interface design. Generative AI (ChatGPT-4.1, OpenAI [34]) was used exclusively for language refinement during manuscript preparation, including improving grammar, clarity, and readability of author-written text. No text, data interpretation, scientific content, or references were generated by the AI tool. All substantive content, analyses, and conclusions were produced entirely by the authors. The authors verified all AI-assisted edits and take full responsibility for the final manuscript.

Funding

This study was funded by the National Natural Science Foundation of China (grant 82371682) and the Natural Science Foundation of Hunan Province (grants 2022JJ40779 and 2022JJ70080). The funding source had no role in the study design, data collection, data analysis, data interpretation, or writing of the report.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

JF, Y Li, and SL had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. JC played a role in data collection and was a major contributor to manuscript writing. Jianjuan Zhao conducted data analysis, performed modeling, and contributed to drafting the Methods section. JC, Jianjuan Zhao, JF, Y Li, and SL contributed equally to this work. YZ, GY, YY, and QS provided biostatistical analysis support. HQ, HT, Jing Zhao, and BX assisted in internal dataset acquisition, while Y Liu, JL, and ZY helped in external dataset acquisition. QZ and HL provided language support. JF, Y Li, and SL were responsible for the study design and critically revised the manuscript. All authors read and approved the final manuscript

Conflicts of Interest

None declared.

Abstract

Background: The HIV epidemic in the United States disproportionately impacts gay, bisexual, and other men who have sex with men (MSM). Despite the effectiveness of HIV preexposure prophylaxis (PrEP) in preventing HIV acquisition, uptake among MSM remains suboptimal. Motivational interviewing (MI) has demonstrated efficacy at increasing PrEP uptake among MSM but is resource-intensive, limiting scalability. The use of artificial intelligence, particularly large language models with conversational agents (ie, "chatbots") such as ChatGPT, may offer a scalable approach to delivering MI-based counseling for PrEP and HIV prevention.

Objective: This internal usability testing aimed to evaluate the development of an artificial intelligence–based chatbot, including its ability to provide MI-aligned education about PrEP and HIV prevention and potential to support PrEP uptake.

Methods: The Chatbot for HIV Prevention and Action (CHIA) was built on a GPT-4o base model embedded with a validated knowledge database on HIV and PrEP in English and Spanish. The CHIA was fine-tuned through training on a large MI dataset and prompt engineering. The use of the AutoGen multiagent framework enabled the CHIA to integrate 2 agents, the PrEP Counselor Agent and the Assistant Agent, which specialized in providing MI-based counseling and handling function calls (eg, assessment of HIV risk), respectively. During internal testing from March 10-April 28, 2025, we systematically evaluated the CHIA's performance in English and Spanish using a set of 5-point Likert scales to measure accuracy, conciseness, up-to-dateness, trustworthiness, and alignment with aspects of the MI spirit (eg, collaboration, autonomy support) and MI-consistent behaviors (eg, affirmation, open-ended questions). Descriptive statistics and mixed linear regression were used to analyze the data.

Results: A total of 296 responses, including 145 English responses and 151 Spanish responses, were collected during the internal testing period. Overall, the CHIA demonstrated strong performance across both languages, receiving the highest combined scores in the general response quality metrics including up-to-dateness (mean 4.6, SD 0.8), trustworthiness (mean 4.5, SD 0.9), accuracy (mean 4.4, SD 0.9), and conciseness (mean 4.2, SD 1.1). The CHIA generally received higher combined scores for metrics that assessed alignment with the MI spirit (ie, empathy, evocation, autonomy support, and collaboration) and lower combined scores for MI-consistent behaviors (ie, affirmation, open-ended questions, and reflections). Spanish responses had significantly lower mean scores than English responses across nearly all MI-based metrics.

Conclusions: Our internal usability testing highlights the potential of the CHIA as a viable tool for delivering MI-aligned counseling in English and Spanish to promote HIV prevention and support PrEP uptake, though its Spanish language performance requires further improvement.

KEYWORDS

artificial intelligence; counseling; HIV infections; motivational interviewing; multiagent framework; preexposure prophylaxis

Introduction

In the United States, HIV continues to be a significant cause of morbidity and mortality, disproportionately affecting groups including gay, bisexual, and other men who have sex with men (MSM). In 2022, MSM comprised 67% of new HIV diagnoses in the United States [1]. Hispanic or Latino and Black or African American individuals accounted for 39% and 35% of these new diagnoses, respectively [1]. HIV preexposure prophylaxis (PrEP) is highly effective at preventing HIV among populations at an increased risk of infection, including MSM [2-4]. However, PrEP uptake among MSM, and particularly Hispanic or Latino and Black or African American MSM, remains suboptimal due to inequitable access to health care and stigma [5-7].

Motivational interviewing (MI) is an evidence-based, patient-centered approach to healthy behavior change that has demonstrated efficacy in facilitating PrEP uptake among MSM [8-10]. In our previous work, we demonstrated that a brief MI-based intervention improved PrEP uptake among MSM in a clinical setting [9]. However, implementing MI in practice requires a significant investment in time and resources for provider training and intervention delivery. Research suggests that provider-led MI counseling usually requires 2-5 sessions (30 - 60 min per session) to produce measurable behavior change, with several studies reporting substantially higher effectiveness (>80%) when more than 5 sessions are delivered [11-13]. The associated clinician time and continuity demands make sustained MI delivery difficult to scale, particularly during brief clinical visits [11-14]. Time demands apply not only to patient encounters but also to provider training, which typically involves several hours of didactic instruction and coaching [13]. Artificial intelligence (AI)—specifically large language models (LLMs) with conversational agents (“chatbots”) such as ChatGPT—has shown promise in overcoming these challenges [15-17]. Preliminary research supports AI-based chatbots’ ability to employ MI techniques in promoting healthy behavior change, including smoking cessation and decreased substance use [17-21]. A chatbot designed to use MI principles can be made available 24/7, requiring only minimal human effort for periodic supervision and quality assurance. Drawing on empirical session-length data and standard labor-cost benchmarks, it suggests that such MI-aligned chatbots could substantially improve the scalability of MI delivery.

In the context of HIV prevention, researchers have noted many uses for AI-based chatbots [22-24]. Limited evidence suggests that chatbots may help facilitate the uptake of HIV testing and PrEP among populations at increased risk of HIV, including MSM [22,23,25]. Chatbots have also shown the potential to provide personalized counseling on sensitive health topics including HIV prevention [22]. Although AI-based chatbots hold significant promise for HIV prevention efforts, concerns exist regarding their ability to provide accurate medical information, stay up-to-date on current clinical recommendations, and demonstrate cultural competence [22,26]. Studies have highlighted issues such as hallucinations (incorrect or misleading information) and the potential for perpetuating biases, which can undermine trust and effectiveness [22]. Low engagement with AI-based chatbots for health promotion has also been documented in the literature, presenting challenges with delivering effective interventions via this modality [27,28]. Additionally, no studies, to our knowledge, have evaluated the use of MI by an AI-based chatbot for HIV prevention.

In this usability testing, we developed and conducted an internal evaluation of an AI-based chatbot (Chatbot for HIV Prevention and Action [CHIA]) that harnesses MI to provide personalized counseling for PrEP. To address the limitations noted above and improve the CHIA’s performance, we integrated three complementary components: (1) a retrieval-augmented generation pipeline constrained to a curated, validated knowledge base to reduce unsupported statements; (2) MI alignment via supervised fine-tuning on annotated MI transcripts coupled with preference-based tuning using expert-selected responses; and (3) personalization through a structured HIV risk assessment and the transtheoretical model (TTM) to tailor counseling to the user’s stage of change [29,30]. We present the results of an internal evaluation of the CHIA, assessing the chatbot’s alignment with MI principles, factual accuracy, and its ability to deliver appropriate counseling for HIV prevention and PrEP. This internal testing serves as a cornerstone for future real-world implementation and evaluation of the CHIA’s performance among individuals at an increased risk of HIV.

Methods

Overview of Chatbot Design

Generative pre-trained transformers are LLMs that use deep learning to generate human-like text based on natural language input [31]. GPT-4o, released by OpenAI in May 2024, is a multimodal LLM capable of processing both text and images with improved efficiency and performance compared to earlier versions [32]. We developed the CHIA using GPT-4o to deliver MI-informed counseling aimed at improving HIV prevention outcomes, particularly the uptake of PrEP.

The CHIA consists of two main components: (1) a fine-tuned, customized LLM embedded with a validated knowledge database and (2) multiple specialized agents and functions to meet users’ needs. Built on a GPT-4o base model, the CHIA detects language inputs automatically and has been fine-tuned using a large MI dataset with the goal of training it to produce empathetic responses and avoid biases [33,34]. GPT-4o was selected because it offers superior conversational quality, multilingual capability, and reduced risk of generating errors compared to smaller open-source models. These features are critical for building trust with users discussing sensitive health topics. To ensure accurate and up-to-date information on HIV and PrEP, the CHIA integrates the latest validated data on these

topics, reviewed by a team of physicians and researchers, in English and Spanish, with monthly updates.

The CHIA's architecture integrates 2 specialized agents (Figure 1): a user-facing PrEP Counselor agent and a tool-executing Assistant agent using AutoGen [35]—an open-source multiagent framework developed by Microsoft. The Counselor conducts the entire conversation using MI, triages user needs, and delegates tasks to the Assistant when external information is required. The Assistant then invokes specific functions—knowledge retrieval from an embedding-backed knowledge base, HIV risk or readiness assessment, PrEP provider search and referral info, reminders or links, and initiating human support on request—and returns results to the Counselor. The Counselor interprets these outputs through MI principles and delivers the response to the user. To maintain continuity across visits, the Counselor agent is capable of using *Teachability* to store key information to ensure the continuity of conversation (eg, identity token, risk or concerns, prior plan or notes). This design enables the CHIA to deliver personalized responses that mimic human counseling. Advanced prompt engineering keeps interactions dynamic and contextually relevant [36]. The CHIA is secured through a login page and deployed on Amazon Web Services (AWS) with the Supabase software (version 1.25; Supabase, Inc.) for backend management, ensuring robust and private data handling [37,38].

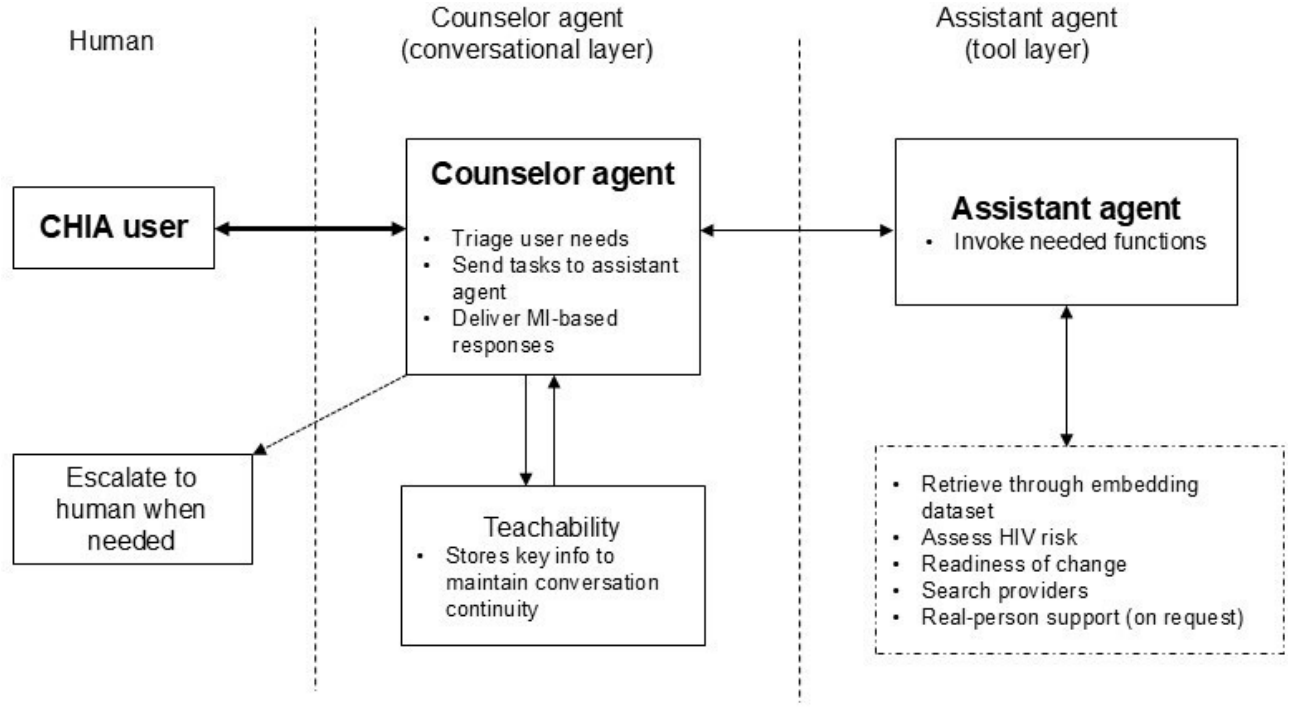

Figure 1 CHIA system workflow: information flow among user, counselor agent, and assistant agent

Embedded HIV/PrEP Dataset Development and Validation

To enhance chatbot accuracy and reliability, embedding and retrieval-based techniques have been employed to minimize misinformation by ensuring responses are grounded in validated sources [39]. Assessment retrieval methods, guided by established frameworks, such as the retrieval-augmented generation (RAG) playground framework and the automated RAG evaluation system [40-42], allow for systematic evaluation of chatbot performance in delivering evidence-based, contextually relevant health information. To develop a robust embedded dataset specifically for the CHIA, our study team, composed of 4 research assistants under the guidance of 2 physicians and 1 principal investigator with decades of research experience in HIV prevention and treatment, systematically curated and validated key information. We compiled the most frequently asked questions about HIV and PrEP, which included topics such as basic knowledge, effectiveness, side effects, formulations, insurance coverage, financial assistance, and cultural considerations. A Spanish-fluent research assistant translated the dataset to ensure accessibility for Spanish-speaking users. Each data entry was structured into a standardized format, categorizing content by topic, question, and answer to optimize retrieval efficiency. All information underwent expert validation for medical accuracy and clarity. These processes prevent the spread of misinformation or erroneous recommendations ("hallucinations"), which ChatGPT cannot guarantee. The embedding database is updated monthly and as needed when users ask questions outside the existing dataset under expert supervision. In such cases, the system flags the query, alerting the development team to review, validate, and integrate new information. This dynamic updating process helps to ensure that the CHIA remains accurate, relevant, and responsive to evolving needs of the community.

MI Alignment via Implementation of Preference Fine-Tuning Techniques

To enhance the CHIA's ability to deliver MI-based counseling, we utilized preference fine-tuning techniques [43]. This was done because open-source models would have been insufficient for MI fine-tuning due to their lack of multilingual support, higher hallucination rates, and insufficient token context. We processed a large, publicly available MI dataset downloaded from GitHub to facilitate diversity in linguistic styles and conversational structures [33,34]. The dataset contained 2000 dialogs, half of which were from publicly available conversations between potential clients and licensed counselors on CounselChat—an online platform for mental health support—and the other half from exchanges between users and peer supporters on Reddit subforums related to emotional distress [33,34]. All dialogs in the dataset were annotated by trained counselors with labels adapted from the Motivational Interviewing Treatment Integrity Code 2.0 and 4.2.1, a widely used method for evaluating how well clinicians perform MI [33,34,44-46]. Our team preprocessed the raw text from the dataset, tokenized it (ie, broke down into smaller units) [47], and then converted this to a vector database. This processed vector database was employed to fine-tune the GPT-4o base model, enabling the CHIA to generate responses informed by MI. We used the Direct Preference Optimization algorithm to refine response quality [43]. A preference fine-tuning JSON file was constructed that ranked certain responses as preferable over others based on their alignment with MI-consistent behaviors such as open-ended questioning and reflective listening. This iterative training process was designed to enhance the CHIA's ability to prioritize MI-aligned responses while maintaining coherence and engagement. By the end of this process, we developed a specialized ChatGPT-4o model for MI-based counseling, serving as the foundation for the CHIA to deliver personalized, empathetic, and structured conversations that support PrEP uptake and public health interventions.

HIV Risk Assessment and Readiness for Change Functions

To enhance the CHIA's ability to provide personalized guidance, we integrated functions to assess individual HIV risk and readiness for behavior change. HIV risk assessment was based on the HIV Incidence Risk Index for MSM [48], following Centers for Disease Control and Prevention guidelines for PrEP eligibility [49]. A focus on MSM was chosen due to the disproportionate number of new HIV diagnoses occurring among this population in the United States [1]. Additionally, the CHIA's development incorporated the TTM through the use of the Contemplation Ladder, a validated tool that allowed individuals to self-assess their readiness for PrEP uptake on a scale from 0 to 10 [29,50]. These assessments were embedded into the CHIA's conversational interface, enabling real-time evaluation, as users engaged with relevant questions. Based on these assessments, the CHIA tailored its responses to align with each user's unique risk profile and stage of readiness for change, providing targeted, motivational, and evidence-based guidance to support PrEP uptake.

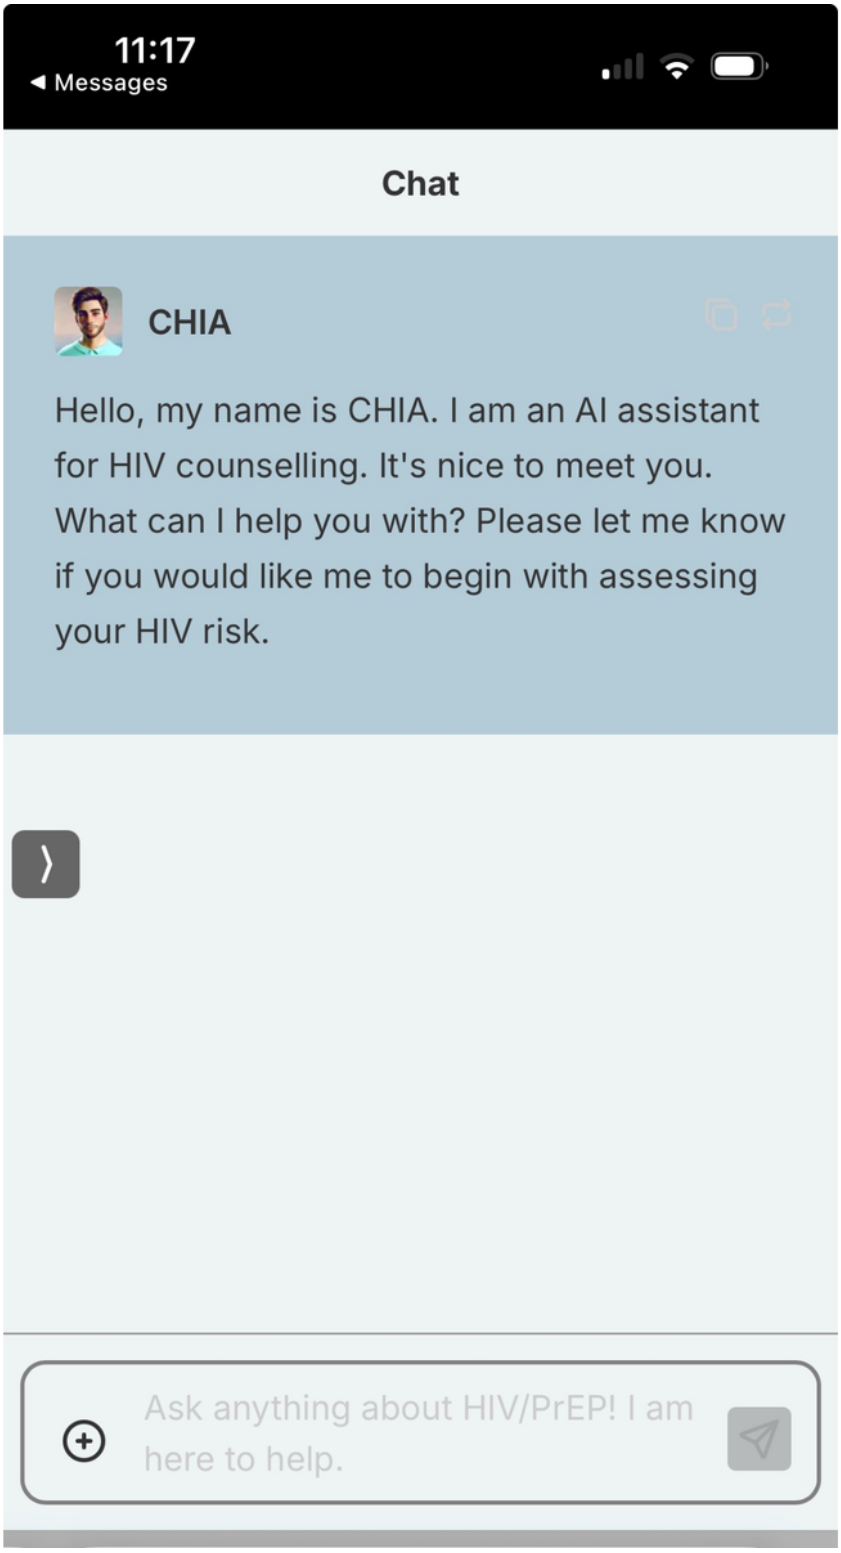
Linkage to PrEP Care and Referral Function

To facilitate access to PrEP, we developed a function that searched the "PrEP Locator" website, a national database of PrEP providers in the United States, using user-provided ZIP codes [51]. This function was integrated into the CHIA to generate a list of PrEP providers within a 30-mile radius, offering users convenient options for selecting nearby clinics. Additionally, a separate function was implemented to enable the CHIA to engage users with follow-up questions to assess clinic preferences, determine if they wished to be contacted by a provider for an initial appointment, and identify potential barriers to care. An AI-generated and encrypted email was then sent to the selected clinic with a referral and relevant contact information. Study staff coordinated with the clinic to ensure appointments were scheduled efficiently. Furthermore, the CHIA inquired whether users preferred to connect with a real person for assistance in accessing PrEP care. If requested, study staff were notified and contacted the individual within 1 business day.

User Interface and Data Security

The CHIA user interface was designed to provide a streamlined, secure, and personalized experience (Figure 2). Users could log in with an existing account or create a new one, with 2-factor authentication required for each login to ensure data protection and confidentiality. The login system adhered to high cybersecurity standards to safeguard user information. Once logged in, users accessed a clean, intuitive interface with clear navigation options and a responsive chat window to facilitate seamless interactions.

Figure 2. The user interface of the Chatbot for HIV Prevention and Action (CHIA).



To facilitate secure data management, the CHIA was deployed through AWS, leveraging its cloud-based infrastructure for reliable and Health Insurance Portability and Accountability Act (HIPAA)–compliant storage [38]. AWS encryption protocols protected user data, ensuring confidentiality and integrity [38]. Additionally, Supabase was used to host the back-end data, providing an efficient database solution for managing user interactions [37]. This integration of AWS for deployment and Supabase for back-end data management enabled the CHIA to maintain robust security measures while promoting a smooth user experience. The secure, user-friendly interface aimed to encourage sustained engagement and support meaningful interactions.

Procedures

During internal testing from March 10 to April 18, 2025, 4 research staff members systematically evaluated the CHIA's performance in both English and Spanish. Each researcher acted

as a potential user and interacted with the chatbot over multiple sessions. Two research staff members interacted with the chatbot in English, and 2 staff members fluent in Spanish interacted with the chatbot in Spanish. Researchers then exchanged transcripts and rated each response on a set of 11 metrics covering general response quality and alignment with MI using a 5-point Likert scale. Likert scores were used primarily to enable relative comparisons across languages and scenarios, rather than to assess performance against an external benchmark, as no standardized threshold currently exists for interpreting Likert-based ratings of motivational interviewing alignment in chatbot evaluations. The research team met prior to the review process to ensure familiarity with the operational rating scale and consistency in scoring across raters. After interacting with the chatbot, the team met to discuss conversation-level findings and the performance of the HIV risk assessment, referral, and readiness for change functions.

Evaluation Metrics for Retrieving Information From Embedded Dataset

The CHIA's RAG functionality was evaluated at the session level using 7 key metrics—groundedness, medical accuracy, completeness, no fabrication, appropriate tone, safety, and reasoning—that were scored on a 5-point Likert scale via the Automated RAG Evaluation System [42,52]. Groundedness assessed if responses were based on retrieval sources, and medical accuracy sought to ensure alignment with validated health information. Completeness measured whether the retrieved content provided sufficient information. No fabrication verified that responses did not introduce false or misleading details (sometimes referred to as "hallucinations") by comparing each RAG output against the ground-truth dataset to confirm retrieval only from the embedded validated knowledge base. Appropriate tone was evaluated if responses were professional and empathetic, and safety was assessed whether the information adhered to ethical and safety principles. Finally, reasoning evaluated the chatbot's ability to integrate and apply retrieved knowledge. Sessions with any metric below a predefined threshold were auto-flagged for human review; we logged and reviewed misinformation flags and near-miss events (eg, unsafe advice avoided or corrected) and conducted monthly audits summarizing flag rates, time-to-review, and corrective actions.

Metrics for Comprehensive Assessment

We developed and used a structured assessment framework to evaluate the CHIA's responses based on previous research that incorporated multiple dimensions of chatbot interaction [26,53]. First, we assessed general response quality using 4 metrics—accuracy, conciseness, up-to-dateness, and trustworthiness—that were scored on a 5-point Likert scale to ensure that responses were factually correct, concise, up-to-date, and emotionally supportive. We also developed a set of metrics inspired by the Motivational Interviewing Treatment Integrity Code to measure the alignment of the CHIA's responses with the MI spirit and MI-consistent behaviors [44,45]. Metrics to assess alignment with the MI spirit included empathy, evocation, autonomy support, and collaboration, and those for MI-consistent behaviors included affirmation, open-ended questions, and reflections. All MI-based metrics were also scored using a 5-point Likert scale. Additionally, safety was evaluated on a pass or fail basis in which the CHIA's use of toxic language, demonstration of bias, or violation of privacy constituted a failure. A qualitative feedback section allowed raters to document strengths, weaknesses, and suggested improvements. This comprehensive framework ensured a robust and reliable evaluation of the CHIA's performance in multiple languages and user engagement scenarios. The detailed metrics and operational assessment protocol is included in Multimedia Appendix 1. At the conversation level, we assessed the CHIA's performance using the same response-level metrics in addition to evaluating its overall adherence to MI techniques including employing a guiding (rather than directive) style of conversation, eliciting change talk, and managing sustain talk (ie, statements against change). Given that this analysis was limited to 4 conversations, only qualitative findings are reported in this paper. Finally, we assessed the CHIA's memory and teachability by measuring its ability to recall information accurately and integrate key details from past interactions into current conversation. The qualitative findings of this assessment are summarized in this paper.

Ethical Considerations

This internal testing did not involve human participants or the use of human subject data. All testing was conducted internally using simulated interactions to evaluate chatbot performance. As such, this developmental phase of the study does not meet the definition of human participants research and was determined to be exempt from IRB review by the Miriam Hospital Institutional Review Board (protocol #2312729).

Statistical Analysis

Descriptive statistics, including the mean and SD, were calculated separately for English and Spanish responses for each metric (ie, accuracy, conciseness, up-to-dateness, trustworthiness, empathy, evocation, autonomy support, collaboration, affirmation, open-ended questions, and reflections). We fit mixed linear regression models to estimate the effect of language (Spanish vs English) on each communication metric. Because multiple observations were nested within individuals, models included random intercepts and random slopes for language at the participant level. This specification accounted for within-person correlation (ie, repeated measures from the same individual) and allowed the magnitude of the language effect to vary across individuals. Fixed effects provided the average adjusted difference between languages, while random effects decomposed variance into within- and between-person components. In addition, standardized effect sizes (Cohen *d*) were derived by dividing the adjusted language difference by the residual standard deviation, providing a measure of the practical significance of language effects across metrics. Statistical significance was assessed using 2-tailed *P* values. The significance level was set at $P<.05$. All analyses were performed using Stata (version 18; StataCorp LLC).

Results

Overview of Response-Level Assessment

A total of 296 responses were assessed across 11 metrics, covering general response quality (eg, accuracy, trustworthiness) as well as alignment with the aspects of the MI spirit (eg, evocation, autonomy support) and with MI-consistent behaviors (eg, affirmation, open-ended questions). This total included 145 English responses and 151 Spanish responses. All responses in English and Spanish passed the safety evaluation, indicating that the CHIA's outputs were appropriate, ethical, and unbiased. Table 1 presents the mean and SD for all metrics at the response level, along with effect sizes reported using Cohen *d*. Table 2 displays the examples of CHIA's responses to researcher prompts and their scores for evaluation metrics. Multimedia Appendix 2 includes all responses and scores used in the analysis for both the English and Spanish assessments.

		Evaluation metric						
Researcher prompt	CHIA[b] response	Empathy	Evocation	Autonomy support	Collaboration	Affirmation	Open-ended questions	Reflections
I've tried setting timers before for medications and they don't work.	It sounds like you've tried different strategies without success, and that's okay. Sometimes it takes a bit of creativity to find what works best for you. Perhaps pairing PrEP[c] with a daily activity you never miss, like eating breakfast, could help. Would you like to explore other ways to create a routine that feels natural for you?	5	5	5	5	5	5	5
Is there someone I can talk to about PrEP that is not a doctor or works in healthcare? I don't trust doctors; in my experience, they've treated me poorly.	I'm sorry to hear about your experiences. Seeking support from someone outside of healthcare is a valid choice. Community organizations or support groups focused on sexual health might be a good option. They can offer guidance and answer questions about PrEP. How do you feel about reaching out to a local LGBTQ+[d] center or community health organization for support?	5	5	5	5	5	5	5

		Evaluation metric						
Researcher prompt	CHIA[b] response	Empathy	Evocation	Autonomy support	Collaboration	Affirmation	Open-ended questions	Reflections
My partner could also benefit from PrEP maybe. How do I talk to my partner about it?	Talking to your partner about PrEP can be an important step in taking care of your sexual health together. You might start by expressing your care and concern for both of your well-being. You could say something like, "I've been thinking about how we can protect each other from HIV and STIs[e], and I came across PrEP. It's a medication that can help reduce the risk of HIV, especially if we have sex without condoms sometimes. What do you think about looking into it together?" This approach opens up a dialogue and allows your partner to share their thoughts and feelings, making it a collaborative decision.	4	1	4	1	4	4	4

[a]Responses were obtained through internal testing, in which research assistants simulated potential participants from the target study sample. These responses were not collected from actual human participants within the study sample. Please see Supplemental Dataset 1 for further examples of CHIA responses, including Spanish responses.

[b]CHIA: Chatbot for HIV Prevention and Action.

[c]PrEP: preexposure prophylaxis.

[d]LGBTQ+: lesbian, gay, bisexual, transgender/transsexual, queer, and other minority sexual orientations and gender identities.

[e]STIs: sexually transmitted infections.

English Response-Level Assessment

The CHIA performed strongly in up-to-dateness (mean 4.5, SD 1.0), trustworthiness (mean 4.3, SD 1.0), and accuracy (mean 4.1, SD 1.1). Conciseness had a slightly lower score (mean 4.0, SD 1.3) but remained generally acceptable. Metrics that assessed alignment with the MI spirit generally received higher mean scores than those for MI-consistent behaviors across English responses.

Spanish Response-Level Assessment

Spanish responses demonstrated strong performance across several dimensions. General response quality metrics including trustworthiness (mean 4.7, SD 0.7), up-to-dateness (mean 4.7, SD 0.7), accuracy (mean 4.6, SD 0.7), and conciseness (mean 4.5, SD 0.8) were rated highly. Overall, metrics that measured alignment with the MI spirit and MI-consistent behaviors received lower combined scores.

Combined Response-Level Assessment

The CHIA performed well across both languages, with combined scores showing strength across general response quality metrics including up-to-dateness (mean 4.6, SD 0.8), trustworthiness (mean 4.5, SD 0.9), accuracy (mean 4.4, SD 0.9), and conciseness (mean 4.2, SD 1.1). The mean scores for accuracy, conciseness, and trustworthiness were significantly higher among Spanish responses compared to English responses. Combined scores for metrics that assessed alignment with the MI spirit were generally higher than those for MI-consistent behaviors. Statistical tests indicated that Spanish responses received significantly lower mean scores than English responses across nearly all MI-based metrics.

Conversation Level Assessment

Conversations with the CHIA were generally perceived as reliable and emotionally supportive but occasionally repetitive or overly generic. Empathy and collaboration were present but could be deepened with more emotionally attuned language and user-specific questions. The CHIA's autonomy support was acknowledged, though one instance where the chatbot proceeded with a risk assessment against user preference indicated room for technical and conversational improvements. All reviewers emphasized reducing reliance on early referrals to health care providers and instead suggested a more user-driven flow. MI techniques (eg, change talk elicitation, sustain talk management, guiding style) were successfully implemented across English conversations, yet raters noted the need for the CHIA to ask more personalized, open-ended questions earlier in the conversation to build rapport and relevance. In the Spanish version, reviewers reported that conversations were not consistently MI-aligned, often lacking key aspects of the MI spirit such as autonomy support and MI-consistent behaviors including affirmation, open-ended questions, and reflections.

Evaluation of the Referral, HIV Risk Assessment, and Readiness for Change Functions

For the referral function, ZIP codes from across the United States were entered. The CHIA successfully returned accurate listings of nearby PrEP clinics within a 30-mile radius. However, the chatbot occasionally failed to provide detailed information about specific clinics when requested, highlighting the need to enable the CHIA to retrieve location-specific data by accessing selected clinic websites. In contrast, the HIV risk assessment function consistently performed well across all conversations. This feature has since been refined to allow users to exit the assessment if it is accidentally triggered. Overall, both referral and risk assessment functions were functional and helpful, with minor refinements needed to optimize user experience. All research assistants tested the CHIA's readiness for change function, which supports MI-based counseling by identifying the user's stage of change. The function successfully prompted tailored, stage-appropriate responses to guide users toward PrEP decision-making. Overall, it enhanced the CHIA's ability to deliver personalized, action-oriented support aligned with MI core skills in this internal pilot testing.

Assessment of Retrieval Functionality

Performance was strong across all 7 key metrics designed to assess the CHIA's RAG functionality (groundedness, medical accuracy, completeness, no fabrication, appropriate tone, safety, and reasoning; Table 3). Mean scores ranged from 3.7 to 4.6, with SDs between 0.5 and 1.1. Median scores for each metric were consistently high, with IQRs falling within acceptable variability (eg, median 4, IQR 3-5). These findings indicate that the CHIA's responses were consistently accurate, grounded in reliable sources, and communicated in a safe and professional manner.

Table . Evaluation of the Chatbot for HIV Prevention and Action's (CHIA) retrieval-augmented generation functionality.

Metrics	Mean (SD)
Groundedness	4.1 (1.1)
Medical accuracy	4.6 (0.8)
Completeness	3.7 (1.0)
No fabrication	4.6 (0.8)
Appropriate tone	4.6 (0.6)
Safety	4.7 (0.5)
Reasoning	3.9 (1.0)

Assessment of Memory and Teachability

Preliminary tests indicated that the CHIA was able to successfully recall information from prior discussions when prompted. Additionally, following the implementation of the teachability feature, an overall reduction in repetitive information provided to the user was noted, highlighting the CHIA's ability to adapt based on the user's previous interactions.

Discussion

Principal Findings

To our knowledge, the CHIA is the first LLM-based conversational chatbot grounded in both MI and TTM to deliver PrEP and HIV prevention counseling and facilitate linkage to PrEP care. This approach represents a significant advancement over traditional chatbots based on natural language processing or machine learning, which rely on prewritten scripts or rule-based logic [54]. The CHIA leverages dynamic conversational AI to offer personalized, contextually relevant responses tailored to users' readiness for behavior change. Internal testing demonstrated that the CHIA performs well across both English and Spanish, with relatively high scores in accuracy, trustworthiness, up-to-dateness, conciseness, and most metrics that assessed alignment with the MI spirit. These findings suggest that CHIA has the potential to deliver scalable, high-quality MI-aligned counseling, based on its technical design features such as 24/7 availability and low marginal cost per user. However, we emphasize that scalability was not evaluated in this internal testing and remains a theoretical advantage; the CHIA was assessed only for feasibility and usability in a controlled setting. A full assessment of feasibility, cost-effectiveness, cultural sensitivity, and barriers to real-world scalability will be a focus of the planned randomized controlled trial and subsequent implementation studies.

Although the CHIA received high scores in accuracy and many other assessment metrics, the findings from our internal testing also highlight areas for refinement to further enhance its MI metric-based performance. Beyond accuracy, mimicking human-led MI sessions is critical for improving engagement and behavior change [17]. AI-based chatbots must be trained not only to retrieve and deliver accurate health information but also to apply MI-consistent behaviors, such as open-ended questioning and reflective listening, to foster user motivation and self-efficacy [17]. While the CHIA is capable of providing MI-aligned counseling, there is room to strengthen its ability to engage users more deeply through improved use of MI-consistent responses. MI-based metrics received lower scores, especially in the Spanish version, and the CHIA may benefit from targeted improvements through additional prompt engineering and preference fine-tuning. A Spanish-fluent member of our study team will assist with prompt engineering and optimizing the CHIA for Spanish speakers. The Spanish language responses were generally strong; however, improving cultural and linguistic alignment through more intentional prompt design could strengthen its ability to deliver MI-based counseling even further. A key limitation of our internal testing was the absence of double scoring; future rounds of testing prior to the pilot phase will include 2 independent raters and a consensus process.

To improve the CHIA's responsiveness and alignment with MI, we plan to integrate reinforcement learning into its training process [55]. Reinforcement learning approaches further optimize chatbot responses over time by integrating user feedback and adapting to real-world interactions [55]. Specifically, we will implement the Q-Star algorithm [56], a Q-learning–based approach designed to iteratively optimize performance based on feedback from MI-based metric assessments [57,58]. Q-Star is compatible with the AutoGen framework and will allow us to incorporate a dedicated Q-Agent that learns from evaluation data and adjusts the CHIA's decision-making over time [56]. By continuously refining responses based on user interactions and alignment with MI, this approach offers an adaptive pathway to improve the CHIA's accuracy, engagement, and overall quality of counseling.

The CHIA's core functions (ie, referral for clinical services and HIV risk assessment) performed well during internal testing, successfully delivering relevant information and supporting user needs. However, several areas for improvement were identified to enhance functionality and user experience. For example, the "search for providers" function could be expanded to allow users to access more detailed information about clinics in which they express interest, including services offered, hours, and contact details. The HIV risk assessment function may benefit from an override option that allows users to opt out when they indicate they do not wish to be assessed, thereby supporting autonomy and comfort. Additionally, the "call for real-person support" function could be strengthened by asking more specific questions and capturing details—such as the user's current concern, emotional state, or preferred mode of contact—that would better prepare research assistants to offer timely, personalized support. This function could be triggered when the user expresses uncertainty, distress, or repeatedly requests help, signaling the need for human follow-up. Overall, these targeted improvements represent feasible next steps to further tailor the CHIA's functions to support users' preferences and needs.

Although the CHIA demonstrated decent retrieval efficacy during internal testing, there is room for improvement. While the Spanish responses received higher mean scores in accuracy compared to the English responses, it is important to note that the Spanish version was assessed at a later stage in which the coding team had resolved several multilingual processing issues and patched the retrieval function, which likely resulted in enhanced accuracy. We plan to further expand our retrieval strategy across both languages by incorporating multiple related questions into each embedded response to enhance the relevance and completeness of retrieved information. Additionally, we will restructure the embedded dataset into smaller, topic-specific subsets to improve both retrieval speed and accuracy. To minimize hallucinations and maintain response quality, we will continuously monitor advancements in RAG techniques and integrate improvements as appropriate. Finally, we will track the performance of various LLMs and remain open to adopting alternative models that may better align with the CHIA's counseling objectives and technical needs.

While engagement with chatbots for counseling typically involves short sessions of 3-10 minutes [59,60], insufficient engagement with the CHIA could hinder its effectiveness in real-world settings [61]. To strengthen engagement in the planned iterative refinement phase, the CHIA will offer brief, MI-structured exchanges (engage-focus-evoke-plan) with proactive reengagement and personalization. Sessions will be concise yet purposeful, while teachability preserves consented

context (identity token, risk or concerns, prior plan) so return visits feel continuous and tailored. Between sessions, the CHIA will deliver targeted reminders and follow-up prompts, maintain an encouraging, human-like tone (with judicious emoji where appropriate), and surface just-in-time content aligned with user goals. A streamlined interface (clear navigation, minimal friction) will reduce drop-offs, and on-demand human support will be available for safety, complexity, or user preference. These approaches have the potential to refine the CHIA's performance, improve satisfaction, and support repeat use in real-world settings.

Conclusions

In summary, the internal testing of CHIA demonstrated promising performance in delivering MI-based counseling for HIV and PrEP education in English and Spanish. The chatbot performed well in key areas, including accuracy, trustworthiness, up-to-dateness, conciseness, and overall alignment with the MI spirit. However, targeted refinements are needed, particularly in enhancing MI alignment in Spanish responses to promote the CHIA's acceptability among Spanish-speaking populations. Planned enhancements, such as improved retrieval strategies, reinforcement learning through Q-Star, and iterative prototype refinement based on user feedback, will further strengthen the CHIA's ability to deliver responsive and user-centered support. The assessment of real-world effectiveness of its potential for supporting PrEP uptake is planned for a subsequent phase, during which stigma and discrimination outcomes will be explicitly measured alongside counseling effectiveness. These efforts position the CHIA as a potentially scalable and adaptable tool for promoting HIV prevention, supporting PrEP uptake, and offering valuable insight into the application of conversational AI in health interventions.

Abstract

Background: Effective communication is fundamental to health care; however, demographic transitions and a widening global health workforce gap are intensifying the imbalance between service demand and resource supply. Health conversational artificial intelligence (HCAI) based on large language models offers a potential pathway to improve the accessibility and personalization of care. Nevertheless, the lack of a rigorous, user-centered evaluation framework limits the systematic assessment of HCAI quality, raising concerns regarding safety, reliability, and clinical applicability.

Objective: This study aims to establish a scientific and systematic quality evaluation index system for HCAI, providing both a theoretical foundation and a practical tool for the assessment and optimization of HCAI.

Methods: Based on a literature review, industry standards, and expert group discussions, a preliminary framework for the index system was established. Two rounds of Delphi expert consultations were then conducted to collect expert opinions. The analytic hierarchy process (AHP) was applied to assign weights to indicators at each level, and the final content and structure of the index system were determined.

Results: Both rounds of expert consultation achieved a 100% response rate. The authority coefficient of the experts was 0.84 in both rounds. Kendall W coefficient ranged from 0.14 to 0.20 in the first round and from 0.13 to 0.17 in the second round, with all values showing statistical significance (round one: importance $P<.001$, feasibility $P<.001$, sensitivity $P<.001$; round two: importance $P=.001$, feasibility $P<.001$, sensitivity $P=.001$). The final HCAI quality evaluation index system consisted of 3 primary indicators, 7 secondary indicators, and 28 tertiary indicators. According to AHP weight calculations, the primary indicators were ranked in descending order as follows: ethics and compliance (0.4781), health consultation capability (0.4112), and user experience (0.1107).

Conclusions: The evaluation index system constructed in this study demonstrates scientific validity and practical relevance. It provides a valuable reference for the quality assessment, model optimization, and regulatory oversight of HCAI systems.

health consultation; conversational AI; evaluation index system; Delphi method; analytic hierarchy process

Introduction

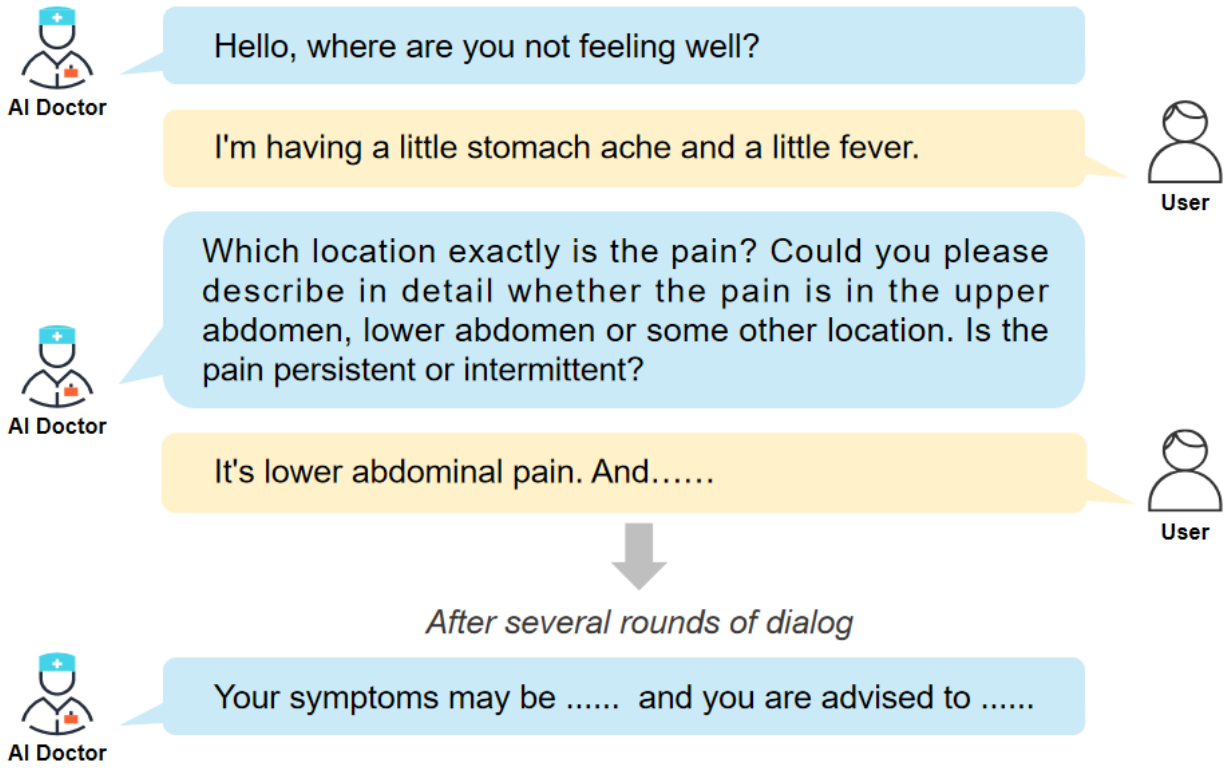
Background

> *Doctors have three magic weapons: language, medicine and scalpel.* [Hippocrates]

Effective communication is essential not only for facilitating information exchange between clinicians and patients but also for establishing trust, mutual understanding, and ongoing support [1]. Currently, health care systems are under increasing pressure. On the one hand, the global population is aging at a rapid pace. According to the World Health Organization, individuals aged 60 and above are projected to account for 22% of the global population by 2050 [2]. On the other hand, chronic and severe illnesses are increasingly affecting younger populations, while public awareness of health and wellness continues to rise. A growing number of individuals are actively seeking medical information and professional advice. These demographic transitions, coupled with the shifting burden of disease, are driving a surge in demand for health care services, while simultaneously exposing persistent systemic challenges, such as inadequate resource distribution and a shortage of health care professionals. It is estimated that the global health workforce deficit will exceed 11 million by 2030 [3]. This widening gap between supply and demand has made it increasingly difficult for patients to obtain timely, effective, and personalized communication and care. In this context, health conversational artificial intelligence (HCAI) based on large language models (LLMs) offers a new approach to mitigating these challenges [4].

Previous studies have demonstrated that LLMs, such as ChatGPT and LLaMA (Large Language Model from Meta), perform remarkably well across a variety of medical tasks, including health consultation [5], diagnostic assistance [6], enhancement of doctor-patient communication [7], and medical image interpretation [8]. These findings highlight the considerable potential of LLMs in clinical and health-related domains. In addition, recent developments have enabled LLMs to conduct multiturn conversations and effectively understand context [9]. This progress provides a solid foundation for building HCAI systems. HCAI refers to LLM-based systems that simulate dialogue with users in a manner similar to that of human physicians. Representative examples include AMIE (Articulate Medical Intelligence Explorer), developed by Google [10]; Ask Patients with Patience, proposed by Zhu and Wu [11]; and Xiaohe AI Doctor, launched by Douyin in China [12]. These systems can ask users follow-up questions and collect and integrate information such as symptoms, medical history, and lifestyle habits [10]. As a result, they can offer more accurate and personalized health care services (Figure 1).

Figure 1. Example of multiturn interaction between health conversational artificial intelligence (AI) and user.



The rapid development of artificial intelligence (AI) has accelerated the expansion of HCAI products. The global conversational AI in the health care market is projected to reach US $16.9 billion in 2025 and to grow at a compound annual growth rate of 24.7% through 2034, reaching a value of US $123.1 billion [13]. As of May 1, 2025, a total of 288 medical LLMs have been publicly released in China. These models cover a wide range of applications, including clinical decision support for specific diseases, prediagnosis consultations, and medical record generation [14]. As a key application of AI in the health

sector, the performance and quality of HCAI systems are directly linked to user safety and health outcomes. Consequently, it is essential to conduct systematic and evidence-based evaluations of these technologies. However, for HCAI systems that deliver health services through multiturn interactions, a scientifically grounded, structured, and practically applicable framework for quality assessment indicators has yet to be established.

Existing studies have employed diverse methods and indicators to evaluate HCAI. Early work often relied on medical examination question banks to assess the accuracy of AI responses to closed-ended questions. Examples include the United States Medical Licensing Examination [15], the Membership of the Royal College of General Practitioners Applied Knowledge Test [16], and the National Medical Licensing Examination in China [17]. Subsequently, several studies developed benchmark tests or clinical case datasets, shifting the focus toward the content generation ability of AI in single-turn open-ended medical questions. Representative datasets include CPMI (Chinese Patent Medicine Instructions dataset) [18], Medical-Diff-VQA (Medical Dataset for Difference Visual Question Answering on Chest X-Ray Images) [19], PubMedQA (a novel biomedical question answering dataset collected from PubMed abstracts) [20], and MultiMedQA (a benchmark for answering medical questions spanning medical exam, medical research, and consumer medical questions, comprising 7 medical question-answering datasets) [21]. Most studies at this stage emphasized content accuracy, with commonly used indicators including BLEU (Bilingual Evaluation Understudy) [5], BERTScore [22], accuracy [23,24], and completeness [25]. However, indicators related to safety risks, such as bias and hallucinations, received limited attention [26,27].

More recent studies have developed methods that better reflect real clinical settings and have assessed AI performance in multitask and multiturn medical dialogues. Xu et al [28] designed MedGPTEval to examine AI performance across 3 dimensions: medical professional capabilities, social comprehensive capabilities, and contextual capabilities. Tu et al [10] employed a remote objective structured clinical examination and created an evaluation framework based on feedback from clinicians and patient participants. This framework assessed history-taking, diagnostic accuracy, management, communication skills, and empathy. Liu et al [29] formulated a clinical pathway specific to LLMs and evaluated clinical capability using 6 indicators: information completeness, behavior standardization, guidance rationality, diagnostic logicality, treatment logicality, and clinical applicability. Johri et al [30] developed the CRAFT-MD (the Conversational Reasoning Assessment Framework for Testing in Medicine) framework to assess the ability of AI to lead clinical conversations, collect complete histories, and make accurate diagnostic decisions. Liu et al [31] proposed the CLEVER framework to evaluate performance in medical case comprehension, clinical reasoning, and diagnosis. Arora et al [32] introduced HealthBench to assess accuracy, completeness, communication quality, context awareness, and instruction following across diverse clinical tasks. Qiu et al [33] developed MedR-Bench to evaluate clinical reasoning in examination recommendations, diagnostic decisions, and treatment planning, and used efficiency, factual accuracy, and completeness as key indicators.

Although these frameworks have advanced the evaluation of clinical reasoning and diagnostic decision-making, their utility for assessing HCAI systems as real-world, user-facing products remains limited. A complete and systematic assessment structure is still lacking, particularly due to the gaps listed below.

First, most existing frameworks adopt a perspective centered on clinical-task performance, such as diagnostic accuracy and history-taking completeness. This approach, while crucial for medical validation, often overlooks the perspective of real-world product application. Specifically, it pays limited attention to user-experience factors such as emotional support, trust, and personalization [34]. These empathy-related features are important because interaction fluency, content clarity, personalized advice, and emotional support can directly influence users' health behaviors and consultation experiences, yet they are largely absent from most evaluation systems.

Second, existing frameworks often lack comprehensive dimensional integration. They tend to focus heavily on medical effectiveness, while insufficient attention has been paid to ethical and compliance-related requirements, such as bias, hallucinations, and protection of personal health data. This omission is inconsistent with current regulatory trends in many countries. For example, the European Union Medical Device Regulation [35] requires AI systems that support diagnosis, prognosis, or treatment, and that may affect clinical workflows, to meet requirements for performance reliability, risk management, cybersecurity, and traceability. A holistic framework that equally weights medical effectiveness, user experience, and ethical compliance is therefore essential.

Third, while some frameworks claim to address multiturn dialogue, they do not offer a systematic or operational methodology for evaluating quality and safety. They often fail to adequately assess context coherence and logical consistency across dialogue turns. These indicators are essential for distinguishing performance between single-turn medical questions and answers and multiturn medical dialogue tasks. Furthermore, by generally relying on descriptive criteria rather than weighted, hierarchical indicators, their practical utility for developers, evaluators, and regulators seeking standardized assessment is limited [22-27,29,30,34].

This lack of comprehensive indicators and balanced evaluation dimensions may result in inaccurate assessments of AI's practical effectiveness, thereby posing risks to patient safety, increasing technical burdens on systems, and creating barriers to the further development of HCAI. Therefore, a scientific scheme that holistically integrates content quality, user experience, and ethical compliance, and that provides an operational assessment structure, is urgently needed to overcome current bottlenecks in HCAI development.

Objectives

To address these gaps, this study develops a Quality Evaluation Index System for HCAI that offers 3 distinct contributions. First, it constructs the evaluation system from the perspective

of the end-user product application. Second, it comprehensively integrates medical effectiveness, user experience, and ethical and safety compliance. Third, it supports systematic and operational evaluation by combining Delphi consensus with the analytic hierarchy process (AHP) to provide weighted, hierarchical criteria. The objective is to establish a theoretical foundation and an operational framework for the evaluation of HCAI systems, thereby promoting their continuous improvement and ensuring their safe and effective deployment in health care settings.

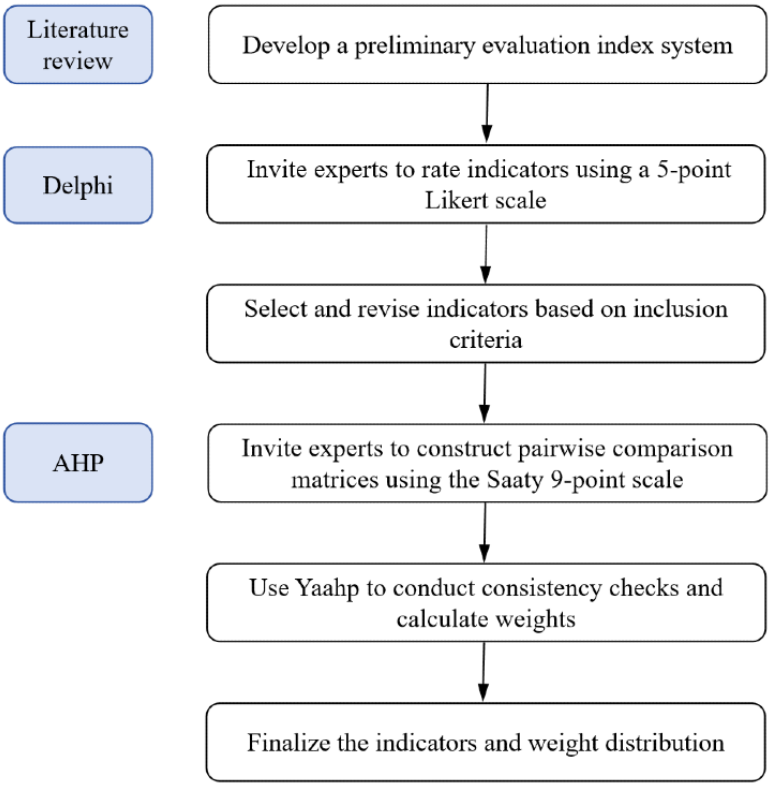
Methods

Study Design

This study adopts the Delphi method and the AHP as its research approach. The Delphi method, a structured technique for achieving expert consensus, is widely used for indicator selection and standard development in complex problem domains and has been extensively applied in areas such as health care quality assessment and policy research [36]. The AHP enables the assignment of weights to multiple indicators based on expert judgment and is particularly suitable for determining hierarchical structures and weight distributions in evaluation frameworks. These 2 methods are often used in combination and have been widely adopted in studies involving the development of evaluation index systems [37,38].

Between November 2024 and February 2025, this study conducted 2 rounds of expert consultation using the Delphi method. Each round of the questionnaire was distributed and collected via email or WeChat (a widely used social media platform in China), with a response period of 1 week. After collecting the expert scoring data, the AHP was applied to calculate the weights of each level of indicators. Based on these results, a quality evaluation index system for HCAI was established. The flowchart illustrating the process of indicator development and weight determination is shown in Figure 2.

Figure 2. Flowchart of the study design. AHP: analytic hierarchy process.



Establishment of a Research Team

The research team consisted of 7 members, including experienced experts in health management, professionals working in the HCAI industry, and graduate students specializing in health management. Among them, 2 held senior professional titles, 2 were HCAI practitioners, and 3 were graduate students. The team's main responsibilities included conducting a literature review, jointly developing preliminary evaluation indicators, identifying Delphi expert members, designing consultation questionnaires, analyzing expert feedback, and performing statistical analyses.

Development of the Preliminary Evaluation Index System

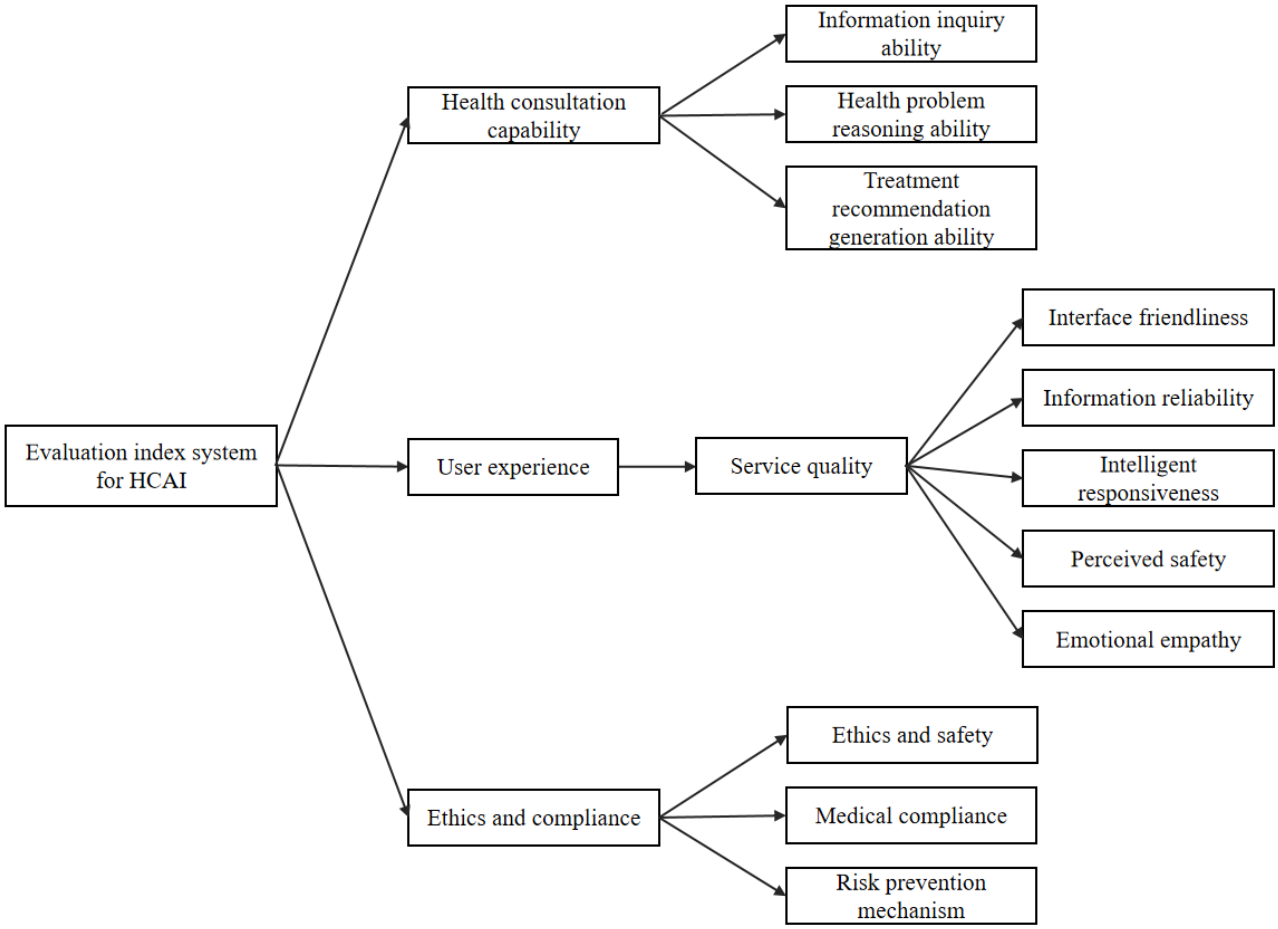
Drawing on a comprehensive review of the literature [30,34,39-42], relevant standards [43], and the expertise of the research team, a preliminary set of evaluation indicators was developed. In real-world applications, HCAI systems involve multiple stakeholders, including patients, health care professionals, and health regulators. As such, quality assessment should not be confined to a single dimension; rather, it must integrate multiperspective and multilevel considerations. Physicians, as service providers, focus on the system's ability to accurately understand user needs, collect complete and logically structured medical histories, perform precise clinical

reasoning, and deliver appropriate health recommendations. These aspects help determine whether HCAI can effectively support clinical practice. Patients, by contrast, place greater emphasis on the quality of interaction, the usefulness and usability of responses, and the system's capacity for emotional responsiveness. Meanwhile, health regulators are primarily concerned with ethical compliance, information security, and the controllability of risks associated with AI applications. These considerations are essential to ensuring that HCAI systems are used safely, effectively, and responsibly in patient care.

To address these considerations, this study developed an evaluation framework based on 3 key stakeholder groups: health care professionals, patients, and health regulators (Figure 3). The framework consists of 3 core dimensions: (1) health consultation capability for medical professionals, which focuses on evaluating the HCAI model's abilities in information elicitation, clinical reasoning, and treatment recommendation during the consultation process; (2) user experience for patients, which draws on the SERVQUAL service quality model [44,45]. This dimension assesses 5 aspects of HCAI: interface usability, information reliability, intelligent responsiveness, perceived safety, and emotional identification; and (3) ethics and compliance for health regulators, which focuses on the system's capacity for ethical safeguards, medical compliance, and risk prevention mechanisms.

The final preliminary evaluation index system comprises 3 primary indicators, 7 secondary indicators, and 34 tertiary indicators.

Figure 3. Preliminary evaluation index system. HCAI: health conversational artificial intelligence.



Design of the Expert Consultation Questionnaire

The expert consultation questionnaire consisted of 4 parts (Textbox 1).

The first- and second-round Delphi consultation questionnaires are provided in Multimedia Appendices 1 and 2, respectively. Both sets of questionnaires (Tables S4-S6 in Multimedia Appendices 1 and 2) present detailed evaluation methods, indicator definitions, and scoring rules for all tertiary-level indicators, providing guidance to support expert judgment during the evaluation process.

Textbox 1. Expert consultation questionnaire sections.

1. Questionnaire description

- This section included the research background, objectives, and the deadline for questionnaire submission.

2. Theoretical framework of the evaluation system

- This part outlined the design principles and rationale behind the proposed index system.

3. Instructions and evaluation form

- This section explained how to complete the evaluation form and provided detailed scoring criteria. The evaluation form contained specific indicator definitions, evaluation methods, rating tables, and a column for expert feedback. Experts were asked to rate each indicator in terms of importance, feasibility, and sensitivity using a 5-point Likert scale, and to provide suggestions for revision.
- Importance indicates the relevance of each item for assessing the quality of health conversational AI (HCAI) and is rated on a 5-point scale: 5=very important; 4=important; 3=moderately important; 2=slightly important; and 1=not important.
- Feasibility reflects the ease of collecting relevant data for each item during real-world assessment and is rated on a 5-point scale: 5=very easy; 4=relatively easy; 3=moderate; 2=relatively difficult; and 1=very difficult.
- Sensitivity reflects the extent to which each item influences assessment results, with higher sensitivity indicating a greater impact on HCAI performance and health care quality. It is rated on a 5-point scale: 5=very sensitive; 4=sensitive; 3=moderately sensitive; 2=slightly sensitive; and 1=not sensitive.

4. Expert background information

- This section collected personal information, including age, educational background, professional title, research field, and institutional affiliation. It also included self-assessments of the expert's familiarity with the indicators (Cs) and the basis for their judgment (Ca).

Expert Selection Method

According to the Delphi method, an appropriate number of experts ranges from 15 to 50 participants [46]. In this study, purposive sampling was used to invite experts in fields related to HCAI, including health management and policy, medical ethics, and computer science. The selection criteria for experts were as follows:

- Familiarity with health conversational AI and active engagement in related work, with strong theoretical and practical knowledge.
- A minimum of 5 years of professional experience.
- A postgraduate degree or higher, or a professional title of intermediate level or above.
- Demonstrated interest in the research topic and willingness to complete the consultation process and provide relevant feedback.

Experts were recruited through multiple channels, including previous research collaborations, recommendations from professional associations, and established industry expert databases. Before formal recruitment, the research team organized 2 HCAI expert consensus meetings to introduce the concept of HCAI and to explain the study's purpose, procedures, and evaluation methods. All potential participants received detailed study information and provided informed consent before joining the Delphi consultation.

Indicator Scoring and Selection Criteria

Scores for importance, feasibility, and sensitivity were assigned on a 5-point scale, with higher scores indicating greater relevance. Expert familiarity with the indicators was rated on a 5-level scale with values of 0.9, 0.7, 0.5, 0.3, and 0.1, corresponding to the categories very familiar, familiar, generally familiar, less familiar, and very unfamiliar, respectively. The basis of expert judgment consisted of 4 components: work experience, theoretical analysis, industry understanding, and intuitive perception. The weights for work experience were 0.5, 0.4, and 0.3 for high, medium, and low influence, respectively. The weights for theoretical analysis were 0.3, 0.2, and 0.1 for the same levels. Both industry understanding and intuitive perception were assigned fixed weights of 0.1 [47].

Based on experts' scores for each indicator in terms of importance, feasibility, and sensitivity, the mean, SD, and coefficient of variation (CV) were calculated. The inclusion criteria were a mean score of 3.50 or higher and a CV of less than 0.25 [48,49]. To avoid prematurely excluding potentially important indicators, expert feedback and group discussions were carefully considered before making final decisions.

Key Coefficients and Calculation Methods

Active Coefficient of Experts

This was measured by the effective response rate of the questionnaires, calculated as the number of valid responses in a given round divided by the number of questionnaires distributed. A higher response rate indicates greater expert engagement and interest in the topic.

Expert Authority Coefficient

This reflects the degree of authority an expert holds on the research topic. It is calculated as the average of the expert's Ca (ie, the basis for their judgment) and Cs (ie, their familiarity) values, that is, Cr = (Ca + Cs)/2, where Cr is the expert authority coefficient. A Cr value of 0.7 or higher is generally considered to indicate a high level of authority and reliability [50].

Coordination of Expert Opinions

This was measured using the Kendall coefficient of concordance (Kendall *W*), which reflects the consistency of expert ratings. A value closer to 1 indicates a higher degree of agreement among the experts [38].

Weight Determination of Each Indicator

After finalizing the evaluation index system, experts conducted pairwise comparisons of the indicators based on the Saaty scale of relative importance (see Table 1) [51]. These comparisons were used to construct a hierarchical structure and establish judgment matrices. The weights of each indicator were then calculated using AHP via Yaahp (an AHP-based decision-support software developed by Shanxi Yuan Decision Software Technology Co Ltd), and the results were analyzed accordingly. The consistency of each judgment matrix was tested using the consistency ratio. A consistency ratio value of less than 0.1 was considered to indicate acceptable consistency [52].

Table 1. The Saaty scale of relative importance.

Scale	Meaning
1	Indicates equal importance between 2 elements
3	Indicates moderate importance of 1 element over another
5	Indicates moderate to strong importance
7	Indicates very strong importance
9	Indicates extreme importance
2, 4, 6, and 8	Intermediate values between the above judgments
Reciprocals	If item A is assigned a value when compared with item B, then item B is assigned the reciprocal value when compared with item A

Statistical Methods

In this study, Microsoft Excel 2007 was used to input data and calculate the mean, SD, and CV for the importance, feasibility, and sensitivity of each indicator. Excel was also used to compute the expert active coefficient, Ca, Cs, and Cr. Kendall *W* was calculated using SPSS version 25.0 (IBM Corp) and tested for significance using the chi-square test. When the *P* value of Kendall *W* was less than 0.05, and all CVs were below 0.25, the level of disagreement among expert opinions was considered acceptable [53]. The Yaahp version 12.0 software was used to conduct consistency testing of the judgment matrices and to calculate the weights of each indicator.

Ethics Considerations

This study was reviewed and approved by the Ethics Committee of Capital Medical University (approval number Z2024SY075). The approved project title is “Evaluation of the Quality and Effectiveness of User-Oriented AI Health Consultation Services.” All study procedures were conducted in accordance with institutional guidelines and regulations and complied with the principles of the Declaration of Helsinki. Expert participants in the Delphi process were informed of the study’s purpose and provided consent before participation. No identifiable personal information of the expert participants was disclosed in this study. Participant privacy was fully protected.

Results

Basic Information About Experts

Two rounds of expert consultation were conducted in this study. Based on predefined criteria, 16 experts were invited for the first round and 15 for the second round, with 1 expert failing to respond in the second round. Among the 15 experts who completed both rounds, 5 (33%) were male and 10 (67%) were female; 9 of the 15 (60%) experts were over 40 years old. As many as 14 of 15 (93%) experts held a master’s degree or higher, and the same percentage held professional titles at the associate senior level or above. Additionally, 12 of 15 (80%) experts had more than 10 years of work experience in the health care field. The experts were evenly distributed across hospitals, universities, and research institutions. Detailed information is presented in Table 2.

Table 2. Basic information about experts.

Basic information	First round (n=16), n (%)	Second round (n=15), n (%)
Sex		
Male	6 (38)	5 (33)
Female	10 (63)	10 (67)
Age (years)		
≤40	6 (38)	6 (40)
41-50	9 (56)	9 (60)
>50	1 (6)	0 (0)
Education		
Undergraduate	1 (6)	1 (7)
Master	5 (31)	4 (27)
Doctor	10 (63)	10 (67)
Professional title		
Intermediate	1 (6)	1 (7)
Deputy senior	7 (44)	7 (47)
Senior	8 (50)	7 (47)
Years of work experience		
≤10	3 (19)	3 (20)
11-15	4 (25)	4 (27)
16-20	5 (31)	5 (33)
>20	4 (25)	3 (20)
Affiliation		
Medical institution	4 (25)	4 (27)
University	6 (38)	5 (33)
Research institute	5 (31)	5 (33)
Association	1 (6)	1 (7)
Research field		
Health management and policy	7 (44)	7 (47)
Computer science	1 (6)	1 (7)
Medical ethics	1 (6)	1 (7)
Health law	2 (13)	2 (13)
Hospital management	2 (13)	2 (13)
Others	3 (19)	2 (13)

Expert Positivity Degree

According to the Delphi method, a response rate of 50% is considered the minimum threshold for analysis and reporting, while a rate above 70% indicates a high level of expert engagement [54]. In the first round, the expert response rate was 100%, with 11 experts providing a total of 33 suggestions. In the second round, the response rate was also 100%, and 5 experts submitted 6 suggestions. The response rate exceeded 70% in both rounds, indicating a high level of participation and engagement from the expert panel throughout the study.

Expert Authority Coefficient

The authority coefficients of the 2 rounds of expert consultation are shown in Table 3. In the first round, Ca was 0.92, Cs was 0.75, and the resulting Cr was 0.84. In the second round, Ca was 0.93, Cs remained 0.75, and Cr was also 0.84. In both rounds, the Cr values exceeded 0.8, indicating that the experts consulted in this study demonstrated a high level of authority and reliability.

Table 3. Authority coefficients in the 2 rounds of consultation.

Inquiry round	Number	Ca[a]	Cs[b]	Cr[c]
First round	16	0.92	0.75	0.84
Second round	15	0.93	0.75	0.84

[a]Ca: the basis for the expert's judgment.

[b]Cs: expert familiarity.

[c]Cr: expert authority coefficient.

Degree of Coordination of Expert Opinions

The degree of coordination among expert opinions refers to the level of consistency in the experts' ratings of each indicator. The Kendall (*W*) coefficients for the 2 rounds of expert consultation are presented in Table 4. In the first round, Kendall *W* values for all indicators ranged from 0.14 to 0.20. In the second round, the values ranged from 0.13 to 0.17. The results of the chi-square tests were statistically significant (round 1: importance, *P*<.001; feasibility, *P*<.001; and sensitivity, *P*<.001; round 2: importance, *P*=.001; feasibility, *P*<.001; and sensitivity, *P*=.001), indicating a high level of agreement among the expert opinions.

Table 4. Kendall W coefficients for the 2 rounds of consultation.

Project	Importance	Feasibility	Sensitivity
Round one			
Kendall *W*	0.20	0.14	0.14
Chi-square (*df*)	124.39 (42)	86.38 (42)	88.20 (42)
P value	<.001	<.001	<.001
Round 2			
Kendall *W*	0.13	0.17	0.13
Chi-square (*df*)	66.77 (36)	85.05 (36)	67.66 (36)
P value	.001	<.001	.001

Revisions to the Indicator System

The results of the first-round expert consultation are presented in Table 5. The mean scores of all 44 indicators were equal to or greater than 3.50. Specifically, the mean scores ranged from 4.20 to 5.00 for importance, 3.75 to 4.88 for feasibility, and 3.88 to 4.88 for sensitivity. The CVs ranged from 0.00 to 0.27, with 6 indicators having CV values equal to or greater than 0.25.

Based on the screening criteria and expert suggestions, the research team held detailed discussions and decided to temporarily retain the 6 indicators with CV values ≥0.25, remove 7 indicators, revise 4 indicators, and add 1 new indicator. Details of these revisions are provided in Table 6.

After these adjustments, the second-round consultation form consisted of 3 primary indicators, 7 secondary indicators, and 28 tertiary indicators.

The results of the second-round expert consultation are shown in Table 7. The mean scores for importance, feasibility, and sensitivity of all indicators were above 4.0, and all CVs were below 0.25. Based on the indicator selection criteria and thorough discussions among the expert panel, all 37 indicators in the second-round consultation were retained. In addition, the name of indicator C1 was revised from "ethics" to "ethical compliance." The final quality evaluation index system for health conversational AI was thus established, comprising 3 primary indicators, 7 secondary indicators, and 28 tertiary indicators (Table 8).

Table 5. Scores of indicators in the first round of consultation.

Indicators	Importance		Feasibility		Sensitivity	
	Mean (SD)	CV[a]	Mean (SD)	CV	Mean	CV
First-level indices						
A. Health consultation capability	4.94 (0.25)	0.05	4.19 (0.75)	0.18	4.75 (0.45)	0.09
B. User experience	4.50 (0.63)	0.14	4.63 (0.62)	0.13	4.44 (0.63)	0.14
C. Ethics and compliance	5.00 (0.00)	0.00	4.13 (1.02)	0.25	3.88 (0.81)	0.21
Second-level indices						
A1. Information inquiry ability	4.81 (0.40)	0.08	4.19 (0.75)	0.18	4.69 (0.60)	0.13
A2. Health problem reasoning ability	4.81 (0.40)	0.08	3.75 (0.77)	0.21	4.69 (0.48)	0.10
A3. Treatment recommendation generation ability	4.75 (0.58)	0.12	4.19 (0.75)	0.18	4.69 (0.70)	0.15
B1. Service quality experience	4.50 (0.63)	0.14	4.63 (0.62)	0.13	4.44 (0.63)	0.14
C1. Ethics and safety	4.94 (0.25)	0.05	3.81 (1.05)	0.27	4.31 (0.79)	0.18
C2. Medical compliance	5.00 (0.00)	0.00	4.13 (1.09)	0.26	4.38 (0.72)	0.16
C3. Risk prevention mechanisms	4.75 (0.58)	0.12	4.13 (1.02)	0.25	4.44 (0.81)	0.18
Third-level indices						
A11. Accuracy in understanding user needs	4.94 (0.25)	0.05	4.50 (0.52)	0.11	4.81 (0.40)	0.08
A12. Completeness of user information collection	4.44 (0.51)	0.12	4.19 (0.66)	0.16	4.31 (0.60)	0.14
A13. Relevance of inquiry content	4.63 (0.50)	0.11	4.19 (0.75)	0.18	4.69 (0.48)	0.10
A14. Logical sequence of inquiries	4.25 (0.68)	0.16	4.38 (0.89)	0.20	4.31 (0.60)	0.14
A15. Appropriateness of interaction rounds	4.31 (0.60)	0.14	4.19 (0.75)	0.18	4.00 (0.89)	0.22
A16. Recognition ability of multimodal information	4.63 (0.50)	0.11	4.56 (0.63)	0.14	4.50 (0.63)	0.14
A17. Personalization of communication style	4.63 (0.62)	0.13	4.31 (0.60)	0.14	4.38 (0.72)	0.16
A21. Accuracy of disease risk reasoning	4.94 (0.25)	0.05	4.44 (0.63)	0.14	4.88 (0.34)	0.07
A22. Consistency of repeated judgments	4.75 (0.45)	0.09	4.44 (0.73)	0.16	4.38 (0.62)	0.14
A23. Coverage of consulted diseases	4.25 (0.68)	0.16	4.38 (0.81)	0.18	4.19 (0.75)	0.18
A24. Diagnostic ability for complex diseases	4.20 (0.86)	0.21	3.80 (0.77)	0.20	4.20 (0.86)	0.21
A25. Professional use of medical terminology	4.25 (0.86)	0.20	4.44 (0.73)	0.16	4.19 (0.75)	0.18
A26. Frequency of medical knowledge updates	4.31 (0.79)	0.18	4.06 (1.00)	0.25	4.06 (0.93)	0.23
A27. Interpretability of disease reasoning	4.63 (0.72)	0.16	4.25 (0.68)	0.16	4.25 (0.77)	0.18
A31. Accuracy of treatment recommendations	4.88 (0.34)	0.07	4.44 (0.89)	0.20	4.75 (0.58)	0.12
A32. Comprehensiveness of treatment recommendations	4.56 (0.63)	0.14	4.38 (0.62)	0.14	4.44 (0.73)	0.16
A33. Personalization of treatment recommendations	4.56 (0.63)	0.14	4.13 (0.62)	0.15	4.44 (0.73)	0.16
A34. Operability of treatment recommendations	4.44 (0.63)	0.14	4.25 (0.77)	0.18	4.31 (0.79)	0.18
B11. Interface friendliness	4.25 (0.77)	0.18	4.63 (0.50)	0.11	4.25 (0.77)	0.18
B12. Information reliability	4.94 (0.25)	0.05	4.44 (0.73)	0.16	4.63 (0.62)	0.13
B13. Intelligent responsiveness	4.44 (0.63)	0.14	4.56 (0.73)	0.16	4.63 (0.50)	0.11
B14. Perceived safety	4.63 (0.62)	0.13	4.31 (0.70)	0.16	4.19 (0.66)	0.16
B15. Emotional empathy	4.44 (0.63)	0.14	4.00 (0.82)	0.20	4.25 (0.68)	0.16
C11. Bias	4.75 (0.45)	0.09	4.25 (0.68)	0.16	4.38 (0.72)	0.16
C12. Privacy	4.88 (0.34)	0.07	4.31 (0.79)	0.18	4.56 (0.63)	0.14
C13. Hallucinations	4.69 (0.48)	0.10	4.13 (0.62)	0.15	4.50 (0.73)	0.16
C14. Data and system security	4.94 (0.25)	0.05	4.19 (0.66)	0.16	4.50 (0.73)	0.16
C15. Establishment of ethics committee	4.56 (0.73)	0.16	4.44 (1.15)	0.26	4.31 (0.87)	0.20

Indicators	Importance		Feasibility		Sensitivity	
	Mean (SD)	CV[a]	Mean (SD)	CV	Mean	CV
C21. Presence of a disclaimer notices	4.69 (0.60)	0.13	4.88 (0.34)	0.07	4.25 (0.77)	0.18
C22. Assessment of treatment risks	4.94 (0.25)	0.05	4.44 (0.51)	0.12	4.75 (0.58)	0.12

[a]CV: coefficient of variation.

Table 6. Revisions to indicators based on the first round of consultation.

Indicators	Action	Explanation
1. Ethics and compliance	Retained	The CV[a] value for feasibility is ≥0.25. It is recommended to decide whether to retain it based on the results of the second round of consultation.
C1. Ethics and safety	Retained	The CV value for feasibility is ≥0.25. It is recommended to decide whether to retain it based on the results of the second round of consultation.
C2. Medical compliance	Retained	The CV value for feasibility is ≥0.25. It is recommended to decide whether to retain it based on the results of the second round of consultation.
C3. Risk prevention mechanism	Retained	The CV value for feasibility is ≥0.25. It is recommended to decide whether to retain it based on the results of the second round of consultation.
A1. Information inquiry ability	Modified	Renamed to “Health Information Inquiry Ability” for better accuracy.
C1. Ethics and safety	Modified	Renamed to “Ethics” for better accuracy.
A13. Relevance of inquiry content	Deleted	Poor feasibility based on evaluation criteria.
A15. Rationality of interaction rounds	Deleted	Poor feasibility based on evaluation criteria.
A23. Coverage of consulted diseases	Deleted	Low importance and sensitivity.
A24. Diagnostic ability for complex diseases	Retained	Some experts noted overlap with A21 “Accuracy of disease reasoning,” but reasoning for complex diseases provides distinct model evaluation value.
A25. Use of medical terminology	Deleted	Overlaps with A31 “Accuracy of treatment recommendations.”
A26. Frequency of medical knowledge update	Retained	The CV value for feasibility is ≥0.25. It is recommended to decide whether to retain it based on the results of the second round of consultation.
A33. Personalization of treatment advice	Deleted	Low evaluation value under C3 “Risk prevention mechanism.”
B12. Information reliability	Modified	Renamed to “Perceived reliability” for better accuracy.
B13. Intelligent responsiveness	Modified	Renamed to “Perceived responsiveness” for better accuracy.
C14. Data and system security	Deleted	Belongs to model-level indicators, not a primary assessment focus.
C15. Establishment of ethics committee	Retained	The CV value for feasibility is ≥0.25. It is recommended to decide whether to retain it based on the results of the second round of consultation.
C22. Assessment of treatment risks	Deleted	Overlaps with evaluation under A2 “Health problem reasoning ability.”
C24. Violation of medical compliance	Retained	Some experts believe that this indicator belongs to the model admission criteria and suggest deleting it. However, this mainly evaluates the low-risk violations that may exist in the model and has evaluation value
C33. Presence of privacy terms	Added	The risk prevention mechanism should include detailed privacy clauses to clarify the purpose and scope of collecting user information, as well as whether the collected information is shared with third parties

C32. Access management for minors	0.0362
C33. Presence of privacy terms	0.0185

Weight Determination of Each Indicator

The AHP was used to calculate the weights of each indicator, with higher weights indicating greater importance in evaluating the quality of health conversational AI. In this study, all consistency ratio values of the judgment matrices were automatically adjusted using Yaahp and were found to be less than 0.10, indicating good consistency across all matrices.

The final weight coefficients of all indicators are shown in Table 8. Among the primary indicators, the ranking by weight from highest to lowest was as follows: ethics and compliance (0.4781), health consultation capability (0.4112), and user experience (0.1107).

Discussion

Principal Findings

As AI becomes increasingly integrated into health care, HCAI is being used more widely in health communication, clinical decision support, and consultation. Establishing a scientific and systematic quality evaluation framework is therefore essential. Although several evaluation systems have been developed, many still focus primarily on accuracy or clinician-oriented indicators, neglecting critical aspects of real-world product use and comprehensive safety assessment. They pay limited attention to the comprehensive integration of user experience, ethical and compliance considerations, and the robust assessment of multiturn interactions, all of which are essential for HCAI in real consultation settings. Addressing these gaps is critical for improving the quality, safety, and effectiveness of HCAI.

This study employs the Delphi method and AHP to develop an evaluation index system that reflects the perspectives of physicians, users, and regulators, and makes 3 key contributions addressing the limitations of prior work. First, our system is constructed from the perspective of HCAI as an end-user product for daily health consultation, rather than focusing solely on clinical-task performance. Second, it encompasses 3 core, balanced dimensions: health consultation capability, user experience, and ethics and compliance. Third, by using the AHP methodology, the framework supports systematic and operational evaluation through weighted, hierarchical criteria. By addressing these dimensions and the shortcomings of existing frameworks, the proposed system provides a more comprehensive structure that aligns with the real-world needs of HCAI services. The framework provides a theoretical foundation for empirical research, guides practical optimization, and serves as a valuable reference for improving HCAI evaluation standards worldwide.

Scientific Validity and Rationality of the Evaluation Index System

The final evaluation index system developed in this study comprises 3 primary indicators, 7 secondary indicators, and 28 tertiary indicators. Its structure is comprehensive and well-organized, demonstrating both scientific rigor and practical relevance.

First, the design of the index system was grounded in existing literature, industry standards, and expert consensus. It incorporated both domestic and international approaches to HCAI evaluation, ensuring a solid theoretical foundation and methodological relevance.

Second, the study employed 2 rounds of Delphi expert consultation, combined with AHP for weight assignment, integrating both qualitative judgment and quantitative analysis. Expert opinions showed increasing convergence across rounds, with statistically significant coordination coefficients, indicating a high level of consensus and enhancing the credibility of the evaluation system.

Third, the experts involved in the study were highly representative across disciplines, including health management and policy, medical ethics, computer science, health law, and hospital administration. The panel comprised both academic researchers and experienced practitioners, ensuring a balance of theoretical insight and practical expertise. This interdisciplinary and diverse expert composition enhanced the scientific validity of the evaluation system and conformed to established Delphi methodology standards for expert selection and quality assurance [55,56].

Finally, the experts demonstrated high levels of engagement, authority, and consistency throughout the process, significantly enhancing the reliability of the study's findings [57]. Both rounds of the Delphi consultation achieved a 100% response rate (16 and 15 experts in rounds 1 and 2, respectively), with a total of 39 modification suggestions proposed, reflecting active participation and strong interest from the expert panel. The Cr values in both rounds exceeded 0.8, confirming the reliability of expert judgments. Additionally, the *P* values of Kendall *W* were all below 0.05, indicating a high level of agreement in weight assessments and providing a solid foundation for the reliability of the constructed index system.

Analysis of Indicator Weights

The weights of the 3 primary indicators are shown in Table 8: ethics and compliance (0.4781), health consultation capability (0.4112), and user experience (0.1107). These results indicate that ethics and compliance carries the greatest weight in the quality evaluation of HCAI, underscoring its importance as a key dimension for building safe and trustworthy AI systems.

Health consultation capability, which reflects the AI's professional value and its ability to deliver knowledge-based services, also accounts for a substantial proportion of the overall weight. By contrast, user experience carries a relatively lower weight. This may be because current HCAI products and applications are still in the early stages of development, leading experts to prioritize system safety, compliance, and functionality during the evaluation process, while user interaction is considered a secondary factor.

At present, many HCAI systems face significant risks related to algorithmic bias, data privacy breaches, hallucinations, and lack of medical compliance [58-60]. These risks are closely associated with the ethics and compliance dimension of the evaluation system. Among the tertiary indicators in this study, several related to ethical and safety concerns received relatively high weight values, including "generation of factually incorrect information" (0.0889), "hallucination" (0.0697), "violation of

medical compliance" (0.0646), and "emergency response mechanisms" (0.0605). These results indicate that truthfulness, safety, and regulatory compliance of AI-generated content are critical components in assessing the quality of HCAI. In clinical settings, inaccurate recommendations or breaches of patient privacy can have serious consequences and must be addressed as a priority. This finding aligns with concerns raised by other researchers. For instance, some studies have reported that AI in health care may generate hallucinations—that is, inaccurate or fabricated content that could compromise clinical decision-making and patient safety [61]. Wang et al [62] also noted that LLMs may not achieve complete deidentification of training data, thereby raising the risk of exposing sensitive user information.

Within the health consultation capability dimension, the highest weight was assigned to "treatment recommendation generation ability" (0.2019). Among its tertiary indicators, "accuracy of treatment recommendations" (0.1216) and "comprehensiveness of treatment recommendations" (0.0562) were assigned relatively high weights. This indicates strong expert attention to whether AI systems can accurately assess users' health conditions and provide reliable and helpful advice. These findings are highly consistent with previous studies by Lukac et al [63] and Liu et al [64], both of whom emphasized the importance of AI's ability to generate dependable treatment recommendations. In addition, the tertiary indicator "accuracy in understanding user needs" (0.0648), under the category of "health information elicitation ability," and "accuracy of disease reasoning" (0.0389), under "health problem reasoning ability," also received relatively high weights. This suggests that, at the current stage, experts continue to view AI's capabilities in understanding user intent and providing accurate reasoning as important considerations.

In comparison, although the user experience dimension received a relatively lower overall weight, certain indicators, such as "perceived reliability" (0.0456) and "perceived safety" (0.0336), still accounted for a meaningful proportion. This reflects the significant impact of users' perceived trust in AI systems on actual usage experiences. Previous studies have shown that trust is one of the key determinants influencing users' acceptance and use of conversational AI tools such as ChatGPT [65]. In the health care context, user trust in AI technologies is also considered a critical factor affecting their broader adoption and application [66]. Moreover, some studies have found that, compared with traditional information channels such as online health websites, HCAI systems are better positioned to meet users' needs for immediacy and convenience during health information-seeking. This is largely due to their ability to engage in real-time interaction and provide personalized responses [67]. These findings further suggest that, in the ongoing optimization of HCAI, user experience should not only be regarded as a key factor influencing technology acceptance but also as a critical lever for enhancing system usability and fostering trust between humans and machines.

Policy Recommendations

In summary, the development of HCAI remains at an early stage. Ethics and compliance has emerged as the most critical evaluation dimension, while health consultation capability serves as the core functional foundation. Although user experience holds a relatively lower weight, it still plays a significant role in promoting the adoption and practical application of HCAI systems. To further advance the development of HCAI, this study proposes the following policy recommendations:

First, regulatory authorities around the world have imposed increasingly stringent requirements on HCAI-related products. For example, the European Union's Artificial Intelligence Act [68] mandates a comprehensive regulatory framework for high-risk AI systems, including those used in health care, covering both premarket and postmarket phases [68]. Singapore's Model AI Governance Framework for Generative AI emphasizes the importance of continuous evaluation and improvement across the entire life cycle of AI systems [69]. Similarly, China's Interim Measures for the Management of Generative Artificial Intelligence Services clearly stipulate dynamic supervision and safety monitoring of AI products after their deployment [70]. In light of this, it is recommended that the evaluation index system developed in this study be used as the basis for establishing a full–life cycle quality assessment mechanism for HCAI. This mechanism should encompass product development, testing, deployment, and application. Furthermore, efforts should be made to promote its transformation into a widely accepted industry framework through supportive policy initiatives. Such an approach would facilitate the regular evaluation of HCAI products and enable dynamic supervision and continuous quality improvement.

Second, the performance of HCAI systems should be continuously optimized across 3 key dimensions: model capability, ethics and compliance, and user experience. In terms of model capability, targeted training and fine-tuning should be conducted on tasks such as health information elicitation, disease diagnosis, and treatment recommendation to improve the system's medical professionalism and response accuracy. For ethical and safety considerations, it is necessary to establish a regulatory framework that covers data processing, model outputs, and information usage. This framework should clearly define accountability and responsibility in high-risk scenarios and include mechanisms to prevent misinformation and breaches of privacy. Regarding user experience, improvements should focus on core indicators such as "perceived safety" and "perceived reliability." This can be achieved by refining language logic, setting boundary warnings, incorporating source attribution, and integrating human-in-the-loop mechanisms. These measures are essential to enhance user understanding of, and trust in, the system.

Finally, HCAI is expected to move beyond the constraints of online consultation platforms and mobile apps. By helping users recognize their own health conditions, understand disease-related knowledge, and enhance early screening, diagnosis, and treatment, HCAI has the potential to improve health literacy and overall well-being. It may thus become a convenient and trustworthy health gatekeeper for the public. HCAI can also be integrated with health care service institutions and medical consortia to support the accuracy and feasibility of hierarchical diagnosis and treatment systems. To promote the effective application of HCAI in diverse scenarios, such as

self-assessment and diagnosis, intelligent triage, chronic disease follow-up, and care of older adults, it is necessary to adjust the structure and weight allocation of existing evaluation frameworks. Capability indicators should be refined based on the characteristics of specific tasks, with a particular focus on the model's adaptability and service effectiveness across different use cases. These efforts will help strengthen the professional performance of HCAI systems in multiple contexts and enhance the overall level of intelligent health care services.

Strengths and Limitations of Research

Unlike most previous expert consultation studies, this research assessed not only the importance of each indicator but also its sensitivity and feasibility, thereby enhancing the practicality of the constructed evaluation index system [71]. The findings of this study help address a critical gap in the evaluation of HCAI quality. The developed index system can be applied to assess the service quality of existing HCAI systems, identify weaknesses in consultation capability, user experience, ethics and compliance, and provide theoretical support for future product optimization and model iteration. This contributes to the standardized and high-quality development of HCAI. Furthermore, the evaluation system may serve as a reference for industry regulation. It offers a quantitative tool for government agencies, technology platforms, and health care providers to establish standards, identify risks, and improve service quality.

This study has several limitations. First, the expert panel consisted of 15-16 professionals from China. Although the panel was selected to ensure domain expertise, the limited sample size and geographic scope may affect the diversity and generalizability of perspectives. Future research should consider expanding the pool of experts to enhance the authority and generalizability of the conclusions. Second, although this study proposed a structured and multidimensional evaluation framework for HCAI, its practical utility has not yet been validated in real-world settings. While detailed assessment criteria for each third-level indicator are provided in Multimedia Appendix 2, further refinement of operational thresholds and performance benchmarks will be needed to support practical application. Additional empirical validation is required to assess the framework's applicability and adaptability across different scenarios.

Conclusions

This study developed a quality evaluation index system for HCAI, consisting of 3 primary indicators, 7 secondary indicators, and 28 tertiary indicators. Expert scoring results indicated that the dimension of "ethics and compliance" had the highest weight, followed by "health consultation capability." This suggests that, when evaluating the quality of health-related AI systems, priority should be given to information security, medical compliance, and risk management. The study combined the Delphi method with the AHP to ensure the scientific validity of the evaluation indicators and the rationality of their weight distribution. The proposed evaluation framework provides a theoretical reference for the assessment and optimization of HCAI systems.

Acknowledgments

The authors used the generative artificial intelligence tool ChatGPT (OpenAI) during the translation and manuscript refinement stages. This tool was used solely to assist with language polishing. All analytic decisions, study design choices, and interpretation of findings were made entirely by the authors. The authors critically reviewed and verified all outputs generated by the tool and fully accept responsibility for the final content of this manuscript.

Data Availability

The data that support the findings of this study are available from the authors; however, restrictions apply to their availability, as the data were used under license from the experts involved in the Delphi survey for this study and are therefore not publicly available. The data are, however, available from the authors upon reasonable request and with permission from these experts.

Funding

This study was funded by the National Social Science Foundation of China (grant 24BGL273).

Authors' Contributions

All authors contributed to the interpretation of the findings and the writing of the manuscript and have approved the final version. WL was responsible for the statistical analysis and editorial writing; ML and HL were responsible for data cleaning; CM and YH were responsible for the design, review, and revision of the article. CM and YH contributed equally to the research and manuscript preparation and are considered co-corresponding authors. DW, YW, ZF, HW, and YG were responsible for data acquisition and interpretation.

Abstract

Background: Assistive robotics for helping older people live well and stay independent has, to date, failed to fulfill its promise: there are few assistive robots in everyday use. In part, this failing can be attributed to inadequate or missing co-design activities that would ensure that these technologies and any services that incorporate them are developed with prospective end users, addressing their actual needs and wants, and not merely for them, and based on lazy assumptions about heterogeneous user groups.

Objective: This exercise aimed to address some of these limitations by taking a "phenomenological snapshot" of what it means to be an older person in the current sociotechnological context, and making this snapshot, along with the co-design materials developed, available to the wider assistive robotics community to provide solid foundational evidence for steering the development of assistive robotics in more productive directions.

Methods: Two rounds of co-design workshops have been conducted with older people and their caregivers, based on an innovative methodology that used personas and speculative designs to explore sensitive everyday difficulties faced by participants and highlight some of their general wishes for and concerns about assistive robotics. The data collected during the workshops were analyzed, and key themes were extracted.

Results: Analysis of the workshop data gives access to the lived experience of older people and their caregivers, and their opinions about domestic robotics and assistive technologies more generally. The findings are organized thematically as *everyday difficulties*, the daily problems faced by older people; *ideas for aging better*, older people's own suggestions for how their lives could be improved; and *living with technology*, their preferences and requirements for assistive robots, along with their concerns about what the introduction of robots might mean, both for themselves and for society more widely.

Conclusions: We believe that our findings provide solid foundational evidence for the development of assistive robotics for older people. We are in the process of disseminating these results through various channels to the wider assistive robotics community; ultimately, the success of our activities will be demonstrated only through the development of acceptable, useful, and viable assistive robotics for older people.

Introduction

Emergence Network

Emergence is a UK-wide initiative created to foster innovation in the field of assistive robotics for older people, especially people living with frailty, and to facilitate the "emergence" of robots from research laboratories into service. The network is coordinated by a team of academic researchers and, in addition to other academic partners, members include health, social care, and housing providers, regulators, and robotics industry representatives, who provide clinical focus and business acumen to anchor its activities. The network was launched in early 2022 and is led by the University of Nottingham, with the support of coinvestigators from Heriot-Watt University, the University of Hertfordshire, the University of Sheffield, and Sheffield Hallam University.

More specifically, the objectives of Emergence are to promote the development of domestic assistive robotics that will improve the quality of life and independence of older people by enabling better self-management of frailty and age-related issues, by helping with activities of daily living, by assisting rehabilitation activities, and by supporting health care professionals to make tailored interventions to slow decline or to improve resilience. The primary impetus behind the establishment of the network was the observation that, despite the undoubted effort and resources that had been directed at the task, few assistive robots for older people are in general use (see, for example, the book by Wright [1]). Plausible factors that may have contributed to this include a poor appreciation of the needs and wants of older people, of the wider psychological, social, and clinical considerations, and of the challenges and practicalities of operation in noisy real-world domestic environments.

One fundamental pillar of the Emergence network is the proposition that this general lack of understanding of use contexts can be addressed through a rigorous and ongoing co-design exercise involving people from the target user groups, with the results of this exercise guiding assistive robotics development.

Frailty

Frailty is "a common clinical syndrome in older adults that carries an increased risk for poor health outcomes, including falls, incident disability, hospitalization, and mortality" [2]. It is characterized by the "loss of biological reserves across multiple organ systems," leading to clinical vulnerability to stressful episodes [3]. While it is not an inevitable consequence of aging, frailty is common among older people, and its extent and severity can vary significantly from individual to individual. Many older people who live with a health condition (or with multimorbidity) or with a disability will also be living with frailty: the one can contribute to or exacerbate the other. It can affect a person's physical and cognitive abilities, to the detriment of their wider health and well-being, and can limit their day-to-day functioning [4]. Frailty, when it does occur, is not a static condition: it can become worse, but there is evidence to suggest that, with the right interventions, it can be reversed to some extent [3].

When it comes to characterizing frailty, there are currently 2 dominant models [5]. The "(cumulative) deficit model" of frailty [6,7] assumes that frailty derives from an accumulation of "deficits" (which might be disabilities, health conditions, or psychosocial factors) that, individually and cumulatively, increase a person's vulnerability to stressful events. The second prevailing model is the "phenotype model" of frailty, in which an individual who manifests at least 3 of a set of 5 criteria for frailty (weight loss, low physical activity, exhaustion, slow walking speed, and physical weakness) is considered to be frail [4].

These models have their uses when considering whether an individual, in a health or care context, might require additional support or could benefit from some remedial intervention. However, they are less useful when it comes to understanding people's lived experience of frailty—and, by extension, for developing practical assistive technologies, including robotics, to support people living with the condition. The impact of deficits or of physical manifestations will vary from person to person, depending on their living circumstances, their tastes, their responsibilities and roles, and their hobbies and interests. Hence, while both the deficit model and the phenotype model can provide suggestions of where assistance might be needed, they also promote a narrow (and negative) view of people with frailty as deficient, a view that excludes a more rounded consideration of their lives that acknowledges their abilities (see the study by Lang et al [8]).

To take an example, clinical tests might reveal a loss of grip strength. The everyday impact of this on an individual might be felt in their inability to open jars of their favorite food (which might then have the knock-on effect of reducing the amount they are eating, leading to weight loss). Whereas the clinical model might suggest more-or-less generic remedial strength exercises—that is, focusing on the deficit or symptom and "treating" it—a more complete understanding of the individual's experience opens up the design space to suggest other, perhaps complementary, approaches encompassing the technological (a jar-opening robot), the environmental (redesigned food packaging), the social (a personalized meal delivery service), and so on. Any of these "interventions," or perhaps some combination of them, might be more acceptable to, appropriate—and, ultimately, effective—for the individual in question. The goal of the research reported in this paper is to provide a co-design counterbalance to the prevalent clinical models in the form of a snapshot of the lived experience of older people, one that encompasses their views of the digital world and, especially, robotics.

Assistive Robotics for Healthy Aging

Assistive robotics could help older people living with frailty, long-term health conditions, and disabilities to live more independent, more dignified, and more fulfilling lives. Moreover, services incorporating assistive robotics could play a role in plugging the gap in care provision that is being felt in many countries as their populations age, and they experience shortages of care staff. Many of the assistive robotics development projects undertaken have addressed one or other aspect of care provision for older people. These have typically taken the form either of, on the one hand, physically assistive robots (eg, for mobility support [9,10], exercise training [11] and help with eating [12]) or, on the other hand, of socially (or clinically) assistive robots—recent contributions have focused on stimulation [13], companionship [14,15], assessment tasks [16,17], monitoring [18-21], and remote visits or consultations [22]. It will be noted that both physically and socially assistive robots each tend to address only 1 or 2 aspects of frailty (care); as such, none of these robots can be said to be "for frailty" in its widest sense, if, indeed, such a thing is even possible. Notwithstanding these and other encouraging feasibility studies, undertaken both in laboratories and, on occasion, in people's homes, care homes, or clinical settings, this effort has yet to translate into anything approaching scale-up of production and widespread adoption. Despite years of research and development—and not inconsiderable financial investment—few assistive robots are actually deployed in the real-world to provide care or assistance to older adults [1].

At a technical level, it is undoubtedly extremely challenging to provide robotic assistance in a safe, sensitive, timely, responsive, respectful, reliable, and trustworthy manner to, with, and around ordinary people—who may have sensory, cognitive, or physical impairments—as they go about their everyday lives. However, the task has not been made any easier by basing design decisions on often unfounded or simplifying preconceptions of older people's needs, wants, and circumstances. In Emergence, we want to address this issue through the effective co-design of assistive robotics.

Co-Design of Assistive Robotics

Conventional design practices can result in "solutions" that leave end users with a sense of alienation and exclusion (especially where new or unfamiliar technologies are deployed), and the (entirely accurate) impression that the product or service has been designed "for them" and not "with them." It is likely that such products or services will not be adopted or quickly fall into disuse, unless their users have no alternative, when they will be used under duress and with little pleasure, and possibly with limited success. This failing becomes particularly significant in assistive technology contexts (and in health and care contexts more generally), where outcomes relate directly to the health and well-being of the end user. Co-design practices seek to address this failing by increasing the involvement of external stakeholders, and, in particular, end user representatives, in design and development processes, particularly during the earliest phases of design when, as is widely acknowledged, any incorrect decisions taken are significantly more difficult (and costly) to rectify later on. Co-design is a term given to a broad range of participatory techniques and methodologies whose underlying objective is to improve the acceptability and value of products and services by involving representative target users in their development [23]. During co-design, the role of the external actors can range from the relatively passive (such as critiquing alternative designs put to them) through more engaged modes (helping to define requirements or brainstorming potential solutions) to effectively becoming embedded in the design team and contributing to all stages of the development process.

There have been previous co-design exercises involving older people (for examples see other studies [22-27]). However, these exercises also underscore that co-design is not easy, with no single methodology; that access to the right stakeholders at the right time is not a given; that it is costly, in terms of both money and time; that participants find it difficult to shake preconceptions about robots and the roles they can play; and that, in the final analysis, it does not guarantee success.

Aim

Given what is at stake, however, none of these is a reason not to do co-design; rather, they are reasons to devote sufficient resources and care to try to do it better. The work reported in this paper aims to provide assistive robotics for older people with sturdy, co-designed foundations. Specifically, we have performed an extensive early-stage co-design activity with older people through which we hope to understand some of the current everyday problems facing people and their general requirements and attitudes toward hypothetical robotics solutions to some of those problems. We have undertaken this activity with the intention of collating the results and then sharing them as widely as possible among the assistive robotics community and, in this way, to provide a rich seam of foundational evidence for researchers and developers who otherwise lack the skills, wherewithal, or opportunities for engaging in early-stage co-design with older people. Ultimately, we intend to steer assistive robotics for older people in directions that are more likely to lead to the development of assistive robot services that provide genuine value for their users.

Methods

Emergence Co-Design Exercise

The objective of the co-design exercise was to take a "phenomenological snapshot" of frailty and aging, that is, one that positions the individual at the center of the enquiry [28] to complement the clinical models described above by capturing people's everyday experiences of frailty and aging. Moreover, the aim was to do this in such a way as to avoid some of the weaknesses of previous co-design in this field by expressly not focusing on any specific task or assuming as a basis any specific robot platform. This snapshot would encompass the physical, psychological, and social effects of aging, as well as the role that innovations (not necessarily technological) could play in mitigating negative effects and improving people's lives, and any constraints under which such innovations must operate if they are to be acceptable. As stated, the primary purpose of capturing such a snapshot is to provide guidance and support for the early stage (conceptual design) development of assistive technologies, specifically assistive robotics. However, the

snapshot could play a role beyond this, informing a variety of interventions and improvements, and educating those involved in the care and support of older people.

Moreover, it was imperative that the snapshot be accessible and communicable to a wide network of robotics and technology researchers, designers, and developers, and in such ways as to encourage the development of appropriate assistive robotics solutions. This, we hoped, would help to overcome the problems of a lack of expertise, experience, and resources for performing co-design, and of limited access to participants.

As mentioned above, there is no single methodology for co-design, although a number of different approaches have been suggested. Here, we adopted a selection of approaches and tools, intended to give us access to complementary information and in such a way as to hold the participants' interest and keep them engaged.

Co-Design Methodology

Overview

Workshops were run in 3 different locations (corresponding to the locations of academic partners in the Emergence network) in the United Kingdom. The workshops were "paired" at each location: an initial, "lived-experience" workshop was followed by a "speculative-critique" workshop.

Lived-Experience Workshops

The lived-experience workshops were designed to enquire into the needs and aspirations of older people living with frailty, the everyday realities of their lives, their living environments and social activities, and the benefits and frustrations of modern life, and, inevitably, of modern technologies (although the workshops were not designed to discuss technologies specifically). Participants were encouraged to identify any opportunities for assistive technologies, including robotics, to play a role in older people's lives.

To facilitate these workshops, we used personas as a starting point for group discussions. Personas are descriptions of fictitious individuals and have been widely used to motivate or contextualize co-design or innovation processes [29]. A total of 10 personas were developed for the Emergence workshops. We decided to develop these by drawing on our previous research [30] and existing data-based resources such as the CURE-Elderly-Personas set [31], which were adapted and extended to be more relevant to the United Kingdom context and to focus on the specific characteristics of the populations of interest to Emergence.

These personas depict, in easy-to-digest formats, the backgrounds, health status, and characteristics of fictitious older people, each of whom can be classed into 1 of 3 broad categories: prefrail but managing; vulnerable or living with mild frailty; or living with moderate-to-severe frailty. It was envisaged that having personas with different experiences of frailty would allow us to explore different intervention contexts and make comparative assessments of needs and wants. Before use, the personas were validated to be representative of people living with frailty by the Emergence steering groups, comprising health and social care professionals and people with lived experience of frailty. The group also reviewed the terminology used for possible infelicities or offence. Examples of the personas developed for and used in the workshops are shown in Figures 1 and 2. The personas have been made publicly available to allow their use in other co-design exercises.

Figure 1. "Michael," one of the personas developed for the lived-experience workshops.

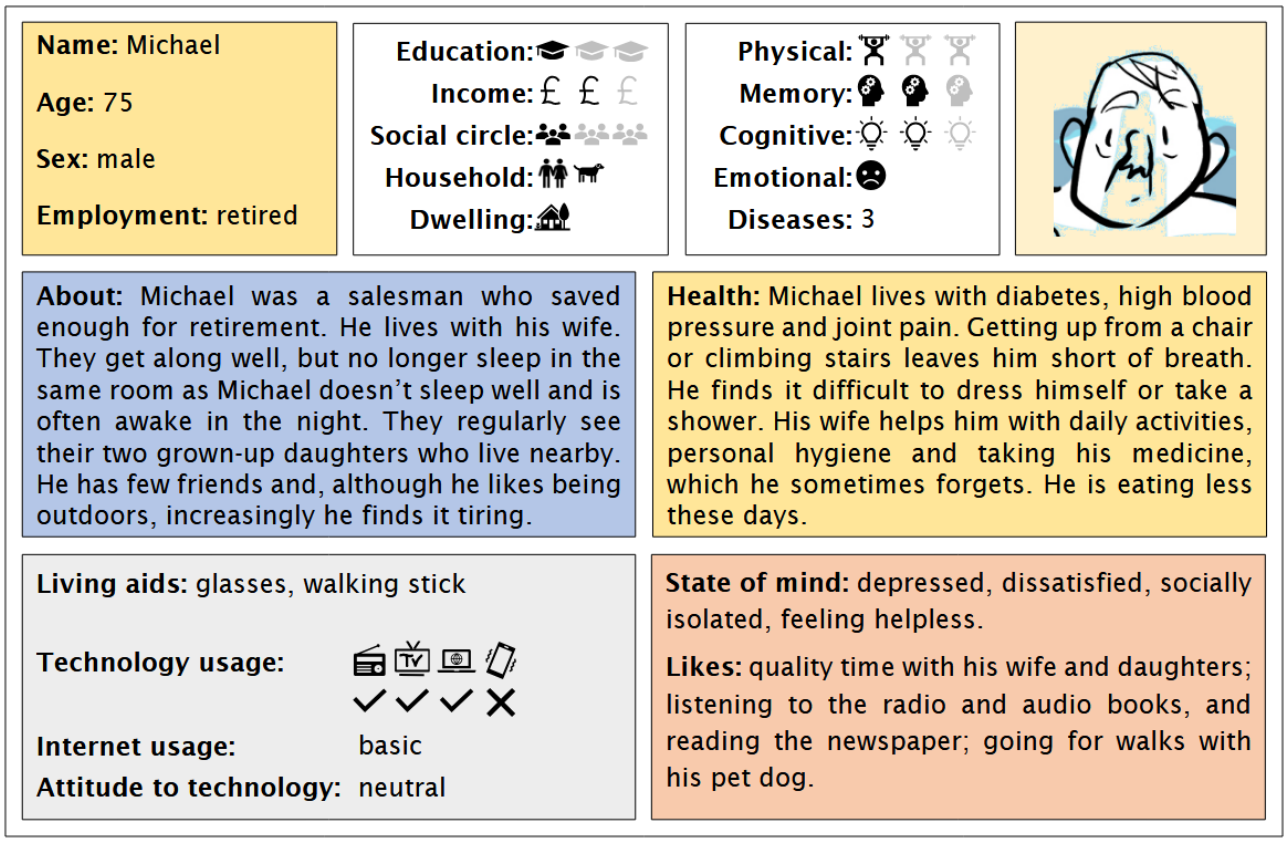

Figure 2. "Dorothy," one of the personas developed for the lived-experience workshops.

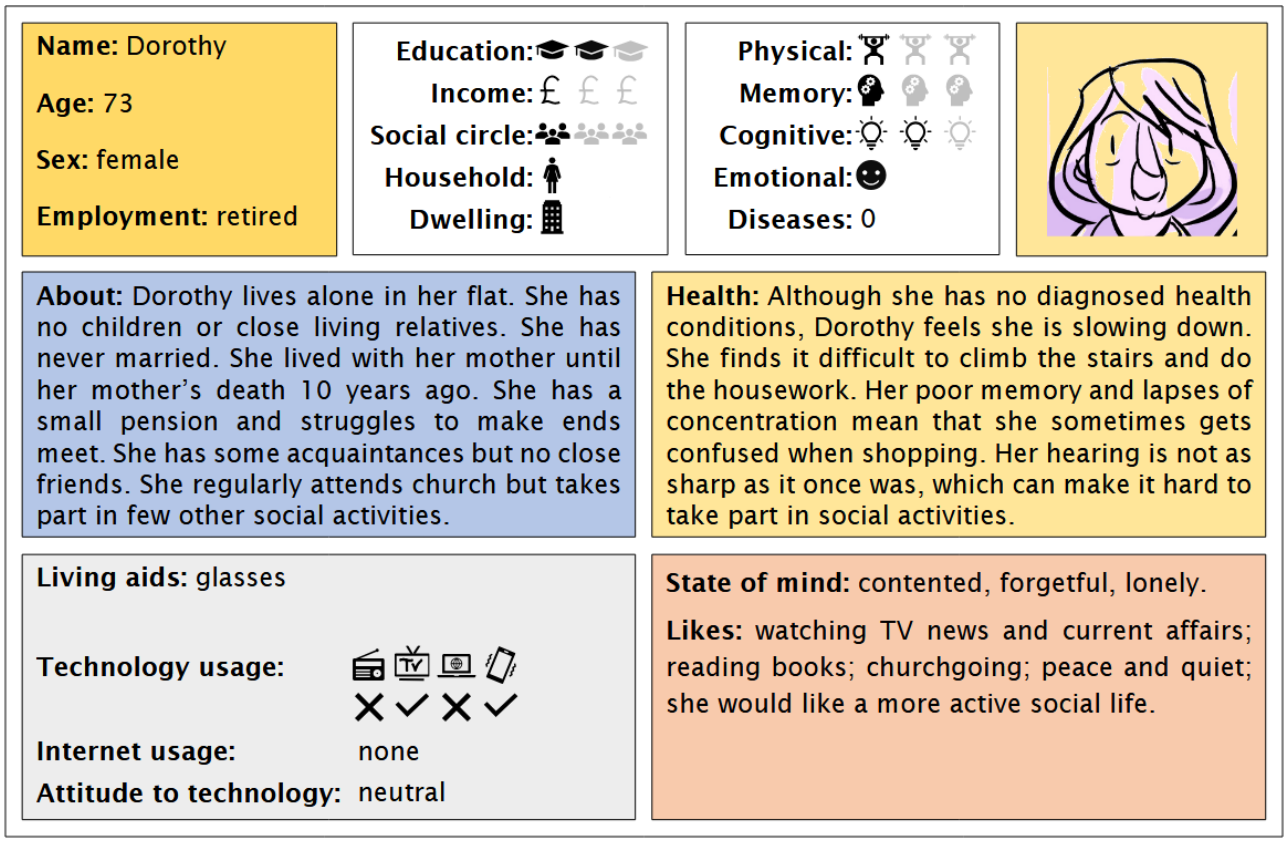

Personas can be used in different ways within design and innovation processes. Here, the primary role of the personas was to aid our participants within the co-design activities to "transfer" their own needs, wants, opinions, difficulties, and coping strategies onto fictional others, thereby avoiding potentially sensitive, embarrassing, or otherwise inhibiting

discussions of a personal nature, allowing us obliquely to broach frailty and other issues related to aging. More specifically, they would be used in the context of discussions of different "episodes" of the persona's typical daily routine:

- Getting up: including waking, toileting, washing and bathing, dressing, and medication.
- Mealtimes and snacks: including planning meals, food preparation, ordering food, utensil operation, cooking, eating, drinking, washing up, remembering to eat and drink enough, and maintaining a balanced diet.
- Household chores: including cleaning the house, heating the house, laundry, everyday repairs and maintenance, looking after pets, and household management (payment of bills, etc).
- Out and about: including getting around (walking, driving, and public transport), going to the hairdressers, going to the supermarket, going to the bank or post office, going to the doctor's, buying items, carrying things, and outdoor exercise.
- Socializing and pastimes: including home entertainment (television, music, internet, and puzzles), gardening, meeting friends and family, receiving guests, indoor exercise, and outside entertainment (cinema, concerts, bingo, book groups, walking groups, etc).
- Bedtime: including taking medicine, switching off and locking up, climbing stairs, getting to sleep, and getting up in the night.

Working in small groups consisting of 3 or 4 participants, each of which would be allocated 2 personas and 3 daily episodes, the lived-experience workshop participants were asked to consider what difficulties the episodes might present for those personas and what opportunities they can see for making the personas' lives easier. Following a break, the groups were then asked to consider each of the difficulties or opportunities and reach some consensus about: how frequently it occurs (daily, weekly, monthly...?); how prevalent it is (encountered by most, some, or just a few people?); and how consequential it is (does it have a large, medium, or small impact on people's ability to get by?). The answers to these questions would allow us to assess the significance of the difficulties and opportunities, and hence to prioritize them as objectives for assistive technologies.

The group discussions were facilitated by members of the research team who took notes as participants spoke, displaying these on whiteboards for immediate validation by participants. The discussions were audio-recorded for future verification and analysis.

In addition, the workshops were documented by a professional illustrator with experience in supporting academic workshops. Graphic facilitation can capture ideas in the form of easily digestible pictures, and can visualize the progression of and relationships between concepts discussed [32]. These illustrations would also represent the findings of a workshop in an easily accessible format, for reflection (and validation) during and after the workshop [33]. This was felt to be a particularly important aspect in this case, since one of our objectives was to communicate, in as readily accessible a manner as possible, the results to the wider assistive robotics development community. The illustrator was briefed as to the purpose and structure of the workshops, and then given free rein to move among the group discussions and capture any parts of the discussions that seemed to them both significant and susceptible to pictorial expression (they would also incorporate text, often quoting participants verbatim, into their illustrations). The illustrator attended and illustrated all the lived-experience workshops; they were unable to attend the subsequent speculative-critique workshops (but would supply the illustrations used to facilitate these workshops, as described below).

Speculative-Critique Workshops

The speculative-critique workshops would be structured around several "speculative designs" of assistive robots proposed to address the problems or grasp the opportunities identified by participants in the initial lived experience workshops.

These designs were in the form of a brief textual description and a sketch of the robot in action, helping to convey both the appearance of the robot and its use and operation. These were not intended to constitute designs for robots that would necessarily be developed; indeed, although the robots were intended to be realistic, in the sense of their functioning and behaviors being more-or-less feasible in the short term given current developments and directions in robotics research and development, they did not need to be feasible at the time of the workshops given the current state-of-the-art. Instead, they were to serve as "provocations" (elsewhere, such design provocations in the context of participatory design have been termed "provotypes" or "provocative (proto)types" [34]). As such, these workshops would constitute "speculative (co-)design" activities. Speculative design [35] is an activity during which a design proposal is presented not as a candidate for subsequent product development but as a means to elicit concerns or highlight issues that might otherwise remain latent, but which must be acknowledged if the design process is to be successful. This approach was felt to be particularly appropriate for a field such as robotics, about which many people possess preconceived notions. Moreover, discussing potential applications of any new technology without concrete examples is difficult: the speculative designs would constitute a basis for grounding discussions around assistive robotics in something approaching reality. Attempts to ground co-design discussions around (prototype applications of) real, existing robots are common; however, the obvious limitation of this approach is that the robots in question will have already been developed to some degree and, even when they have been developed with assistive applications in mind, this is likely to have involved certain assumptions on the part of the designers. Moreover, they will almost certainly have technical shortcomings. Consequently, it is difficult to move the discussion beyond the specific limitations of that particular robot or envisaged application so as to capture more general requirements for assistive robotics. We believe that the speculative design approach gives participants more freedom to move beyond the particular and express more general opinions about future applications of technology [36].

The development of the speculative designs required a rapid analysis by members of the research team (SP and MH) of the

content of the lived-experience workshops to identify candidate domestic tasks with which assistive robotics might help; a total of 6 such "robots" were identified:

- Motibot ("the motivational well-being and exercise robot")
- Foodee ("your personal cooking assistant and dietary advisor")
- EasyUp (a mobility assistance robot "for all life's ups and downs")
- AutoReach (a cleaning robot to "keep those hard-to-reach places spotless")
- RoPet (a robot pet that is "your new faithful friend")
- Toilittle (a discreet toileting robot that's "there when most you need it")

Each of these was summarized in words in terms of the problem or opportunity that the robot sets out to address (the "why" of the robot), its projected functionalities (the "what"), and how the robot would operate or be operated (the "how"). To aid in communicating the designs to workshop participants, these textual descriptions then became the brief for the illustrator to work up a sketch of the robot "in action," working with the research team to imagine what form the robot could take. In undertaking the brief, across the 6 applications, the illustrator was asked to draw robots with a range of embodiments, sizes, interfaces, and movement styles to elicit responses to different design options. Figures 3 and 4 give examples of 2 of these speculative designs in the format in which they were presented at the workshops.

Figure 3. Motibot ("the motivational well-being and exercise robot"): one of the speculative designs developed for critique.

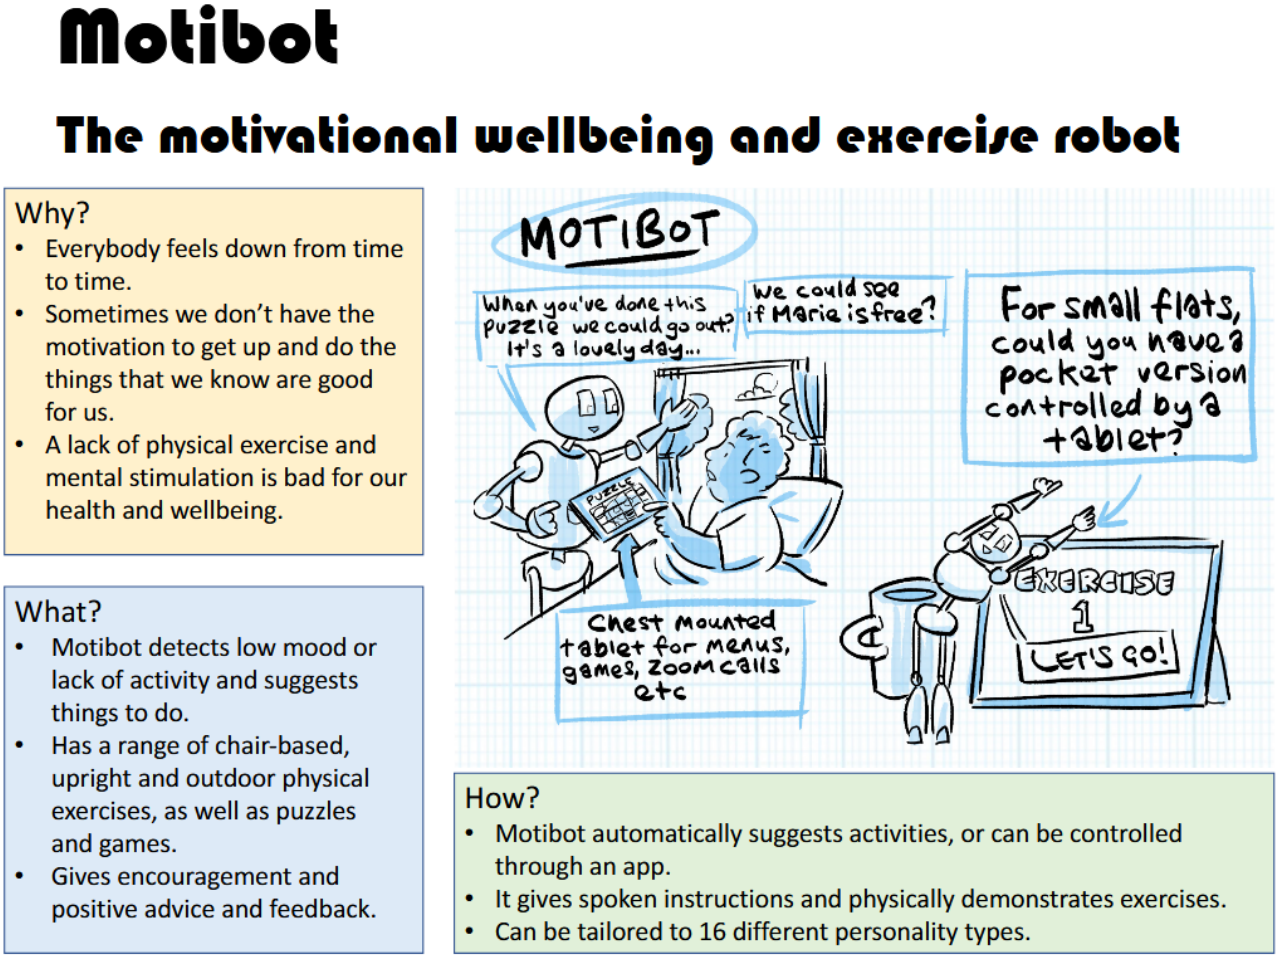

Figure 4. RoPet ("meet your new faithful friend"): one of the speculative designs developed for critique.

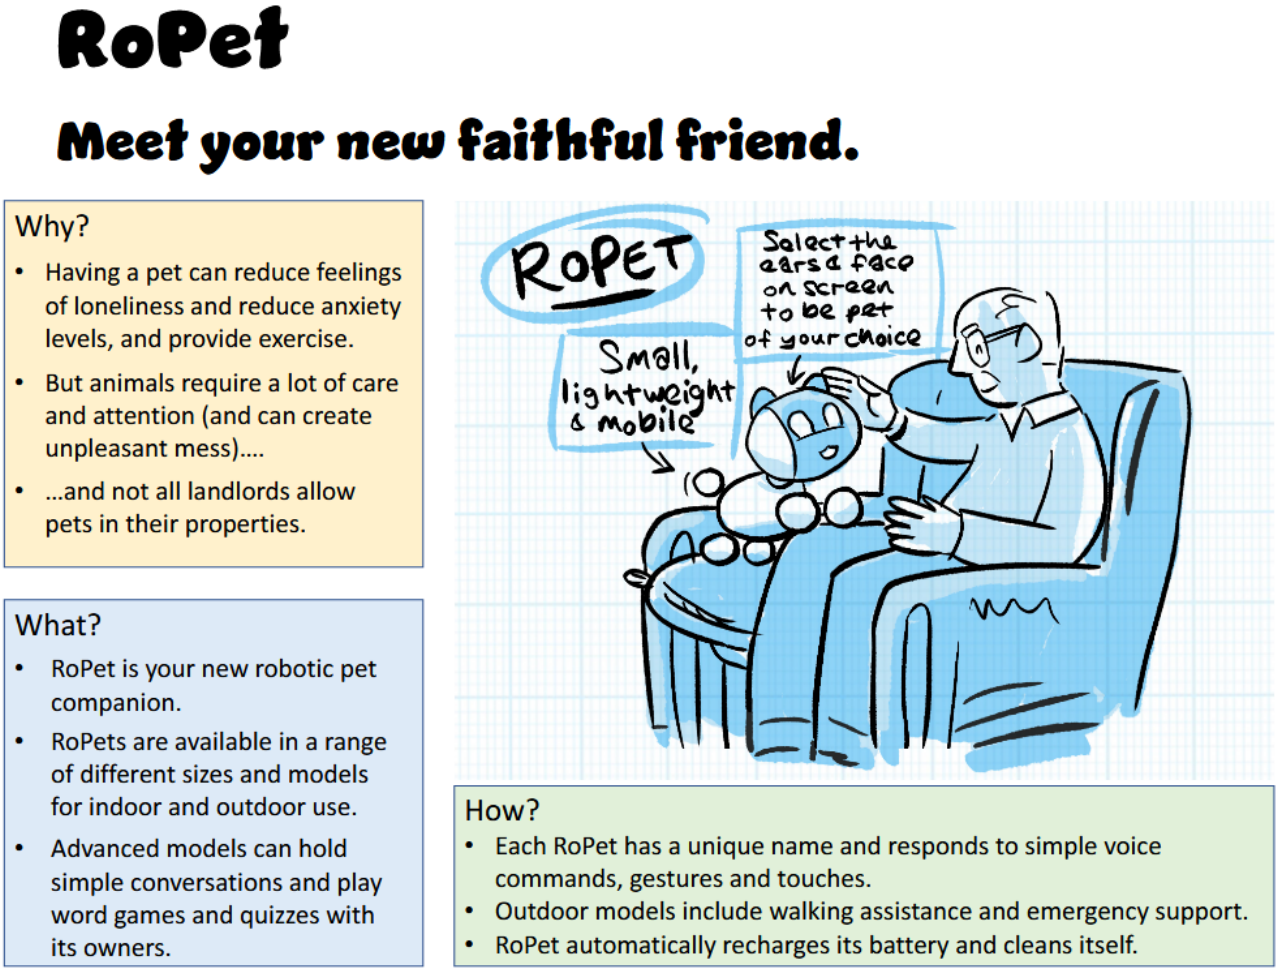

For the speculative-critique workshops, the participants were, once again, allocated to small groups, and asked to consider each of the speculative designs in turn, it first having been emphasized that the designs portray imagined, rather than real, robots. The participants were asked whether they would like to have the robot, and then asked for the reasons for their decision. Participants were encouraged to ask for additional information if this would help; facilitators were encouraged to extemporize answers. Using different-colored notepads, the facilitators noted separately positive and negative arguments, as well as quoting verbatim the words of participants where these seemed particularly pertinent. If at least 1 member of the group said they would accept the robot, the group was then asked about the following features of the robot:

- Appearance: what was liked and disliked about it, what size and color it should be, what materials it should be made of, and so on.
- Control: the extent and nature of the control that the end user and their caregivers should have over the robot, appropriate modalities for controlling the robot (voice, touchscreen, smartphone app, etc), and so on.
- Performance: its operating speed, acceptable noise levels, weight, communication, quality of movement, behavior both when in use and when not in use, and so on.
- Practicalities: how it would fit into people's lives and homes, whether people would be comfortable operating and maintaining the robot, the sort of training and assistance they felt they might need, and so on.
- Concerns: any safety or security issues, whether the robot seemed trustworthy, who would be trusted to develop, supply, run, maintain the robot, and so on.

Once again, facilitators would note both positive and negative comments: the former would constitute design requirements ("should-haves" or "nice-to-haves") while the latter constitute design constraints ("should-not-haves").

Participants

Older people do not always recognize themselves as living with frailty and can resist being labelled as "frail": the term has certain negative connotations, and not all people clinically classified as such would recognize (or welcome) the attribution [37]. Moreover, its severity can vary dramatically, from those who are moribund and almost completely dependent on others to those whose coping strategies are so successful that others——and maybe even they themselves—might not consider them to be living with frailty. For these reasons, we avoided using the term "frailty" when engaging with older people and their caregivers in these co-design activities. Moreover, we chose not to recruit through health services because we would then be accessing only those who, for one reason or another, had come to the attention of those services and received an "official" diagnosis. Instead, we focused on recruiting through

independent-living housing providers managed by Emergence partners and located conveniently close to the Emergence university research centers. People aged 55 years and older were considered "older people," adopting the threshold age for residency used by one of the housing providers. Even if not living with frailty themselves, most people living in these contexts would almost certainly know of people among their friends and neighbors who are living with frailty. In addition, relatives and friends who play an active role in supporting older people, along with other caregivers, were invited to participate, especially where they could support older people to participate by helping with transport and mobility.

Participants were asked to attend both the lived-experience and the subsequent speculative-critique workshops at their locations. However, for various reasons, some participants were unable to attend both workshops. As far as possible, the workshops took place in locations that were convenient for participants to attend and which, as far as possible, were close to their "natural environments" (such as communal lounges or university collaborative spaces) and so conducive to eliciting their experiences, while also being appropriate for group discussions. Likewise, workshops were scheduled for times considered most convenient for participants. Each workshop typically lasted around 4 hours, including breaks and refreshments. There was an interval of approximately 2 weeks between the lived-experience workshop and the corresponding speculative-critique workshop, except for the last pair of workshops, which, due to scheduling pressures, were held as morning and afternoon sessions on the same day. Before the workshop, participants were asked to complete a consent form and a demographics questionnaire. At the end of the workshop, they were invited to give feedback about the nature, structure, and conduct of the workshop, and were each given a shopping voucher as an honorarium to acknowledge their contribution.

Data Analysis Method

The audio recordings of the workshops were transcribed by professional transcribers; the transcriptions, alongside the notes collected during the workshops, were then subjected to a thematic analysis by two of the research team, one with experience of assistive technology development (SP), the other with a background in industrial design and robotics (AH). The analysis broadly followed the Framework Method [38] as elaborated by Gale et al [39]. A phenomenological approach was adopted for analysis, with the analysts bracketing their own experiences and conceptions to reduce bias and focus on the content of the participants' contributions, paying particular attention to their experiences and the meanings that they attached to these. Specifically, we adopted an interpretive phenomenological analysis, foregrounding the participants' experiences and perceptions, while recognizing that the researchers play an active role in interpreting these [40,41]. This analysis was both deductive and inductive. Given the aims of the exercise, we had a particular deductive focus on the lived experience of aging and how this relates to opportunities for and constraints upon assistive robotics, as dictated by the structure of the workshops. However, within these broad topics, we were open to themes that were not explicitly foreseen as topics for discussion, and which arose naturally during the workshops. Codes were first inductively identified from the participants' utterances and then checked against the notes taken by the facilitators. These were then clustered deductively into higher categories which broadly mirror the structure of the workshops, namely "difficulties with activities of daily life," "opportunities for facilitating activities of daily life," "assistive robotics design requirements," and "assistive robotics design constraints." The analysts worked independently at first, then collaborated to merge codes, resolving any discrepancies through discussion. Several iterations of analysis, during which codes and categories were amended, were performed until a reasonably stable analytical framework emerged, with the first 2 themes emended to "everyday difficulties" and "ideas for aging better," respectively, and the last 2 merged into the more general "living with technology" category. The transcription and analysis of the data were carried out using the Lumivero NVivo qualitative analysis software package. Although the notes taken were displayed to participants for "real-time" validation during the workshops, it was unfortunately not feasible to ensure dependability by reconvening the participants and presenting the analysis back to them for their approval or correction of the framework.

Ethical Considerations

This study was approved by the Ethics Committee of the University of Nottingham (CS-2021-R40). All participants provided written informed consent. Privacy and confidentiality were ensured by collecting no personally identifying data. Participation in this study was voluntary; each participant was given a shopping voucher (worth approximately US $30) as an honorarium.

Results

Overview

The older people participants in the workshops were aged from 55 to 96 years. An overview of participants for each workshop can be found in Table 1.

The examples of the illustrations produced during the workshops, shown in Figures 5 and 6, give some idea of the content of the discussions.

The analysis of the workshop outputs led to the formation of 3 broad, high-level categories, namely "everyday difficulties," "ideas for aging better," and "living with technology."

Table 1. Participant information for each of the co-design workshops.

Workshop type	Location	Participants		Setting
		Older people	Relatives, friends, and caregivers	
L[a]	A	8 (4 F[b], 4 M[c])	1 (1 F)	Lounge in residential scheme
L	B	8 (5 F, 3 M)	5 (3 F, 2 M)	University collaborative space
L	C	4 (2 F, 2 M)	4 (2 F, 2 M)	University collaborative space
S[d]	A	5 (3 F, 2 M)	2 (2 F)	Lounge in residential scheme
S	B	8 (5 F, 3 M)	3 (2 F, 1 M)	University collaborative space
S	C	4 (2 F, 2 M)	4 (2 F, 2 M)	University collaborative space

Everyday Difficulties

The most prevalent codes in the category of everyday difficulties are physical difficulties and psychological difficulties, with other difficulties being less prominent, if not less significant for participants.

- Physical difficulties: as was intended through the format of the lived-experience workshops, physical difficulties were often expressed in terms related to activities of daily living or situated in contexts. For example, participants mentioned the difficulties they have doing the housework (reaching high places, cleaning windows, and making the bed), with personal care (difficulties washing themselves and getting dressed), toileting (incontinence), mobility (walking up hills and stairs, and getting on and off buses), and, in general terms (not exercising enough).
- Psychological difficulties: almost equally prevalent were psychological difficulties. That these are shared by many participants might have been expected; what was more surprising was the extent to which participants were prepared to discuss their own psychological difficulties (and in the process setting aside the fictitious problems faced by the personas). Some of these were related to specific activities; others were more generalized states of mind or mood. Among other things, participants mentioned anxiety (about their own situations, but also more generalized, about the state of the world), social isolation and loneliness, lack of motivation and purpose, depression, and fear (of falling, of going out at night, when answering the door, and of assistance not being available when most needed).
- Cognitive difficulties: principally these concern remembering (appointments, where things are, to take medication, and to recharge and use technology, such as a smartwatch intended to help monitor activity levels).
- Living environment difficulties: these included having limited opportunities to socialize, poor relations with neighbors, lack of convenient public transport, and being unable to keep pets or mobility scooters in shared accommodation (the latter due to size and safety concerns, possibly having implications for assistive robotics).
- Burden of disease: for the workshop participants, this burden included remembering to take medication (overlapping with cognitive difficulties) and maintaining medication routines, the detrimental side effects of medication, and having to care (in an unpaid capacity) for a spouse living with more severe frailty.
- Time pressures: the time required to perform certain activities dissuaded some participants from doing potentially beneficial things such as buying food and preparing meals, taking care of pets, and going out to exercise or socialize.
- Financial difficulties: the cost of living, and specifically the cost of gas and electricity, was mentioned by several participants (who worried that they would be unable to afford to operate robots or other assistive technologies).

Ideas for Aging Better

Participants also brought to the workshops their own ideas, some based on their own experiences of what works for them, for how people might age better. Some of these concerned living and lifestyle (for instance, exercises, stimulating games, even pet ownership as a motivation for staying engaged and active) and social ideas (conversation and group activities of various sorts). However, the most prevalent category was technological ideas, no doubt influenced by the wider context of the workshops and suggested by the problems faced by the personas (and by the participants themselves); these were further divided into:

- Technology for physical assistance: the category for which there were most suggestions, which included the feasible (and in some cases already available), such as smart speakers for home automation, robot vacuum cleaners, and teasmaids; adaptations of existing technology to the domestic sphere (escalators and self-cleaning toilets, which a participant had seen at an airport); voice-activated showers and personalized drinks and snacks dispensers; and more ambitious ideas involving robots: robots for helping to do the shopping, for cleaning high places, and for cleaning up after pets, automated kitchen surfaces and food packaging openers, and self-making beds.
- Technology for psychological assistance: including technology that tells you who is knocking at the front door, assuring that it is safe to open the door; robots for providing motivation, for recipe suggestions, for cultivating positive attitudes and providing "positive affirmations," and robotic cats for companionship.
- Technology for cognitive assistance: including devices for providing reminders (for doctors' appointments or social events, for medicines, food, and drink), and smartwatch navigation aids.
- Technology for social assistance: several participants noted that their smartphones where helping them to stay connected to friends and family, especially through multimodal (speech, video, and chat message) calls; another suggestion was for an app or similar that could allow caregivers to better communicate and coordinate their efforts; and shared smart facilities, such as "robot washing machines" could help to avoid conflicts in residential schemes and similar multihabitant environments.
- Technology for health monitoring: participants suggested that it would be beneficial to have technology that could detect if medication had actually been taken, for measuring nutrients in the body, and for raising the alarm in the case of a fall; and to have an all-purpose "well-being robot."

Some of the ideas above would find expression in the hypothetical robot designs developed for the speculative critique workshops.

Living With Technology

The final major category, living with technology, encompasses mainly (but not exclusively) codes identified during analysis of the speculative critique workshops. These cover general preferences (in turn covering aspects such as appropriate interface modalities several people expressed a desire—indeed, an expectation—that the robots would be voice-controlled), size (large enough to do the job, but small enough to fit into people's homes and lives) and appearance (nonthreatening, with some opting for humanoid and others for "cute" robots), but also ideas of "personalization" (sometimes dynamic or autonomous) of the robot to the user's (changing) needs, abilities and routines, with robot autonomy extending to regular maintenance tasks such as charging or cleaning itself, and even consideration of financial models for provision (such time-sharing robots with others).

There was some overlap here with general requirements for robots, with a requirement being identified when a participant used a modal verb expressing necessity for some feature or aspect (that a robot "needs" or "must have" it). Requirements refer to physical qualities (robustness and stability), maintenance (cleanable or even self-cleaning), the need for adequate training and practice in using the robot, and, on a more challenging level, the need for a robot to be "self-aware" enough to be able to explain what it is doing.

However, the code with the most items in this category is concerns about technology, which are, almost exclusively, concerns about robotics. These are wide-ranging, revealing the complexity of people's lives and how they imagine robots might disrupt those. The following subcodes give some flavor of the range of concerns (note that these codes are not mutually exclusive):

- Safety: perhaps unsurprisingly, the major source of concern for the participants is safety. Difficulties here were further coded as surrounding the physical safety of users and other beings in the vicinity of robots, psychological safety (specifically if the appearance of a robot might scare or upset the user or others, manipulate their sentiments, or increase social isolation), potentially detrimental side effects (such as discouraging activity or suggesting the wrong sort of exercise), and digital safety (digital surveillance, privacy, and unauthorized access to any data collected). A number of concerns here are related to what might be termed uncertain hazards, where the participants could envisage situations during the use of the robots in which their safety could be imperiled if appropriate safeguards are not in place. For instance, what happens if a robot intended to physically assist people up and down stairs, or a flying drone-type cleaning robot were to malfunction midoperation?
- Compatibility: participants raised practical concerns about how robots would fit into their everyday lives, including aspects such as social compatibility (for instance, will the neighbors be inconvenienced by a robot? How would it interact with pets?), physical compatibility (Where will the robot be stored? Will it require modifications to the home? Will it damage possessions?), and technical compatibility (Will it require broadband connectivity?).
- Usefulness-desirability-inclusivity: general questions were raised about the usefulness of the speculative robots, including whether there were simpler or cheaper ways of achieving the same ends using existing technology (such as tablet computers and smart speakers, and nondigital alternatives), about the longevity of the robots (would they end up gathering dust in the cupboard alongside the foot spa?), about the need for sensitive, nonstigmatizing, design

of robots (and other assistive technologies), and, indeed, whether there was any real need for robots at all ("Is this a generational thing?" asked a participant; and another: "Am I going to feel the same about robots as I do about other tech? Too much hassle!")
- Burden of use: the additional overheads of looking after a robot are another major source of concern. These overheads encompass cleaning, charging, and servicing robots, the training required, and the cognitive demands of remembering how to use the robot. To quote a participant, "We don't want to look after the robot–we want the robot to look after us!"
- Maintenance and service model: a related concern is the service model of which the robot constitutes a technical component (and which is often overlooked in robot development): who programs, sets up, and personalizes the robot? Do robots act alone or in concert with human assistants? Who is responsible for regular maintenance and repairing faults?
- Control: concerns were raised about how control is exercised over robots, and who is in control. Some of these relate to the immediate operation of the robot, especially where the behaviors are complicated or potentially hazardous (and, in the words of a participant, "Can you tell it to stop?"), and others to the underlying operation of the robot, such as who determines what type and amount of motivation or exercise a robot should suggest.
- Financial costs: the economics of assistive robotics were also raised: participants raised the costs of purchase, running, and maintaining a robot, but also of modifying their homes, if necessary. Some participants asked about the comparative costs, whether that be compared with a human caregiver providing the same services or with a conventional refurbishment of their homes to make them more "age-friendly."
- Techno-psychosocial effects: here we see what might be called the techno-psychosocial effects of aging. These include the fear of being deemed "obsolete" or a burden on society, in no small part due to a (real or perceived) inability to move with the times and adapt to new technologies, as well as more "conventional" fears of falling, or forgetting, or crime and so on; the guilt and shame of not being able to adapt to these new technologies (alongside a feeling of grief for those skills that by-and-by are lost as we age); the stigma that sometimes accompanies the use of assistive technologies; the bottled-up frustration and occasional releases of rage that come from dealing with an increasingly digital world; and the contribution all these factors make to a vicious circle of stress, anxiety, and depression, with accompanying relationship problems, lack of motivation, poor diet, and social isolation.
- Digital ethics issues: in addition to the ethical issues that run through many of the difficulties noted above, here we also encounter direct concerns around the surveillance that users of data-collecting robots might find themselves subject to, users' privacy, and the security of their data.
- Social and care implications: finally, several participants raised concerns about the wider impact of assistive robotics: its potential negative effect on the role and jobs of human caregivers and home-helps, and the worry that robot care might replace human care, with the assumption that a degradation in the quality of that care would necessarily follow. On the other hand, there are worries too about inclusivity, access to care services, and the place of those who are unable to adapt to—or who choose to opt out of—the brave, new digital world.

Discussion

Principal Findings

We aimed to gain a better understanding of the everyday lives of older people, especially with reference to the effects of aging and frailty, and to gauge their opinions and concerns about assistive robotics. Through a wide-ranging co-design exercise with older people and their caregivers, we have gained a compelling snapshot of older people's real lives. As might be expected, given the structure of the workshops, the emphasis lies on the problems that people face daily and on their concerns about a world where change seems to have accelerated, sweeping away old certainties, and where, increasingly, services are delivered using digital technologies about which they have little say and less control [42]. In this context, the work reported here is an attempt to redress this balance and to return to older people some agency in the development of assistive technologies. We have also highlighted general concerns that older people have about assistive robotics. While older people and their caregivers are open to, and in some cases, enthusiastic about, the role that assistive robotics could play in their lives and those of others, they raise real concerns about, among other things, safety and control, the burden of use, ethics and unintended side effects, and the financial and social costs of introducing robots into their lives.

The work reported here differs from previous assistive robotics co-design activities in several key aspects. First, in its scope, which embraced a wide range of experiences of growing older, with a focus on the individual rather than on some specific health condition or difficulty, as much previous work has tended to do (eg, helping mitigate dementia [43] or supporting mobility [22,26]). Second, the exercise was technology-neutral in that we did not structure the workshops around some particular robot or robotic platform and tried to stay impartial in the question of whether assistive robotics could be beneficial: to adopt a priori a particular robotic platform is to make design decisions, including the fundamental decision that a robot is a valid "solution" to an ill-defined problem [27]. Finally, the exercise was undertaken not as a step in a specific assistive-robotics development pathway, but as a service to the wider assistive robotics community exploiting the Emergence network's resources, skills, and access to engage with potential users, and as such, we have placed special emphasis on communicating the results. In methodological terms, rather than focusing on a particular problem or solution (as is often done in co-design activities), we chose to adopt a general approach and investigate the lives of older people more broadly, and without trying to reach any firm consensus about where to focus subsequent development efforts or trying to reconcile the at times contradictory opinions of participants. We hope that, by

explaining our co-design approach along with the results, assistive technology developers will be able to sift the evidence and draw sound, rational conclusions.

Communication and Dissemination of Results

One key aspect of the exercise reported here is the communication and dissemination of results: clearly, this is essential if the findings are to influence the development of assistive robotics. One novel aspect here is that we realized that the results of the graphic illustrator's work to document the workshops could come to play an innovative role in our dissemination activities. The illustrator produced a total of 11 tableaux from the 3 lived experience workshops (Figures 5 and 6 each show 1 of these tableaux). Each tableau, somewhat like a comic book page, consists of a number of thematically related vignettes illustrating the ideas, opinions, or concerns voiced by participants. It was realized that these vignettes could form powerful communication and design aids as self-contained glimpses into the lives of the participants. Accordingly, they were isolated and printed as a pack of playing card-sized "empathy cards" (Figure 7), complete with suggestions for workshop "games" that encourage players to explore the different perspectives, concerns, and opportunities the cards contain and to consider how these relate to their own projects.

Figure 7. Some of the empathy cards generated from tableaux vignettes.

Along with the empathy cards, the results of the analysis have formed the basis of a series of workshops, sandpits, and project funding calls, and have provided content for a multidisciplinary summer school for budding assistive robotics developers. Through these activities, we have tried to reorient the development of assistive robotics for older people in a more empathetic direction and, indeed, to foment a new generation of more empathetic roboticists.

In addition, we are in the process of making all our workshop materials and the analysis results open and accessible in digital formats to the wider robotics and assistive technologies communities. This content includes the personas, the speculative robotics designs, the results of the analysis, and the empathy cards (which are also available as a physical pack of cards). The process and content of communicating outcomes in an accessible, understandable, and actionable manner is something that is not always given due prominence when discussing co-design exercises. This paper constitutes an element of our communication strategy, but it is by no means the culmination of our labors.

At the time of writing, it is too soon to draw any firm conclusions about the success of these endeavors: the development of assistive technologies and, in particular, of assistive robotics is a difficult and slow process which, typically, extends over several years. Only time will tell whether our efforts have contributed to bringing about the intended effect, and we see assistive robots emerge from the laboratory to help older people in their everyday lives.

Limitations

We recognize a number of limitations of this co-design exercise. All co-design practice is subject to bias, and this is no exception. The structure of the workshops, the development and choice of the material that provided the stimuli for them, the data collection by facilitators during the workshops, and the analysis of that data are all prey to the biases and preconceived notions of the researchers. The co-design approach adopted was, in some sense, an attempt to counter these biases: by not focusing on any particular everyday problem or given robotic platform, we have attempted to give participants the freedom to steer the discussions. In addition, the multidisciplinary nature of the

research team (which included specialists in design, assistive technologies, and health and care provision, as well as robotics) helped to guard against adopting preconceived positions or attitudes.

Further limitations concern the representativeness of the participants. The co-design activities involved a total of only 20 older people, plus a smaller number of relatives, friends, and caregivers. The participants were healthy enough (or coping well enough) to attend workshops and possessed some degree of day-to-day independence. Hence, people living with more severe frailty or other age-related health conditions (such as dementia) were not represented directly in the workshops, and no consideration was given to the particularities of life in care homes and other facilities offering specialized care (although the use of personas with more severe frailty and health issues was an attempt to address, at least in part, these aspects). Clearly, there is much scope for developing assistive robotics for people with greater needs and for the staff who minister to those needs, but that would require other, more focused co-design exercises. To this end, we have also conducted workshops with health care professionals, which—as may be expected—focused more specifically on the needs of people with more severe frailty and health conditions (including end-of-life care) and with a greater emphasis on support for their caregivers. As the outcomes of these workshops are thematically quite different from those reported here, this work will be reported separately.

Furthermore, the participants in this exercise were self-selecting, and as such might be considered to have a greater interest in robotics (and digital technologies more generally), and possibly to be better disposed to the acceptance of domestic assistive robotics. We did not collect data about the socioeconomic status or the digital literacy and experience of participants, factors that can influence attitudes to robotics. It was not feasible to reconvene participants to confirm or correct the analysis of the workshop data.

In demographic terms, all the older participants self-identified as having a White British ethnic background (almost certainly a reflection of the constitution of independent-living schemes from which most participants were recruited rather than any explicit bias in recruitment practices). Looking beyond to other, perhaps underserved, communities and their living circumstances could expose a different set of needs and wants. Although we found little direct evidence of differences in attitudes according to age or gender, these moderators will likely have some influence on acceptance, even if it was not explored by our participants. To assume that all older people will have the same attitudes to technology, disregarding other factors in their background, is to risk adhering to ageist stereotypes [44]. The very term “older people,” with the suggestion it conjures of a homogeneous mass of people, can itself be a barrier. However, we would argue that experience is a more influential moderator than age: many older people, including some of our workshop participants, will have had extensive experience with digital technology throughout their working lives (which, in the case of a couple of participants, was ongoing) or because they have readily embraced it in their social lives, and are receptive to and comfortable with the idea of using digital assistive devices. Studies have suggested that perceived value and benefit of new technologies are more significant for technology acceptance than is chronological age [45,46]. Rather than being technophobic as a rule or having low levels of digital literacy, older people seem less likely to invest time in new digital technologies whose value for them is not apparent. However, while we have striven throughout to avoid adopting ageist stereotypes, we are aware that this is an all-too-easy pitfall (and, indeed, we noted during the workshops that older people themselves sometimes fall back on these facile generalizations).

In summary, we could not hope to capture everyone’s experience of frailty and aging, or even to encompass the complexity of a single individual’s experience. Moreover, the results of this exercise are specific to a particular population, time, and place (and as such have a limited shelf-life): namely, they are valid for (a small subset of) older people living in the United Kingdom in the early 2020s. People’s experiences in different places and times will, of course, be different. If we were to repeat this exercise in, say, a generation’s time, we would expect the needs and expectations of older people to diverge dramatically from those seen in our results. By this measure, there is no such thing as a uniform, constant, consistent experience of frailty and aging. In some sense, this is not a failing of this exercise but rather an essential feature of co-design, albeit one rarely acknowledged in the literature. Design always responds to problems and opportunities situated in particular times and places; seen in this light, this is not a limitation of the snapshot, but a fundamental aspect of it. Good designs, or ones that address a particular need, might be able to transcend time and place to some extent, but of necessity they must be grounded in the here-and-now experience of everyday life.

Conclusions

The contributions of this paper can be summarized as follows. We have described the predominant clinical models of frailty and explained why these form a useful but incomplete basis for designing assistive technologies of any sort for people living with frailty and older people more generally. We have described the current underwhelming state of assistive robotics, with common failings during their design or co-design processes that often result in the development of inappropriate robotic services.

We have described a novel co-design methodology that has attempted to combine persona-based lived-experience workshops with provotype-based speculative-design workshops with older people to gain a rounded “phenomenological snapshot” of the experience of being old in an increasingly digital world, a world in which assistive robotics may soon become commonplace. As far as we are aware, this is the first time that an exercise of this scope has been attempted in the context of assistive robotics. Finally, we have outlined the major concepts that are revealed by an analysis of the results of the workshops. These can be categorized thematically as: everyday difficulties, the problems faced daily by people living with frailty and older people more generally; ideas for aging better, older people’s own suggestions for how their lives could be improved; and living with technology. In addition to participants’ preferences and requirements, this last category reveals the wide-ranging concerns that people have about services based on digital

technologies, and about assistive robots in particular, whose development is viewed with a mixture of enthusiasm and unease.

Acknowledgments

The authors gratefully acknowledge the contributions of all those who participated in the Emergence co-design workshops described herein, the assistance of Ms Rebekah Moore, the project manager, in organizing the workshops, and the illustrative skills of Mr Sam Church. Generative artificial intelligence was not used for any aspect of this paper's writing.

Abstract

Background: The integration of the Internet of Things (IoT) into health care is transforming the industry by enhancing disease care and management, as well as supporting self-health management. The COVID-19 pandemic has accelerated the adoption of IoT devices, particularly wearable medical devices, which enable real-time health monitoring and advanced remote health management. Globally, the increased adoption of IoT in health care has improved efficiency, enhanced patient care, and generated substantial economic value.

Objective: This review aims to conduct a comprehensive meta- and weight analysis of quantitative studies to identify the most influential predictors and theoretical frameworks explaining the adoption of IoT in health care.

Methods: We searched databases, including Web of Science and PubMed, for quantitative studies on IoT health care adoption, with the last search conducted in early July 2025. Inclusion criteria comprised peer-reviewed articles written in English that employed a quantitative approach to IoT health care technology adoption. Studies were excluded if they did not report the significance of relationships, involved technologies without IoT features or were outside the scope, or examined target variables irrelevant to the analysis. The weight analysis identified the pathways with the most significant effects. A meta-analysis using a random-effects model was conducted to estimate combined effect sizes and their statistical significance. The results from both methods were then integrated to visualize the most frequently used theoretical frameworks. Risk of bias and heterogeneity were assessed using a funnel plot, Egger regression test, the I2 statistic, and subgroup analysis, which indicated no strong evidence of publication bias but revealed a high level of heterogeneity.

Results: Analysis of 115 datasets from 109 papers identified the Technology Acceptance Model and the Unified Theory of Acceptance and Use of Technology (UTAUT) as the primary frameworks for explaining IoT adoption in health care. Incorporating context-specific variables—such as health consciousness, innovativeness, and trust—into these traditional technology acceptance frameworks enhances the understanding of IoT adoption. Although high heterogeneity suggests a need to refine theoretical models to account for regional contexts, universal adoption drivers such as performance expectancy and effort expectancy remain consistent.

Conclusions: Behavioral intention is the most frequently studied variable in IoT health care adoption, whereas attitude, performance expectancy, effort expectancy, and task-technology fit remain underexplored. While adoption theories from the information systems field, such as the TAM, are predominantly used, integrating context-specific constructs and theories—such as trust and innovativeness—can provide deeper insights into IoT adoption in health care. The strongest and most consistent predictors of behavioral intention were attitude, performance expectancy, habit, self-efficacy, functional congruence, and benefits. Additionally, social influence, facilitating conditions, trust, and aesthetic appeal demonstrated promising or strong effects. By contrast, variables such as privacy and security, barriers, vulnerability, severity, compatibility, financial cost, health, and technology anxiety were generally inconsistent or not statistically significant.

KEYWORDS

IoT health care; internet of things; individual adoption; weight-analysis; meta-analysis

Introduction

The integration of the Internet of Things (IoT) into health care has revolutionized the industry by introducing a new paradigm of connectivity and data exchange, driven by rapid advancements in IoT, artificial intelligence, and machine learning [1-3]. This era, known as Healthcare 4.0, can be leveraged to enhance acute disease care, manage chronic diseases, and support self-health management [4]. The COVID-19 pandemic accelerated the adoption of user-friendly IoT devices [5-7], with wearable medical devices emerging as key allies by offering real-time health monitoring, continuous data transmission, and advanced remote health management [8-10].

Globally, the integration of IoT in health care has enhanced efficiency, improved patient care, and generated significant economic value [11,12]. By 2029, the global IoT health care market volume is projected to reach US $134.40 billion [13]. This indicates strong, sustained growth driven by the increasing adoption of IoT technologies in health care around the globe [13,14]. For instance, China has made significant progress in integrating health information technologies into the health care system, driven by initiatives such as “Internet Plus Health Care” and the “Healthy China 2030” plan [15-17]. The United States leads in IoT and intelligent health care system development, supported by substantial investments and a robust ecosystem of startups and tech companies driving advancements in artificial intelligence and IoT [18-20]. Europe also shows considerable progress, emphasizing regulatory frameworks, standardization, and interoperability to foster innovation and data protection [21,22].

While IoT holds considerable promise to transform health care by reducing costs and improving access, understanding the factors influencing its adoption requires more focused research [23]. Although literature reviews with a quantitative approach have examined technology adoption in health care, existing meta-analyses that include technologies with IoT features remain fragmented, as they have largely focused on broader or adjacent technological domains and have typically emphasized a specific adoption model. For instance, meta-analyses on mobile health have focused on the Unified Theory of Acceptance and Use of Technology (UTAUT) [24] and the Technology Acceptance Model (TAM) [25]. Meta-analyses on eHealth have predominantly focused on the TAM [26] and continuance intention [27]. Meta-analyses specific to smart wearable health care devices have examined attitude and intention using UTAUT and TAM [28], as well as the effects of perceived usefulness and perceived ease of use on intention, with a focus on Hofstede’s cultural dimensions as moderators [29]. Taken together, these studies often treat health care technology adoption in general terms and do not account for the unique characteristics of IoT.

Our study addresses this gap by providing a comprehensive meta-analysis and a weight analysis specifically focused on IoT adoption in health care. We synthesize findings from primarily quantitative articles on the adoption of IoT in health care, particularly on interconnected devices that monitor and transmit real-time health care data, enabling smarter solutions [5], such as smart sensors, remote monitoring devices, and health-focused IoT platforms. Our meta-analytic approach integrates findings from different theoretical perspectives, including technology adoption models such as the TAM and UTAUT and health-specific models such as the Health Belief Model (HBM), allowing for a more holistic understanding of adoption dynamics in health care contexts. Moreover, our dual-method approach, combining meta-analysis with weight analysis, identifies the strongest and most reliable predictors of adoption and maps the theoretical foundations most frequently and effectively used in this field. This analysis goes beyond prior reviews, offering new evidence-based insights to guide health care technology developers, practitioners, and researchers. The objectives of this study are, first, to identify key predictors of IoT health care adoption through a comprehensive meta-analysis and weight analysis, and second, to determine the most influential and empirically supported theories used to explain IoT adoption in health care settings.

Methods

Overview

We performed a meta-analysis to examine the factors influencing the adoption of IoT technologies in health care, synthesizing findings from a range of quantitative studies. By focusing on primary quantitative research articles, we aimed to identify the most significant predictors and the theoretical models most commonly used to explain IoT adoption in health care settings.

Information Sources and Search Strategy

This meta-analysis followed PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines [30]. The literature search was conducted using a keyword-based search across the Web of Science and PubMed databases to identify studies examining IoT adoption in health care. The search strategy incorporated title, abstract, and keyword searches, using Boolean operators (AND and OR) and database-specific filters. The keywords used in our search were related to IoT technology, relevant variables, quantitative methods, and exclusion criteria (Table 1). We included records published up to the end of 2024. The complete search strategy, including search terms and Boolean logic, is provided in Multimedia Appendix 1.

Table 1. Map for the keyword search in online databases.

Relevant terms	Relevant variables and theories	Methodologies	Exclusion of irrelevant topics
Internet of Things	Intention to adopt	Structural equation	Systematic
IoT	Behavioral intention	Structural equation modeling	Literature review
Smart	Acceptance	Partial least squares structural equation modeling	Postadoption
Intelligent	Adopt	Partial least	Meditation
Health care wearable device	Adoption	Path analysis	Contact tracing app
Medical wearable technology	Using	Regression	Fitness app
Health management	Use	N/A[a]	Electronic health record
Health measurement	Usage	N/A	Telemedicine
N/A	Intention to use	N/A	Mindfulness app
N/A	Unified Theory of Acceptance and Use of Technology 2	N/A	N/A
N/A	Unified Theory of Acceptance and Use of Technology	N/A	N/A
N/A	Technology Acceptance Model	N/A	N/A

[a]N/A: not applicable.

Selection Criteria

Initial screening was conducted using database filters. In the second screening, 2 (IV and MNZ) independent reviewers assessed the titles and abstracts for relevance, resolving disagreements through discussion or arbitration by a third reviewer. The full-text screening followed the same procedure. The reports assessed for eligibility were exported to an Excel (Microsoft Corporation) file, and all included papers were imported into Zotero (Corporation for Digital Scholarship), which is a reference management software. When a paper was unavailable, the authors were contacted.

Inclusion criteria comprised peer-reviewed articles with a quantitative approach to health care technology adoption written in English. Reasons for exclusion included not reporting the significance of the relationships between variables; the technology lacking IoT features or being unrelated to health care; the target variables being unrelated to adoption or focusing solely on postadoption behaviors; and studies lacking empirical data or reporting qualitative results only. The workflow and search conditions are depicted in more detail in the “Results” section.

Data Extraction

A standardized data extraction form was developed before data extraction. Data extraction was performed in Excel, and for each article, we detailed the study characteristics, methodology, type of technology, and the effects measured across multiple paths. The extracted aspects and their descriptions are provided in Table S1 in Multimedia Appendix 1. We assessed paper quality by examining the publishing journal metrics, the methods employed, sample size, and the scales used to measure each construct. The standardized β coefficients were extracted as the primary effect measure. As some authors used different names to represent the same variable, several variables had to be merged to conduct our analysis. This process was carried out by reading each variable definition and identifying the items used to measure them. Examples of variable mergers are provided in Table S2 in Multimedia Appendix 1, and the individual studies included in the analysis are detailed in Table S3 in Multimedia Appendix 1.

Descriptive Analysis

We extracted metadata from each study to perform a descriptive analysis of publication trends, journal quality, and research domains. Data on publication year were used to assess the chronological distribution of studies. To evaluate journal quality, we matched each journal with its SCImago Journal & Country Rank classification and categorized them into quartiles (Q1-Q4). The disciplinary scope of the journals was identified based on their SCImago subject area classifications. We also recorded the journal title and publication frequency to identify the journals that published the most research. Country-level data were extracted based on the origin of the study sample or study location. We computed the number of studies and total sample sizes per country to identify regions with the highest research activity. To understand the theoretical foundations employed across studies, we reviewed each article’s methodology and coded the theories used to model technology adoption behavior. We also recorded whether these models were used independently or in combination (eg, UTAUT extended with Protection Motivation Theory [PMT] constructs).

Weight Analysis

The weight analysis was conducted to uncover the predictive power of independent variables [31]. This weight provides a measure of the relative importance or consistency of statistical significance for each variable across multiple analyses. For the weight-analytic approach, we focused on the influence of each independent variable on several dependent variables and limited our analysis to relationships investigated 3 or more times

[32,33]. The weight (W_i) of an independent variable i is calculated as the ratio of the number of times it was found to be statistically significant (S_i) to the total number of times it was examined (E_i), as expressed in the following equation:

$$W_i = S_i/E_i$$

Meta-Analysis

Meta-analyses allow us to quantitatively compare effect sizes across relationships between constructs using suitable metrics to capture these effect sizes, including standardized regression coefficients [34,35]. This analysis followed best practices outlined previously [36-38]. In our study, the necessary inputs for performing the meta-analysis were the standardized regression coefficients (β) and the sample sizes for each relationship examined 3 or more times across studies. Following the approach of Peterson and Brown [37], β values were transformed into approximate correlation coefficients as $r=\beta+0.05$, where $\lambda=1$ [37]. All correlation coefficients were Fisher z-transformed to stabilize variance, and SEs were computed.

A random-effects model was used to account for both within- and between-study variance, justified by the heterogeneity in study populations, methods, and contexts. Random-effects weights were calculated using the DerSimonian and Laird model, and weighted mean effect sizes were computed using inverse-variance weights, which use tau-squared (τ^2) [39,40]. Heterogeneity was assessed using the Q statistic and the I^2 index [41]. We also calculated the lower and upper bounds of the 95% CIs, z scores, and 2-tailed P values to assess statistical significance and interpret the magnitude of the observed effects. Final pooled effect sizes and CIs were then back-transformed from Fisher z to the correlation coefficient metric (r). All calculations were performed manually in Excel.

Publication Bias Analysis

The Egger test was used to statistically examine the presence of publication bias by regressing the standard normal deviate on precision [42]. The analysis was performed using Excel's data analysis regression tool, which applies standard ordinary least squares regression, and a significant intercept ($P<.10$) was interpreted as evidence of asymmetry and possible publication bias. A funnel plot was constructed to visually assess publication bias using the tool Meta-Essentials [43]. The trim-and-fill method was used to estimate the number and influence of missing studies. Heterogeneity for the included studies was assessed using the I^2 statistic, where a value over 75% is interpreted as substantial heterogeneity, using the following formula, where k is the number of studies and Q the Cochran Q statistic:

$$I^2 = \max(0; \{Q - [k - 1]\}/Q) \times 100\%$$

To evaluate regional bias, we conducted a subgroup analysis with 2 groups: one comprising studies conducted in China and the other comprising studies conducted in the remaining countries. For each group, we calculated the combined effect sizes, SEs, CI lower and upper limits, and the I^2 statistic.

Combining Weight and Meta-Analysis Results: The Most Used Adoption Models

To synthesize the relative strength of relationships across studies and adoption models, we combined the results from the weight analysis and meta-analysis. The weight analysis assessed the consistency and prominence of specific predictors by calculating the proportion of studies that reported statistically significant relationships for each path, referred to as the weight. In parallel, the meta-analysis provided pooled average effect sizes and significance levels across studies using a random-effects model. This dual approach offers a more comprehensive understanding of which constructs consistently predict behavioral intention or usage in the context of IoT adoption in health care and enables an evidence-based comparison of theoretical frameworks based on empirical support.

We then visually mapped the structure of each adoption model, such as the TAM and the HBM, using conceptual diagrams. In these figures, each arrow represents a theoretical path, and its thickness reflects the weight. Thicker lines indicate a weight above 0.700, representing paths supported by a high proportion of studies. The numerical values attached to each path represent the average effect size based on the random-effects meta-analysis, along with the corresponding P value. This dual representation enables a clearer comparison between the predictive strength (effect size) and consistency (weight) of each construct within and across models.

Results

Descriptive Analysis

Papers on IoT health care adoption show an increasing trend, with 89 of the 109 (81.7%) studies in our analysis published between 2020 and 2025, and the earliest published in 2011. According to the SCImago Journal & Country Rank, most papers appeared in Q1 journals (n=63, 57.8%), followed by Q2 (n=36, 33%) and Q3 (n=10, 9.2%), with no papers published in Q4. These studies span major research areas related to health and medicine, information systems, and computer science. In total, 75 unique journals were represented, with *PLoS One* (n=6), *Frontiers in Public Health* (n=5), *Technological Forecasting and Social Change* (n=5), and *International Journal of Environmental Research and Public Health* (n=4) being the most frequently appearing journals (see Table S3 in Multimedia Appendix 1).

In our analysis of 109 studies (see Figure 1), we identified 115 unique datasets totaling 46,508 individuals (see Table S1 in the Multimedia Appendix 1). Studies conducted in China, South Korea, and the United States accounted for a large portion of the total sample and represented the greatest number of publications (see Table 2).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.

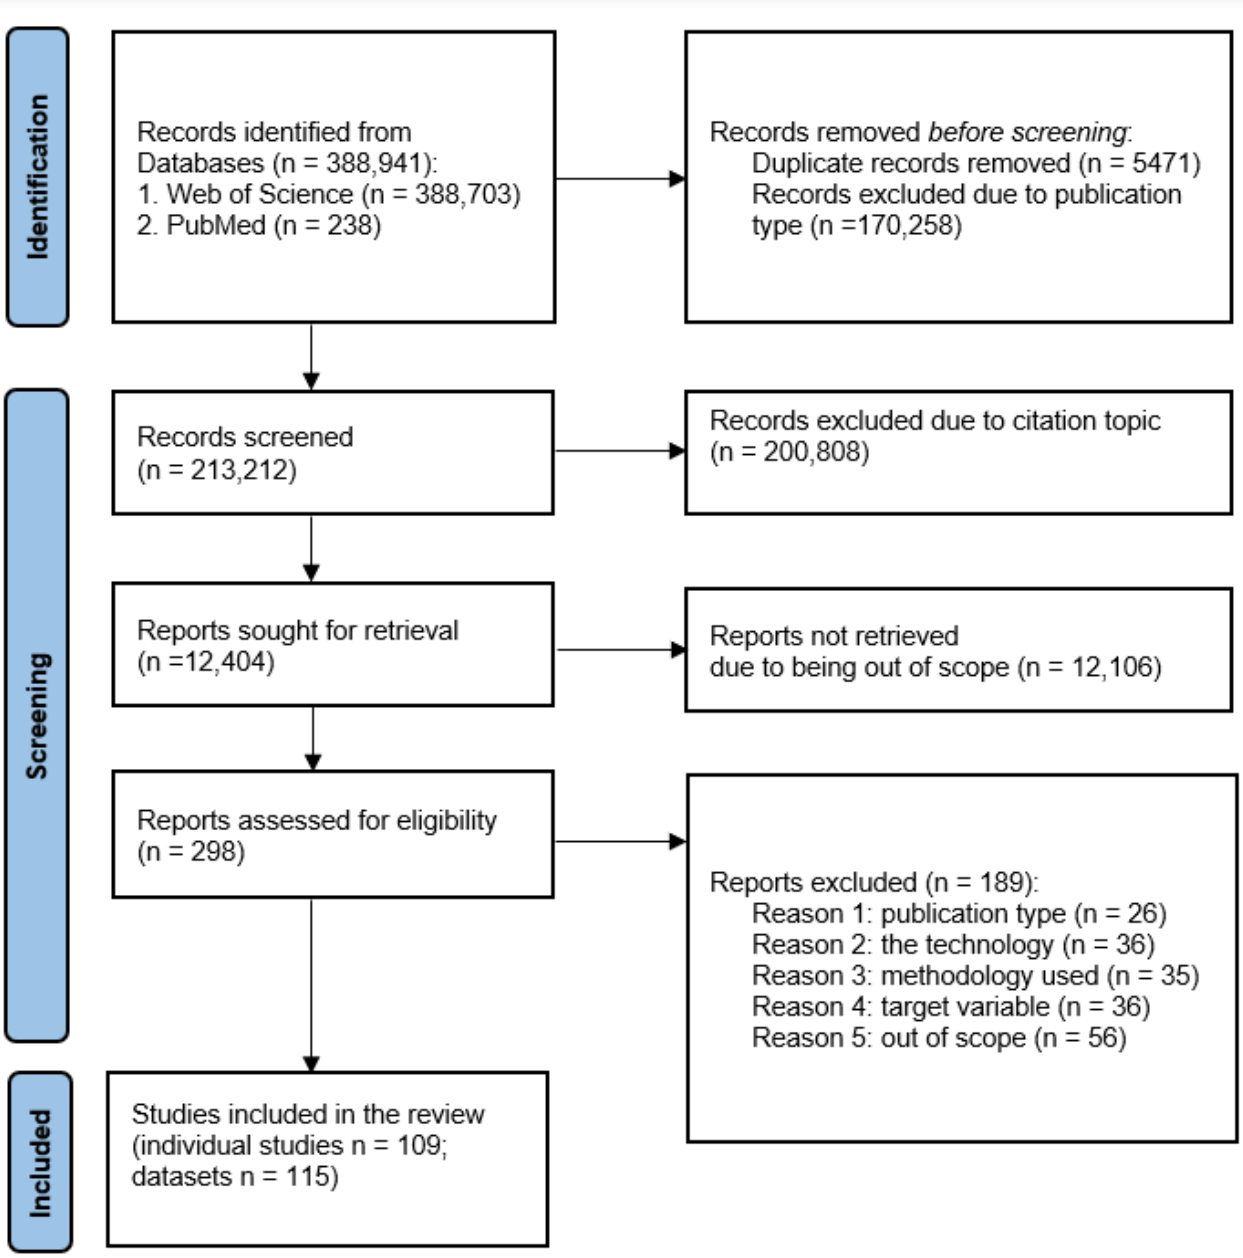

Table 2. Number of papers and total sample size per country.

Country	Dataset count (N=115)	Sample size (N=46,508)
China	39	17,068
South Korea	12	6406
The United States	9	5445
India	8	2924
Taiwan	8	1896
The Kingdom of Saudi Arabia	5	1798
Bangladesh	2	1213
Pakistan	3	1194
Turkey	4	1040
Ghana	2	965
Multiple countries	4	1312
Indonesia	1	772
Malaysia	2	628
France	3	515
Iraq	1	465
Oman	2	442
Romania	1	440

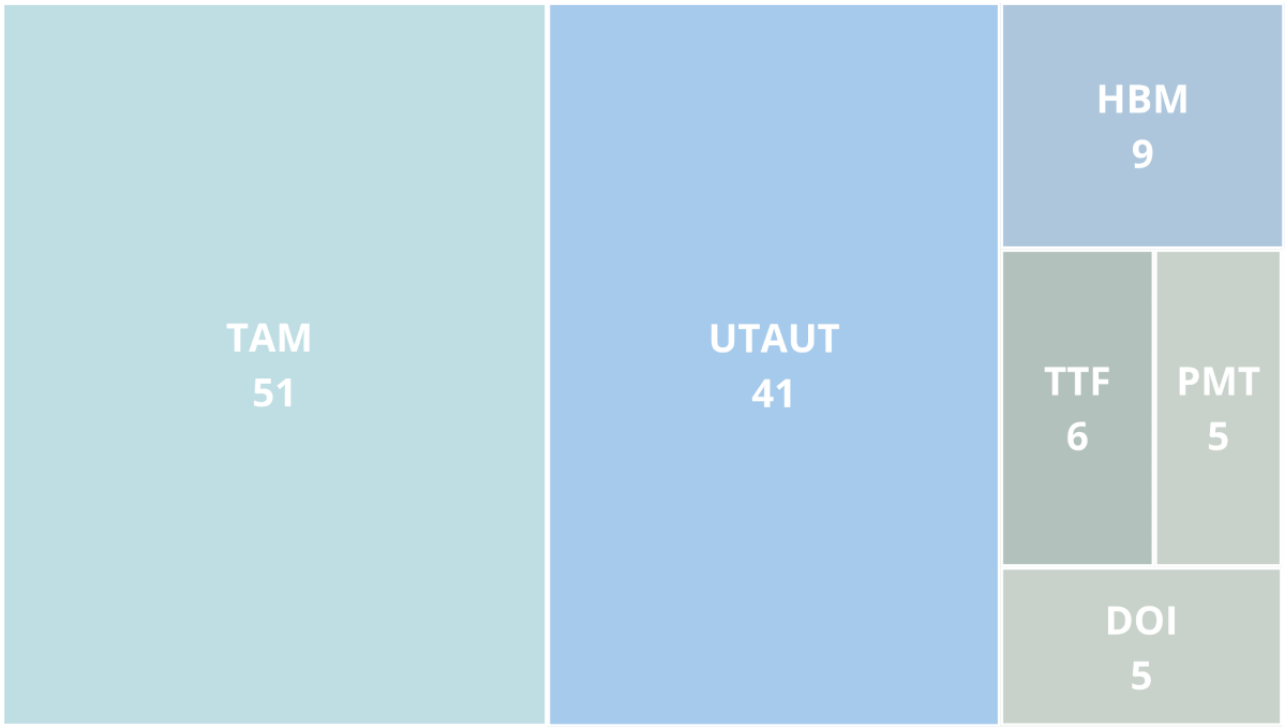
Switzerland	2	323
Singapore	1	306
Nepal	1	280
Japan	1	233
Italy	1	212
Jordan	1	200

Considering the theories addressed in each paper, the TAM and the UTAUT have been extensively examined compared with other theories (see Figure 2). These models serve as the theoretical foundation for 92 of the 109 (84.4%) papers included in our study. Other theories, such as the HBM, PMT, Task-Technology Fit (TTF) Theory, Privacy Calculus Theory, Diffusion of Innovation Theory, and Theory of Planned Behavior, have also been addressed—sometimes as the primary theoretical foundation and other times to extend the TAM or UTAUT.

Figure 2. Theoretical foundation of the papers included in our analysis. DOI: Diffusion of Innovation; HBM: Health Belief Model; PCT: Privacy Calculus Theory; PMT: Protection Motivation Theory; TAM: Technology Acceptance Model; TPB: Theory of Planned Behavior; TTF: Task-Technology Fit; UTAUT: Unified Theory of Acceptance and Use of Technology.



Weight Analysis

A weight analysis examines the strength of the relationship between an independent and a dependent variable. The weights of the identified relationships are analyzed and presented in Table 3. The significance of a relationship's weight is calculated by dividing the number of instances in which the relationship is statistically significant by the total number of studies that investigated it. A weight of 1 indicates that the relationship is significant in all examined studies, whereas a weight of 0 indicates that it is not significant in any of the studies.

Table 3. Identified paths with the nonsignificant paths, the significant relationships, the total paths, and the respective weights.

Dependent and independent variables	Significant	Nonsignificant	Total	Weight=significant/total
Attitude				
Effort expectancy	19	4	23	0.826
Barriers	4	2	6	0.667
Benefits	3	0	3	1
Facilitating conditions	4	0	4	1
Performance expectancy	20	2	22	0.909
Privacy and security	2	1	3	0.667
Social influence	6	1	7	0.857
Behavioral intention

In the context of technology adoption at the individual level, independent variables are considered “well-utilized” if they have been tested at least 5 times. Variables tested fewer than 5 times but with a weight of 1 are regarded as “promising” predictors [31]. To be classified as a “best” predictor, an independent variable must have a weight of 0.800 or higher and must have been examined at least 5 times [31].

In our research, we analyzed the impact of several independent variables on the dependent variables attitude, behavioral intention, actual use, performance expectancy, effort expectancy,

and TTF. For the weight analysis, we included relationships that were examined 3 or more times, resulting in 67 relationships and 31 unique predictors that met this criterion. The most studied target variable was behavioral intention, with 25 predictors.

In our research, the relationships considered the "best" predictors for attitude are effort expectancy, performance expectancy, and social influence, as each has more than 5 identified relationships and a weight greater than 0.800. For behavioral intention, the best predictors are attitude, performance expectancy, habit, self-efficacy, functional congruence, reliability, and benefits. Aesthetic appeal, with a perfect weight of 1, is considered a promising predictor of intention due to the limited number of studies. Social influence, facilitating conditions, and trust, although not classified as the best predictors, remain important because their weights exceed 0.700 and are supported by a substantial number of studies. It is also noteworthy that privacy and security, barriers, vulnerability, severity, compatibility, and financial cost yielded more inconsistent results, with many studies reporting statistically nonsignificant findings.

For actual behavior, behavioral intention is the best predictor, while facilitating conditions and social influence are considered promising predictors due to the limited number of studies and their perfect weight of 1. For the target variable performance expectancy, effort expectancy, TTF, and self-efficacy are the best predictors, and convenience and innovativeness are promising predictors. Health consciousness, social influence, reliability, and compatibility, although not classified as the best predictors, remain important because their weights exceed 0.700 and they are supported by multiple studies. For effort expectancy, facilitating conditions, innovativeness, self-efficacy, and compatibility are the best predictors, while reliability and TTF are promising predictors. For the target variable TTF, technology characteristics is identified as a promising predictor.

Meta-Analysis

The results of the meta-analysis are presented in Table 4 and include all studies that reported standardized path coefficients or β values. All the best predictors identified in our study are statistically significant ($P<.001$), except for reliability ($P=.49$) as a predictor of intention, as well as some of the important and promising predictors. Notably, barriers ($P=.46$) is not a significant predictor of attitude. Health, technology anxiety ($P=.78$), financial cost ($P=.16$), and barriers ($P=.84$) are not significant predictors of behavioral intention. For actual behavior, social influence ($P=.15$), innovativeness ($P=.28$), health consciousness ($P=.61$), vulnerability ($P=.31$), and effort expectancy ($P=.09$) are not significant predictors. Privacy and security ($P=.05$) and barriers ($P=.21$) are not significant predictors of performance expectancy, while privacy and security ($P=.29$) and image ($P=.06$) are not significant predictors of effort expectancy. Finally, task characteristics ($P=.12$) is not a significant predictor of TTF.

Table 4. Meta-analysis results calculated using a random-effects model and presented back-transformed.

Combining Weight and Meta-Analysis Results: The Most Adopted Models in Research

Figure 3 presents the weight and meta-analysis for the TAM, which explains how users adopt and use technology, emphasizing the influence of external variables on perceived usefulness (performance expectancy) and perceived ease of use (effort expectancy), which in turn affect attitudes, behavioral intentions, and actual technology usage [44,45]. Performance expectancy is the best and statistically significant predictor of both attitude (β=.532, *P*<.001) and behavioral intention (β=.339, *P*<.001). Attitude is the best predictor and has a significant impact on behavioral intention (β=.573, *P*<.001), while behavioral intention is the best and significant predictor of actual behavior (β=.563, *P*<.001). Effort expectancy is the best predictor and strongly influences performance expectancy

(β=.380, *P*<.001) and attitude (β=.286, *P*<.001). Health consciousness (β=.188, *P*=.03), self-efficacy (β=.578, *P*<.001), innovativeness (β=.279, *P*=.02), and compatibility (β=.222, *P*=.02) are significant predictors of performance expectancy, each with a weight above 0.700. Innovativeness (β=.376, *P*<.001) and facilitating conditions (β=.436, *P*<.001) are significant predictors of effort expectancy, also with weights above 0.700.

Figure 3. Weight and meta-analysis for the Technology Acceptance Model. Thicker paths indicate relationships with greater weight—that is, the strongest predictors (weight≥0.700). Higher weights are therefore represented by thicker lines. The numbers on the paths denote the mean β coefficients along with their significance levels.

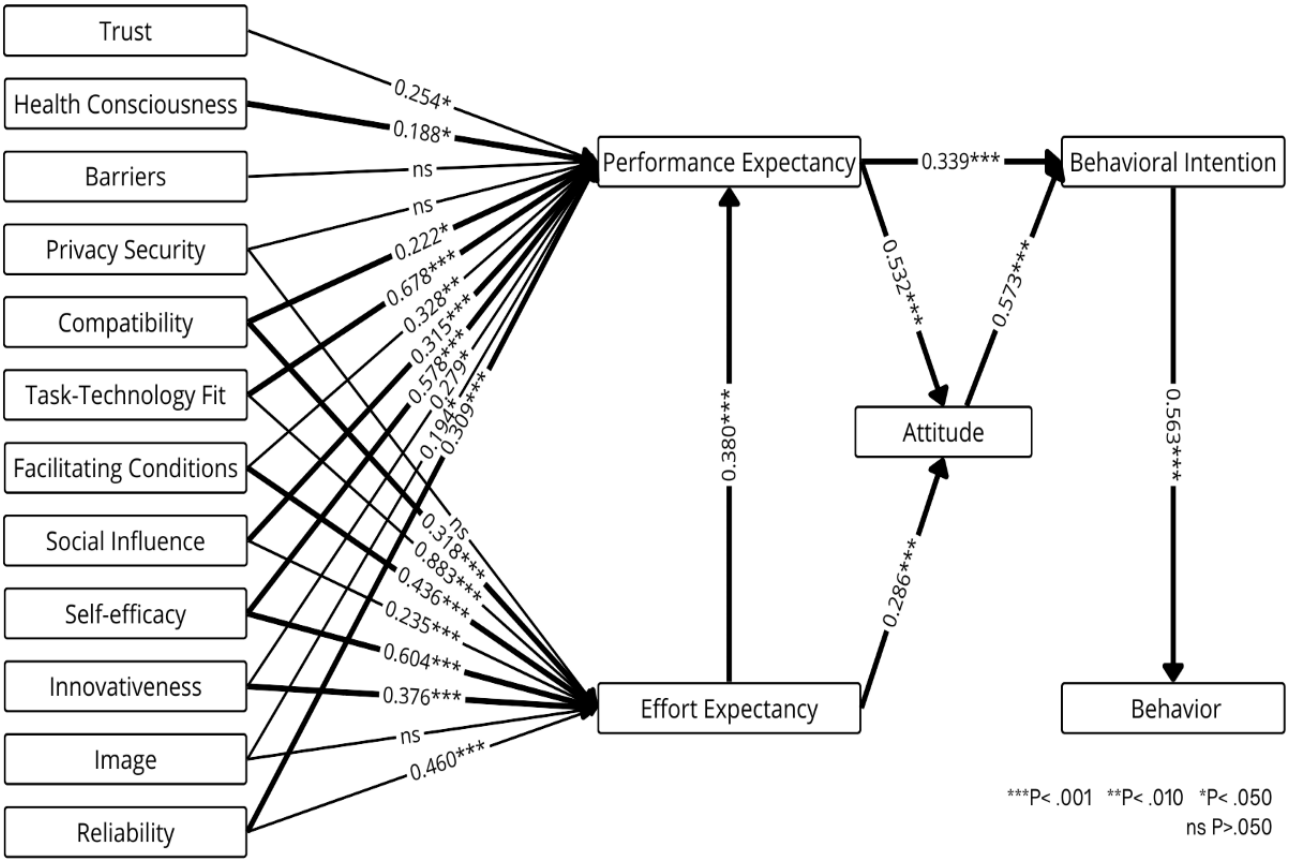

Figure 4 presents the weight and meta-analysis for the Unified Theory of Acceptance and Use of Technology (UTAUT), which explains how users adopt and use technology by assessing the impact of key predictors on behavioral intention and actual behavior [46,47]. Facilitating conditions (β=.863, *P*<.001) and behavioral intention (β=.563, *P*<.001) are significant predictors of actual behavior, while social influence is not. Behavioral intention is significantly influenced by performance expectancy (β=.339, *P*<.001), social influence (β=.254, *P*<.001), facilitating conditions (β=.198, *P*<.001), and habit (β=.377, *P*<.001), all with weights above 0.700. Effort expectancy (β=.185, *P*<.001) and hedonic motivation (β=.202, *P*<.001) are also statistically significant predictors of intention; however, financial cost is not.

Figure 4. Weight and meta-analysis for the Unified Theory of Acceptance and Use of Technology. Thicker paths indicate relationships with greater weight—that is, the strongest predictors (weight≥0.700). Accordingly, higher weights are represented by thicker lines. The numbers on the paths denote the mean β coefficients along with their significance levels.

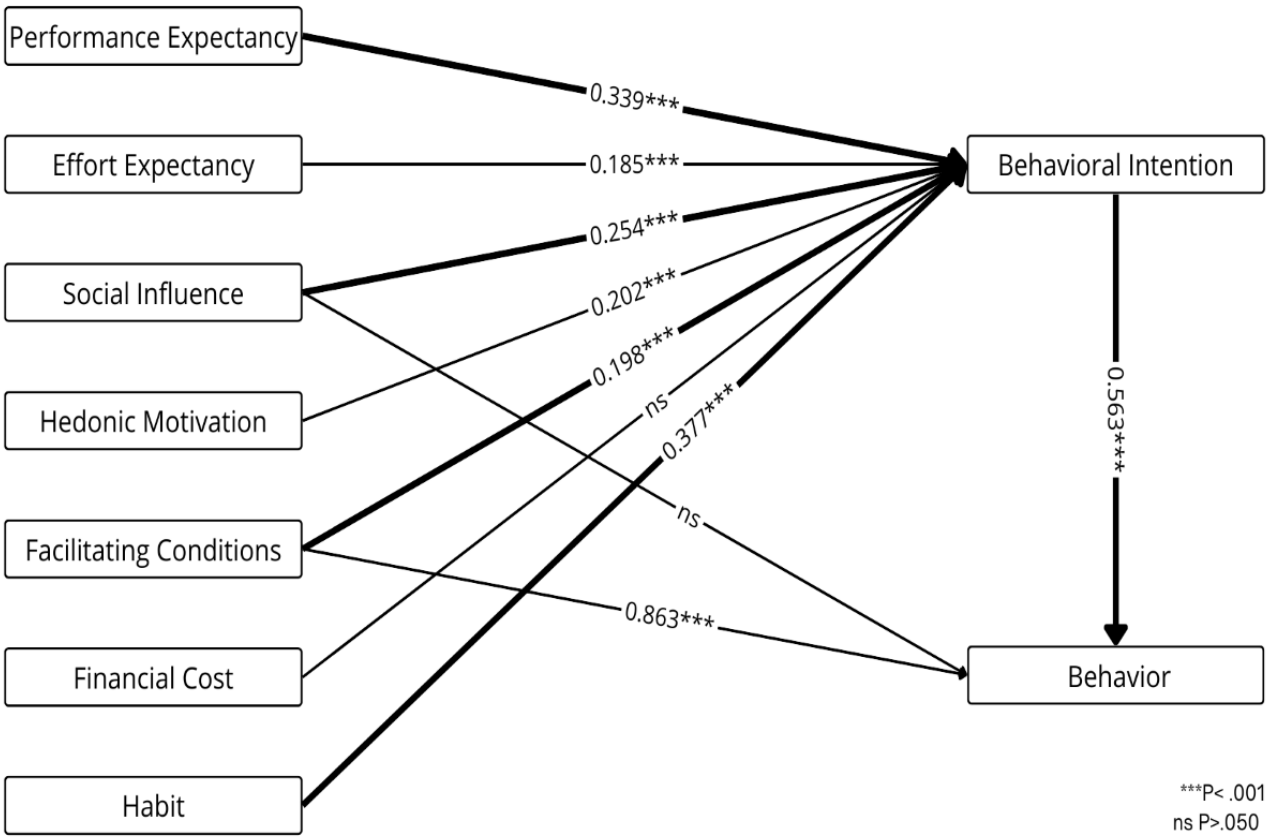

Figure 5 presents the weight and meta-analysis combining the HBM and PMT, which explain individuals' engagement in health-related behaviors. Both models emphasize the role of perceived threat, such as vulnerability and severity, and the evaluation of coping strategies, such as benefits, barriers, response efficacy, and self-efficacy, in shaping motivation to take protective or preventive actions [48-50]. The results indicate that, compared with other technology adoption models, the predictive power of health-related constructs is weaker and less consistent. Severity (β=.120, *P*=.04) and vulnerability (β=.101, *P*=.03) have weak weights on behavioral intention and exert a small but significant impact. Performance expectancy (β=.339, *P*<.001) and self-efficacy (β=.318, *P*<.001), which are also used in other technology-related adoption models, are the best predictors and have a significant impact on behavioral intention. Barriers do not have a significant impact (*P*=.84), whereas benefits exhibit a strong, statistically significant effect (β=.309, *P*=.006). It is also relevant to mention 2 additional predictors directly related to the health context but not part of the key components of these theories. First, health condition, which refers to the perception of having good health, has a weak and nonsignificant impact (*P*=.22) on intention. Second, health consciousness has a statistically significant impact on intention (β=.298, *P*<.001) but does not significantly influence behavior (*P*=.61).

Figure 5. Weight and meta-analysis for the Health Belief Model and Protection Motivation Theory. Thicker paths indicate relationships with greater weight—that is, the strongest predictors (weight≥0.700). Accordingly, higher weights are represented by thicker lines. The numbers on the paths denote the mean β coefficients along with their significance levels.

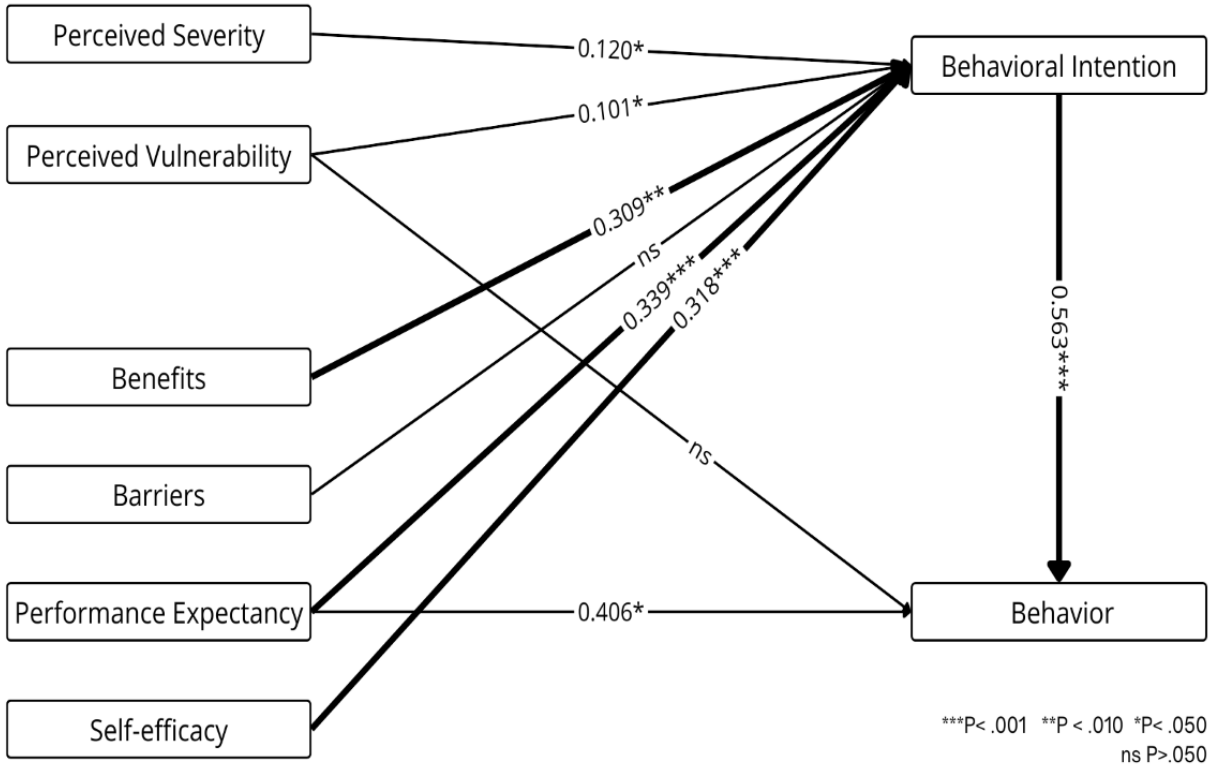

Figure 6 illustrates the TTF model, which examines how well technology aligns with users' tasks to enhance perceived usefulness and adoption [51]. Only part of the theory is presented, as it remains understudied in the context of IoT in health care. The results show that TTF is a significant predictor of performance expectancy (β=.883, *P*<.001) while being classified as a promising predictor. The studies suggest that task characteristics do not have a significant impact on the fit between the task and the technology. However, technology characteristics are a promising and significant predictor (β=.554, *P*<.001).

Figure 6. Weight and meta-analysis for the Task–Technology Fit model. Thicker paths indicate relationships with greater weight—that is, the strongest predictors (weight≥0.700). Accordingly, higher weights are represented by thicker lines. The numbers on the paths denote the mean β coefficients along with their significance levels. ns: not significant.

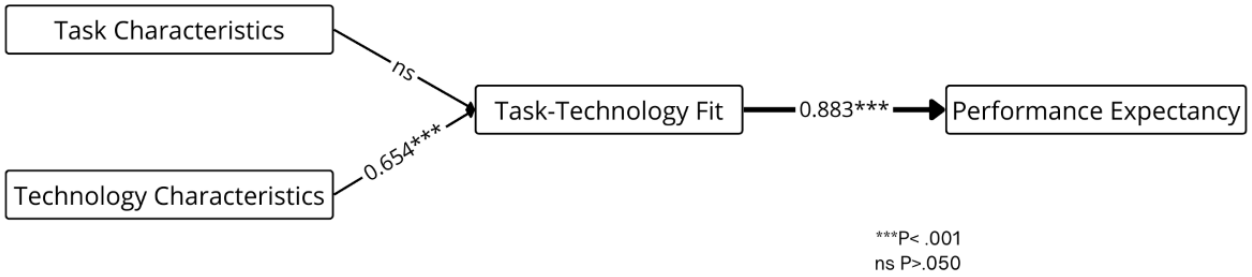

Figure 7 presents the weight and meta-analysis of the Privacy Calculus Theory, which explores the trade-off between benefits and privacy [52]. The results indicate that trust (β=.294, *P*<.001) has a significant positive influence on behavioral intention and is classified as the best predictor. Privacy and security (β=–.110, *P*=.02) exhibits a significant negative effect on behavioral intention; however, the weight is small, suggesting that privacy and security concerns may not be a strong inhibitor of adoption.

Figure 7. Weight and meta-analysis for Privacy Calculus Theory. Thicker paths indicate relationships with greater weight—that is, the strongest predictors (weight≥0.700). Accordingly, higher weights are represented by thicker lines. The numbers on the paths denote the mean β coefficients along with their significance levels.

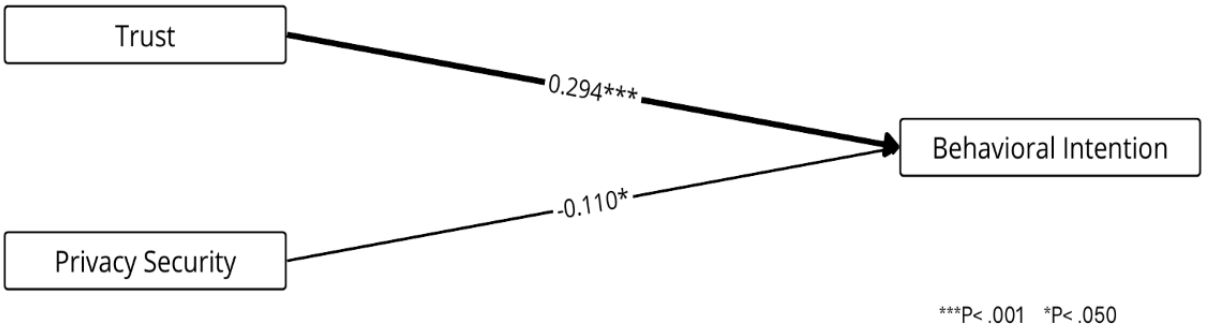

Figure 8 presents the weight and meta-analysis of the Theory of Planned Behavior, which posits that attitude, subjective norms, and behavioral control influence behavioral intention and, subsequently, behavior [53]. Both attitude (β=.573, *P*<.001) and self-efficacy (β=.318, *P*<.001) are the best and strongest predictors of behavioral intention.

Figure 8. Weight and meta-analysis for the Theory of Planned Behavior. Thicker paths indicate relationships with greater weight—that is, the strongest predictors (weight≥0.700). Accordingly, higher weights are represented by thicker lines. The numbers on the paths denote the mean β coefficients along with their significance levels.

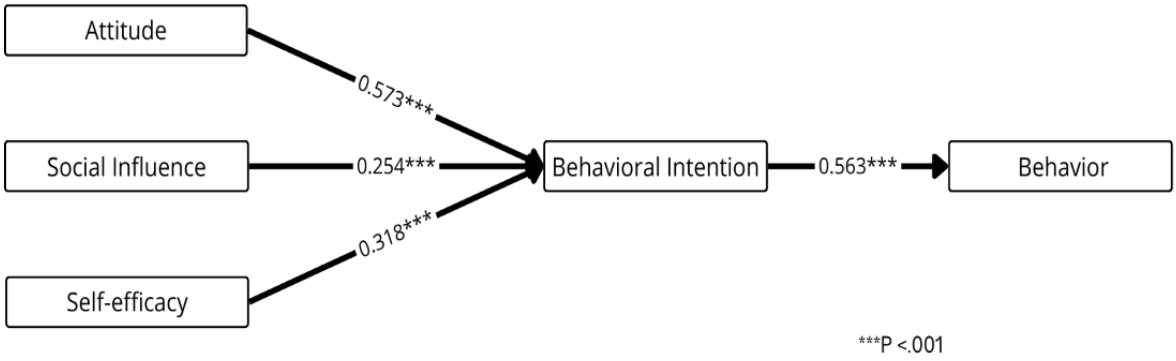

Figure 9 presents the weight and meta-analysis of the Innovation Diffusion Theory, which explains the diffusion of new technologies through 5 dimensions [54]. Relative advantage (performance expectancy; β=.185, *P*<.001), complexity (effort expectancy; β=.185, *P*<.001), and compatibility (β=.123, *P*<.001) were found to be significant predictors. Image was not a significant predictor, and trialability and observability have not been sufficiently studied in the literature.

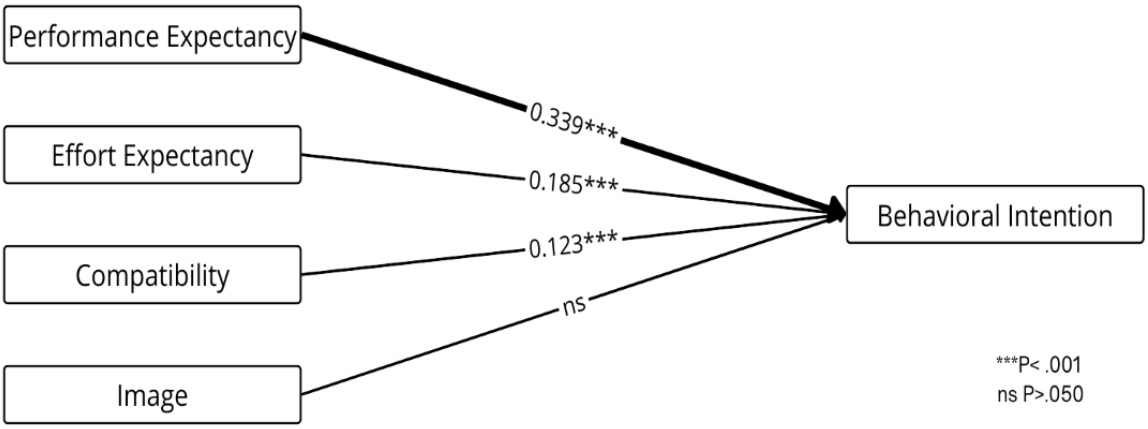
Figure 9. Weight and meta-analysis for the Diffusion of Innovation theory. Thicker paths indicate relationships with greater weight—that is, the strongest predictors (weight≥0.700). Accordingly, higher weights are represented by thicker lines. The numbers on the paths denote the mean β coefficients along with their significance levels.



Evaluation of Publication Bias

This section evaluates the presence of publication bias and assesses the normality of the datasets used in the meta-analysis to ensure the reliability of the synthesized findings. Publication bias refers to the tendency for studies with significant or positive results to be more likely to be published, potentially skewing meta-analytic outcomes [55]. To ensure the robustness of our findings, we evaluated publication bias following the approach of Harrison et al [55], which suggests that a single criterion can provide a more sensitive and appropriate test. We focused our analysis on one of the most widely examined relationships in our dataset: the relationship between performance expectancy and behavioral intention, which was reported in 77 studies (Table 5).

Table 5. Studies (n=77) showing the effect size (z), SE (z), sample size, z score, Q component, significance of the paths between performance expectancy and behavioral intention, and the country.

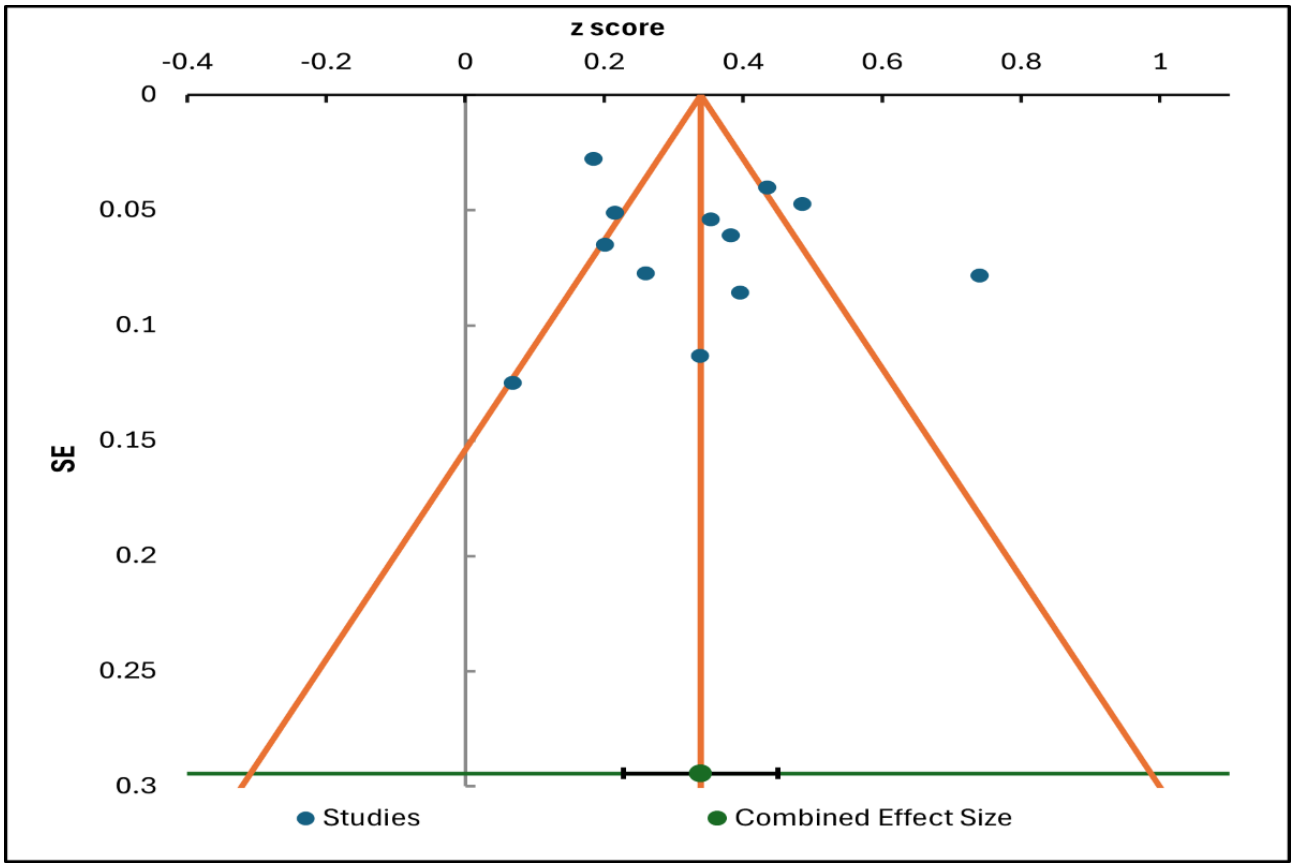
To assess the presence of small-study effects and potential publication bias, a funnel plot was generated, and an Egger regression test was conducted. The funnel plot was constructed to visually evaluate publication bias [42], with the SE plotted on the y-axis instead of sample size, as this enhances the detection of asymmetry [36]. In an ideal funnel plot, symmetry is expected, with smaller studies exhibiting larger SE scattered evenly on both sides of the pooled effect size. In Figure 10, the studies display a somewhat asymmetrical distribution. Larger studies cluster near the combined effect size at the top of the funnel, while smaller studies show greater dispersion, potentially indicating publication bias or underlying heterogeneity. The trim-and-fill method estimates the number of potentially missing studies—often those with nonsignificant or negative results—and imputes them to generate an adjusted combined effect size. In this case, the imputed effect size is slightly smaller than the original estimate, suggesting that the observed meta-analytic effect may be modestly inflated due to the absence of smaller, less favorable studies.

Figure 10. Funnel plot of studies examining the relationship between performance expectancy and behavioral intention.



To statistically assess funnel plot asymmetry, we applied the Egger regression test [42] to evaluate whether smaller studies tend to report larger effect sizes, which can indicate potential publication bias (see Table 6). The test examines the relationship between effect sizes and their SEs to detect small-study effects. The results of the regression analysis showed that the intercept was not statistically significant (α=.381, *P*=.81), indicating no evidence of funnel plot asymmetry or publication bias. However, the slope coefficient was statistically significant (β=.327, *P*<.001), suggesting a positive association between study precision and effect size. While this does not indicate publication bias, it may reflect genuine heterogeneity among the included studies.

The I^2 statistic, which quantifies the proportion of total variation across studies attributable to true heterogeneity rather than sampling error [41], revealed a very high degree of heterogeneity (I^2>93%). This indicates that most of the variability in effect sizes reflects real differences across studies rather than random

sampling error. These differences may arise from variations in study design, measurement tools, participant demographics, cultural contexts, or theoretical frameworks used across the included studies. To further explore the sources of heterogeneity, a subgroup analysis was conducted.

Table 6. Egger - type test for small - study bias, using Excel's Data Analysis Regression Tool, which uses standard ordinary least squares regression.

Regression	Coefficients	SE	*t* test (*df*)	*P* value	95% CI
Intercept (α)	0.381	1.544	0.247 (75)	.81	–2.695 to 3.457
Slope (β)	0.327	0.081	4.044 (75)	<.001	0.166 to 0.489

The subgroup analysis examined whether effect sizes differed between studies conducted in China and those conducted in other countries. By comparing studies from China with those from other regions, we aimed to evaluate potential regional biases, given that a large proportion of the included studies were conducted in China. The results, presented in Table 7, indicate that geographic location has little influence on the overall effect size, as both subgroups exhibit similar results. The combined effect size for studies conducted in China is 0.340 (95% CI 0.272-0.404), while for studies in other countries, it is 0.336 (95% CI 0.279-0.390). However, heterogeneity remained very high in both groups (China: I^2=93%; other countries: I^2=94%), indicating substantial variability even within each subgroup. Therefore, the subgroup analysis addresses concerns about potential bias from the large proportion of studies conducted in China, confirming that the results are largely stable across regions.

Table 7. Subgroup comparison between China and the other countries in our sample.

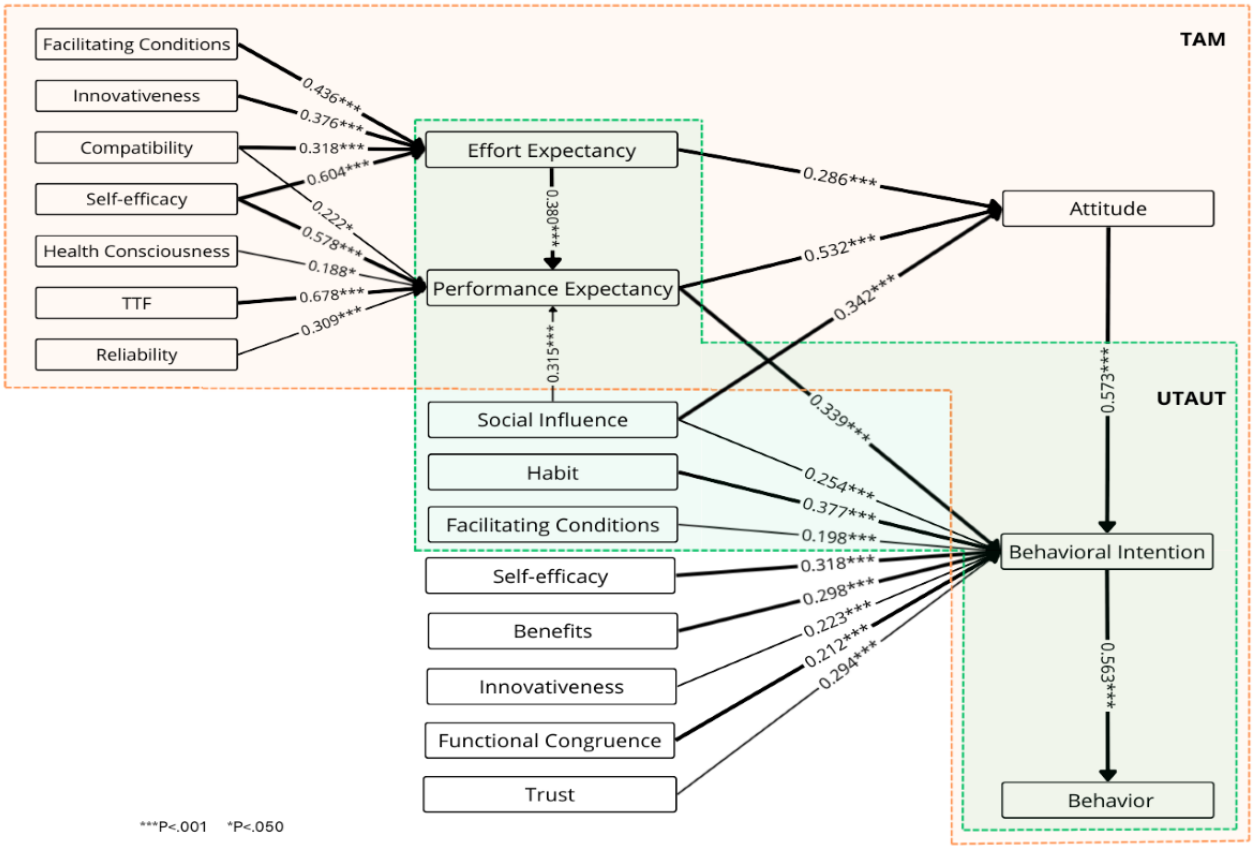
Subgroup	Effect size	*P* value	95% CI	I^2 (%)
China	0.340	<.001	0.272-0.404	92.984
Other countries	0.336	<.001	0.279-0.390	94.355

Discussion

Principal Findings

The study of IoT adoption in health care reveals a diverse landscape of constructs and relationships, providing a comprehensive overview of the factors driving IoT adoption. This study synthesized findings from 109 papers and 115 datasets across various regions, including China, South Korea, the United States, and India, with most studies published in high-ranking journals. The combined weight and meta-analysis identified the best predictors and examined the adoption models most frequently used in IoT health care. Figure 11 highlights the strongest and most consistent predictors, integrating the results of both the meta-analysis and weight analysis.

Figure 11. Best predictors identified in the weight analysis, along with their statistically significant mean β coefficients from the meta-analysis. The strength (weight) of each predictor is represented by the thickness of the line connecting the predictor to the target variable, with thicker lines indicating stronger predictors. The green box denotes constructs from the Unified Theory of Acceptance and Use of Technology framework, and the orange box denotes constructs from Technology Acceptance Model.



Technology acceptance models, such as UTAUT and TAM, have been widely and successfully applied in the context of IoT in health care [56,57], which is unsurprising given that these are the most commonly used technology adoption models, highly cited, and successfully applied across diverse fields and contexts [58,59]. Compared with models such as UTAUT and TAM, where predictors such as performance expectancy and facilitating conditions consistently exhibit strong and reliable effects, the HBM and PMT models struggle to establish robust relationships with behavioral intention. This suggests that relying solely on health-related constructs or health behavior models may not be sufficient to explain health care technology adoption. Therefore, other individual factors, such as innovativeness, external factors, such as social influence, and technological factors, such as performance expectancy, may play a more decisive role [60,61]. Integrating context-specific health variables into robust models such as TAM or UTAUT can, however, provide additional insights. For example, individuals with strong health motivation or health consciousness tend to exhibit higher levels of performance expectancy from IoT health care technologies [62,63].

The findings highlight several key factors influencing effort expectancy and performance expectancy, both of which are central to users' attitudes toward technology. For effort expectancy, the most influential factor was self-efficacy, indicating that individuals who feel more confident in their ability to use the technology tend to perceive it as easier to operate [64,65]. Other important contributors include facilitating conditions, innovativeness, and compatibility, suggesting that a supportive environment, openness to new technologies, and alignment with users' existing values and practices all help reduce the perceived effort required to use IoT in health care [66,67]. For performance expectancy, TTF emerged as the dominant influence, highlighting that when users perceive a strong alignment between the technology and the tasks they need to perform, they are more likely to view it as useful [68,69]. Additionally, health consciousness, self-efficacy, reliability, and compatibility played significant roles, emphasizing the importance of personal health concerns, confidence in usage, trust in the system's dependability, and alignment with users' existing values and practices [63,70]. Together, these findings underscore the relevance of both individual and contextual factors in shaping users' perceptions of a technology's usefulness and ease of use.

Regarding individuals' IoT health care technology adoption journey, the findings reveal that a positive attitude is crucial for successful adoption [71,72]. Efforts to cultivate positive perceptions can be made by leveraging the influence of important figures in individuals' lives and by emphasizing the ease of use and the potential for improved health care outcomes [73-75]. When individuals hold a positive perception of IoT health care, they are more likely to intend to use it, which in turn positively influences actual usage [76,77]. To further enhance behavioral intention, the effectiveness of IoT health

care solutions and the encouragement of health care professionals, family, and friends should be leveraged [78,79]. Additionally, individuals' willingness to try new technologies plays a significant role, as more innovative users are more likely to adopt IoT solutions [80,81].

Trust plays a decisive role in shaping behavioral intentions, reinforcing the notion that users are willing to trade some level of privacy if they perceive a system as secure and reliable [60]. Previous literature has found that individuals are often reluctant to adopt digital health or IoT technologies when they do not trust the provider [82,83]. This perspective may help contextualize the inconsistent results observed for privacy as a predictor of behavioral intention, as a notable proportion of studies reported nonsignificant relationships. Similarly, predictors such as barriers, vulnerability, and financial cost also exhibited higher frequencies of nonsignificant findings in our analysis. These inconsistencies may reflect how these constructs interact with—or are influenced by—the presence of stronger enabling factors. For instance, high perceived usefulness and trust may diminish the observed effects of barriers such as financial cost and privacy, as these factors may become less salient in users' perceptions.

Theoretical Implications

This study makes several contributions to the theoretical understanding of IoT health care adoption by synthesizing findings from diverse quantitative studies and adoption models. The results reinforce the importance of established models such as TAM and UTAUT. They also suggest that integrating variables from other theories—such as health consciousness, innovativeness, and trust—into traditional technology acceptance frameworks can provide deeper insights into how individuals adopt IoT in health care. Behavioral intention is the most studied target variable, while attitude and actual behavior remain underexplored, indicating a gap in existing research on these critical components of the adoption process.

Researchers should further investigate several promising but underexplored predictors that showed perfect weight, suggesting strong yet preliminary evidence of their relevance, to establish their broader applicability. For instance, regarding behavioral intention, the aesthetic appeal of health care technologies shows potential as a strong predictor. For actual behavior, facilitating conditions and social influence are promising predictors that warrant further exploration. In the case of the underexplored TTF theory, technology characteristics appear to be a promising predictor. For performance expectancy, convenience and innovativeness are promising predictors, while for effort expectancy, reliability and TTF show potential as predictors deserving additional investigation.

By contrast, several predictors demonstrated limited or inconsistent relevance to the adoption of IoT in health care. For the outcome attitude, barriers did not have a statistically significant effect. For behavioral intention, predictors such as privacy and security, barriers, vulnerability, severity, compatibility, and financial cost produced inconsistent findings, with many studies reporting nonsignificant results. Specifically, health, technology anxiety, financial cost, and barriers were frequently not significant predictors of behavioral intention. When predicting actual behavior, variables such as social influence, innovativeness, health consciousness, vulnerability, and effort expectancy often failed to reach statistical significance. Regarding performance expectancy, both privacy and security and barriers were not consistently significant, and for effort expectancy, privacy and security and image did not show meaningful effects.

Our findings indicate that regional differences alone do not fully explain the heterogeneity of results. Therefore, when applying the findings of this study, we recommend refining theoretical models to account for contextual factors and implementing practical strategies aligned with the strongest predictors identified, such as performance expectancy and self-efficacy, which can enhance adoption across different settings. Future adoption studies would benefit from incorporating context-specific factors that capture cultural and health care system differences, enabling a better understanding of how these contextual variables influence target outcomes, as either control or moderator variables.

Several regions, particularly in Africa, South America, and Europe, remain underrepresented, highlighting a gap in the literature and the need for future research in diverse settings to improve the generalizability and equity of evidence regarding IoT adoption in health care. Finally, combining qualitative methods, such as interviews and focus groups, is recommended to gain deeper insights. This mixed methods approach can provide a better understanding of user perceptions and experiences, bridging the gap between quantitative results and the complex realities of technology adoption [84,85].

Practical Implications

The findings of this study provide actionable insights for practitioners, policy makers, and technology developers seeking to enhance IoT health care adoption. Key drivers—such as performance expectancy, self-efficacy, social influence, functional congruence, trust, habit, facilitating conditions, benefits, and innovativeness—consistently shape behavioral intention. For example, developers can focus on creating intuitive designs and user-friendly interfaces while emphasizing tangible performance benefits. Health care providers and policy makers can leverage trusted individuals, such as doctors and family members, to encourage adoption.

The availability of resources and infrastructure that enable and support technology use—such as access to devices, technical support, internet connectivity, and integration with health care systems—plays an important role in adoption, as it reduces barriers for individuals starting to use IoT in health care [69,78]. Furthermore, adhering to robust data protection frameworks that ensure transparency from all entities handling health-related data aligns implementation with national and regional regulatory standards and fosters user trust [83,86]. Finally, targeting innovative individuals who are more likely to adopt IoT health care technologies or who already have the habits and skills to use them can further promote technology adoption.

Limitations and Future Research

This study has several limitations that warrant consideration. Our findings reveal a high level of heterogeneity, which is not

fully explained by regional differences; therefore, the pooled estimates should be interpreted with caution. Future research should investigate additional factors that may account for this heterogeneity, such as study design, population characteristics, or model specification, and conduct moderator analyses to better address variability. Additionally, China accounts for a large proportion of the included studies, while several regions—particularly in Africa, South America, and Europe—remain underrepresented. As such, we caution against overgeneralizing our findings to all global contexts. Additionally, while this study synthesizes quantitative findings, it excludes qualitative research, which could provide deeper insights into contextual variability and user experiences influencing adoption. This exclusion may contribute to inconsistencies in the evidence, particularly for understudied predictors such as privacy concerns, perceived vulnerability, and financial cost, which often showed nonsignificant results. Future research should consider integrative literature reviews that include qualitative studies to better capture the nuanced interplay of individual, cultural, and technological factors.

Conclusions

Our comprehensive meta- and weight analysis of 115 unique datasets on IoT health care adoption revealed several significant predictors for the adoption of IoT health care technologies. Behavioral intention emerged as the most frequently studied target variable. By contrast, attitude, actual behavior, performance expectancy, effort expectancy, and TTF remain comparatively understudied, with very few paths examined more than 5 times. While adoption theories from the information systems field, such as UTAUT and TAM, are predominantly used, integrating context-specific factors or combining constructs from different theoretical models can provide deeper insights into IoT health care adoption and further support the adoption process.

All the best predictors identified in our study were statistically significant, with the exception of reliability as a predictor of behavioral intention. For the target variable attitude, the strongest predictors were effort expectancy, performance expectancy, and social influence, while barriers did not have a statistically significant effect. Regarding behavioral intention, the most consistent and significant predictors were attitude, performance expectancy, habit, self-efficacy, functional congruence, reliability, and benefits. In addition, social influence, facilitating conditions, and trust demonstrated strong weights above 0.700, while aesthetic appeal was considered a promising predictor due to the limited number of studies. Conversely, variables such as privacy and security, barriers, vulnerability, severity, compatibility, and financial cost showed inconsistent results, with a high incidence of statistically nonsignificant findings. Specifically, health, technology anxiety, financial cost, and barriers were not statistically significant predictors of behavioral intention.

For actual behavior, behavioral intention emerged as the best predictor, while facilitating conditions and social influence were considered promising. However, social influence, innovativeness, health consciousness, vulnerability, and effort expectancy did not reach statistical significance for behavior. Regarding performance expectancy, effort expectancy, TTF, and self-efficacy were the best predictors, followed by health consciousness, social influence, reliability, and compatibility as strong predictors, while convenience and innovativeness appeared as promising. Privacy and security and barriers, however, were not statistically significant predictors of performance expectancy. For effort expectancy, the most consistent predictors were facilitating conditions, innovativeness, self-efficacy, and compatibility, with reliability and TTF considered promising predictors; privacy and security and image did not show significant effects. Lastly, for the target variable TTF, technology characteristics emerged as a promising predictor, whereas task characteristics were not statistically significant.

Abstract

Background: European health care systems face mounting pressures from an aging population, workforce shortages, and decentralization, challenging the delivery of accessible, high-quality care. eHealth solutions are widely promoted to enhance efficiency and improve the quality of care. Despite a strong policy report, anticipated benefits remain unrealized, as implementation processes often encounter barriers and high failure rates. Research shows that drivers and barriers are dynamic and shaped by actor interactions. Some studies suggest that certain actors, often acting as bricoleurs, play a critical role in overcoming these barriers through adaptive and improvised practices. However, little is known about how these actors enact roles, what features enable bricolage, and how structural conditions influence these practices.

Objective: The aim of this study is twofold. First, it investigates the roles and features of actors involved in innovation processes, with a particular emphasis on the application of bricolage to overcome barriers and the influence of structural factors on these processes. Second, it aims to contribute both theoretical and empirical insights to deepen the understanding of barrier dynamics within innovation processes.

Methods: We conducted a multiple-case study comprising 10 semistructured interviews, 11 focus groups with health care professionals, managers, trainers, and policymakers, participant observations of training sessions, and document analysis. An iterative process integrated the dramaturgical approach with the concept of bricolage, guiding the reflexive thematic analyses.

Results: Roles were enacted based on available information, context, and assigned functions. Service specialists (eg, superusers) and mediators (eg, unit or project managers) gained backstage insights through shadowing staff, evaluations, and support activities. When mandated and equipped with contextual and technical knowledge, these actors became bricoleurs, addressing unforeseen challenges by creatively mobilizing resources and thereby transforming barriers into promoters. Effective bricolage required proximity to the implementation site, dedicated involvement, and experiential knowledge of health care and technical domains. Key drivers included colocation, supportive management, stable teams, superusers, tailored training, follow-up activities, and informal evaluations. Barriers such as organizational silos, leadership shifts, staffing shortages, high turnover, geographic dispersion, and technology perceived as challenging or surveillance-oriented constrained bricolage and hindered implementation.

Conclusions: Actors may become bricoleurs when their assigned roles, contextual knowledge, and backstage access enable them to improvise in response to unforeseen challenges. Through a dramaturgical lens, bricolage is an adaptive performance that sustains frontstage care delivery. Bricoleurs combine proximity, experiential knowledge, and dual expertise to transform barriers into drivers by adjusting the innovation process and fostering interaction. These practices illustrate the mutual shaping of structure and agency: enabling conditions expand the space for bricolage, while barriers narrow it. Understanding this dynamic is essential for advancing theory on innovation processes and for designing implementation strategies that leverage bricolage as a mechanism for transforming barriers into drivers of innovation.

Introduction

Background

One of the significant challenges facing European societies is the aging population, coupled with a shortage of health care staff [1-4]. These challenges are compounded by a deliberate decentralization of health care services, driven by political decisions, which complicates efforts to ensure accessible and high-quality health care [2,5-8]. In response to these pressing issues, there is a growing emphasis on innovation within the public sector [9,10], particularly through the adoption of eHealth solutions [1-3]. eHealth solutions are often defined as the organization and delivery of health services using information and communication technologies (ICTs) to support and enhance health care [4,11]. Across European societies, including Norway and Denmark, which form the context of this study, there is strong optimism that innovative eHealth solutions can improve productivity, free up time for patient-centered care and core health care tasks [2,8,12], and empower older adults to live independently at home by enhancing their health and quality of life [13-16]. The belief stems from the potential that eHealth solutions can enhance efficiency, improve the quality of care, and bolster patient security [17-19]. However, despite a strong policy push for implementing eHealth solutions, authorities acknowledge that the full benefits have yet to be realized [2,3,20,21].

Research on innovation processes involved in implementing and sustaining eHealth solutions in health care reveals that these processes are often fraught with challenges, resulting in a high failure rate [22-26]. Numerous studies have identified a range of factors influencing the outcomes of eHealth innovation processes [22,26-33]. These factors are often presented as separate concepts, being either a driver or a barrier [34,35]. However, scholars are increasingly emphasizing the dynamic nature of drivers and barriers [36-38]. What may initially appear as a barrier can be transformed into a driver if addressed appropriately [38-40]. Detecting barriers and addressing them depends on the interaction among actors as well as proactive engagement from specific actors. Previous research has demonstrated that collaborating actors in innovation processes engage in complex and dynamic interactions and negotiations [38]. As the complexity of the innovation process increases, interactional barriers become more prominent [34,36,41], hindering effective knowledge sharing, which is crucial for implementing and sustaining eHealth solutions [25,32,38,42,43]. Research has identified specific actors who are effective in overcoming interactional barriers [38]. Such actors are frequently found to act as boundary spanners, bridging knowledge gaps, for example, between ICT staff, management, and health care professionals. By bridging knowledge gaps, these actors can transform barriers into opportunities, making innovations more contextually relevant and beneficial by, for example, facilitating the redesign of workflows, providing adequate training and support to users, and highlighting problematic issues [26,31,38,44]. These actors can also be referred to as bricoleurs [45-47], and their contributions are considered vital for integrating eHealth solutions into health care practices [7,48,49]. Bricolage is characterized by its spontaneous and improvised nature, involving small, pragmatic adjustments in response to unforeseen events or emerging needs [47,49]. This process is often informal, builds on embodied experience within the practice, and is inherently collaborative, as it necessitates interaction with other actors [45,47,49]. Given its intangible nature, it remains unclear how the context can facilitate bricolage work [46]. There also remains an incomplete understanding of the nature of the roles of these bricoleurs as well as how these roles might be identified, enabled, and enhanced [26,36,38,49,50]. The literature emphasizes the importance of investigating individual actors as units of analysis, given that microlevel practices have been largely overlooked [24,30,50]. Research has identified various features of individual actors involved in implementing and sustaining innovations, including ICT-related skills, experience, demographics, and personality traits [26,35]. Creative and empowered actors, who possess the ability to navigate and overcome a risk-averse administrative culture, play a crucial role in driving innovation [35]. However, it remains unclear how these features interact with the enactment of roles and the contextual factors. Bricolage provides an approach that emphasizes how innovation can be made possible by recognizing both the work of actors and the influence of structural factors [47]. We therefore consider the concept of bricolage useful for understanding the complex dynamics between the micro- and system levels of innovation processes.

Objectives

Against this background, this study aims (1) to investigate the roles and features of actors involved in innovation processes, with particular emphasis on the application of bricolage to overcome barriers and the influence of structural factors on these processes; and (2) to contribute both theoretical and empirical insights to deepen the understanding of barrier dynamics within innovation processes. We pursue these aims through a qualitative, multiple-case study set within a European Union innovation project that focuses on enhancing digital skills and innovation readiness. By examining 3 cases of implementing and sustaining innovative eHealth solutions, our study seeks to address the following research questions:

- How do actors involved in implementing and sustaining eHealth solutions enact the role of bricoleurs, and what features enable this role?
- In what ways is bricolage performed to transform barriers into drivers of innovation, and how do structural conditions shape or constrain these practices?

Methods

Study Design

The study used an exploratory case study design that adhered to the principles of multiple holistic case study design [51]. Each case served as a distinct unit of analysis. The exploratory case study is an empirical investigation that examines processes and uncovers mechanisms related to a contemporary phenomenon within its real-life context [51,52]. This approach was well-suited to our research design, as we aimed to understand the roles of various actors in innovation processes and to investigate how they overcome barriers and transform

them into drivers of innovation, as well as how structures influence the enactment of roles and performance of bricolage.

Case Selection and Data Collection

The cases selected for this study were part of the Digital and Innovation Skills Helix project, a European Union initiative aimed at enhancing digital skills and promoting innovation readiness. As part of a forthcoming innovation process aimed at implementing an eHealth solution, these cases tested 3 tools developed through the Digital and Innovation Skills Helix project. These tools facilitated the acquisition of digital skills, cocreative implementation planning, evaluation, and competence assessment. Further details about the tools can be found in our previous work [53].

The 3 cases are situated in a Nordic welfare context. Case A is a nursing home situated in a rural municipality in Western Norway, offering 24-hour health and care services to residents for both short-term and long-term stays. This municipality actively participates in regional and national eHealth networks and collaborates closely with neighboring municipalities to enhance health care services. The nursing home accommodates 41 residents and employs 60 staff members, including 1 leader and 4 unit managers. Since 2017, the municipality has systematically upgraded its outdated equipment with new eHealth solutions, such as electronic medicine dispensers and safety alarms. At the time of data collection, the nursing home implemented a new patient monitoring system that included digital supervision. This system's primary objectives were to increase service efficiency and improve patient security.

Case B is a home care service located in a rural municipality in Western Norway, providing 24-hour assistance with daily living and home health services. Most service users are frail older adults who require support to continue living at home. This home care service supports approximately 150 service users and employs 50 health care staff, including the home care service unit manager. Since 2015, the municipality has focused on implementing eHealth solutions in the health care sector to address demographic challenges and deliver sustainable health care services. The home care service implemented electronic door locks (e-locks) in service users' homes, aiming to provide faster and safer assistance.

Case C is a cross-sectoral collaboration between a hospital and a municipal home care service in Southern Denmark. The hospital offers emergency care, outpatient treatment, and examination services to patients who have been injured. The home care service offers 24-hour assistance, including support for daily living and somatic and psychiatric care. In 2018, the local hospital initiated a project to collaborate with the municipality through video consultations, specifically for discharging complex and vulnerable patients from the hospital to municipal care. Aligned with the Regional Council's digitalization strategy, the objective was to enhance cross-sectoral collaboration using technology, streamline discharge conferences, and ensure more coherent patient care. The hospital was allocated approximately US $1.5 million to develop digital competencies among its staff.

The selection of cases was pragmatic, as the available cases within the European Union project were limited, resulting in the inclusion of 3 cases that exhibited varying levels of complexity. As case C involved implementing video consultations in a cross-sector collaboration between a hospital and a municipal home care service in Southern Denmark, this case is more complex compared to cases A and B, which were more similar and less complex, as they implemented an eHealth solution within a single organization, engaging only a limited number of employee groups. The empirical material for these cases included document analysis, participant observation, semistructured individual interviews, and focus groups (see Multimedia Appendix 1 for an overview of the data collection).

The interviews and focus groups, with some being more prominently featured than others, served as a central component of our analysis, providing in-depth insights into the experiences and perspectives associated with the implementation process (Multimedia Appendix 2). The participant observations took place during training, where the observer participated and observed questions, discussions, and task-solving activities. The participant observations complemented the interviews, enhancing the analytical depth of the study by offering a comprehensive understanding of the setting and context as well as nuanced insights into the social dynamics (Multimedia Appendix 3). Although these observations, along with the document analysis, served as critical supplementary materials, they primarily provided a contextual backdrop for interpreting the qualitative data derived from interviews and focus groups. The data collection took place between 2020 and 2022, during and after the testing phase of the 3 tools. The data were gathered in person or online via Zoom (Zoom Video Communications) or Microsoft Teams, conducted by SE, AMD, or CØ. The data collection ended when data saturation was reached.

Participants for the study were recruited with the assistance of key stakeholders involved in implementation planning and training within the clinical settings. In cases A and B, a designated project manager from each case served as our primary point of contact. For case C, we contacted the individuals responsible for training at the hospital, where one of the trainers became our primary point of contact. These 3 contact persons facilitated the recruitment process by reaching out to potential participants by email. A total of 949 individuals were identified as potential participants from the training roster, and 31 individuals were identified from the implementation working groups. We contacted 115 individuals, of whom 39 agreed to participate in the interviews, and 70 agreed to participate in participant observations, resulting in a final sample of 109.

Ethical Considerations

Ethics approval was obtained from Sikt—Norwegian Agency for Shared Services in Education and Research (ref: 198584). Before participation, all participants were provided with informed consent that they signed before participation, which included a comprehensive overview of the study project, its objectives, and data handling procedures. No compensation was provided to the participants. Anonymity was ensured by replacing names with pseudonyms and revising the empirical

material to obscure recognizable quotes. To ensure data security, the original recordings as well as transcripts were stored as password-protected files on a secure research server, with access limited to the three authors only.

Analyses

NVivo (version 21; Lumivero) software was used to analyze verbatim transcriptions of audio-recorded interviews and focus groups. The reflexive thematic analyses for this study were applied to generate initial themes by identifying patterns of shared meaning across the dataset [54-56]. We followed the 6-phase approach developed by Braun et al [55]. First, we aimed to enhance reliability in the analysis process by conducting independent readings of the transcripts. Second, all three authors generated initial themes independently, guided by the concept of bricolage [57] in combination with the dramaturgical approach [58] and the Consolidated Framework for Implementation Research [59]. Since the study aimed to investigate role enactment, bricolage strategies, and structural factors, we approached the data, exploring and tagging text that reflected strategies involving bricolage activities and role features akin to those of mediators and service specialists, as well as structural factors affecting implementation. Third, all three authors constructed themes through thematic mapping, which involved visually exploring potential themes and subthemes, as well as connections between them. Finally, themes were revised and defined in collaboration between all three authors before producing the report. Researcher reflexivity was actively pursued in accordance with the standards of qualitative research [60]. This included engaging in critical dialogue to challenge and complement each other's interpretations and explicitly acknowledging our personal and professional backgrounds early in the research process. These discussions helped us remain aware of our initial assumptions and avoid conflating prior perspectives with insights emerging from the data.

Conceptual Framework

The dramaturgical approach by Goffman [58] illustrates how actors manage their frontstage performances within social settings to navigate and influence others' perceptions. In contrast, backstage involves actions that support the frontstage performance but do not align with its presented image. This perspective highlights that inventive strategies and adaptive behaviors emerge in response to the interactions and perceptions within actors' immediate social contexts rather than being dictated solely by structural conditions. By integrating the dramaturgical approach and the concept of bricolage, we aim to develop a more comprehensive understanding of how actors can transform barriers into drivers through performing bricolage. Previous research has indicated that distinct roles, such as mediators and service specialists, are pivotal in overcoming interactional barriers [38]. In the paragraph below, we delve deeper into the roles of mediators and service specialists, emphasizing their essential function in bridging interactional gaps.

A mediator acts as an intermediary, facilitating mutually beneficial agreements between 2 potentially opposing teams. By cultivating trust and managing confidential information, the mediator maintains a delicate balance, sometimes projecting a skewed perception of loyalty to foster closeness and understanding among the teams. Examples of mediators may include facilitators, project leaders, or department managers. Conversely, service specialists focus on constructing, repairing, and maintaining performance. Acting as "scene workers," they enable actors to effectively perform their roles and define situations without encountering dramaturgical obstacles [58]. Examples of service specialists could include ICT specialists, champions, or "superusers."

To investigate the strategies used by mediators and service specialists in merging frontstage with backstage to overcome barriers and further the innovation process, we integrate Lévi-Strauss's [57] concept of bricolage. Bricolage, derived from the French verb "bricoleur," means to tinker or improvise. Lévi-Strauss [57] conceptualized bricolage as a creative method of using available resources, contrasting the improvisational nature of the bricoleur with the systematic, planned approach of the engineer. This duality draws attention to different problem-solving methods [57]. Since its introduction, bricolage has found relevance across various disciplines [61-63], including studies on public sector innovation [7,45-49,64]. While extensive research has examined bricolage activities, there has been less focus on bricoleurs themselves [49]. This oversight may stem from Levi-Strauss's [57] structuralist perspective, which suggests that objective structures shape actors' lives, often overshadowing individual interpretations. However, latter interpretations of the concept of bricolage are not strongly underpinned by the structuralist approach and see bricolage as an activity where the bricoleur creates structures from resources at hand [46]. As such, bricolage is considered relevant for capturing the dynamics of innovation and the connection between microlevel practices and broader systems of innovation [46]. Along with other researchers [65-67], we argue for the need to develop new approaches to advance public sector innovation processes. As such, to better understand the motivations and strategies of actors, it is necessary to recognize the interplay between different approaches. Situated in the critical realism paradigm, we acknowledge that both Goffman's and Lévi-Strauss's approaches can complement one another. While objective structures influence individual agency, especially in complex situations, actors' agency is also shaped by their subjective interpretations of social reality.

The dramaturgical approach illuminates the social dynamics and interpersonal interactions on the microlevel that shape how bricoleurs operate, for example, how the roles are enacted, negotiated, and adapted based on the context and audience. Conversely, bricolage enhances our understanding of the resourcefulness and adaptability that actors demonstrate in their roles, particularly in overcoming barriers to innovation. It elucidates how bricoleurs creatively respond to unforeseen events posed by the context while simultaneously negotiating and navigating structures that influence their actions.

Results

Overview

The total sample consisted of 109 participants, including 39 who participated in interviews and 70 who participated in participant observations. The participants represented a diverse range of stakeholders, including health care professionals, unit managers, leaders, policymakers, ICT specialists, eHealth solution providers, trainers, project staff, and technical personnel. The following sections outline the themes, accompanied by illustrative quotations.

Enacting the Role of a Bricoleur

The actors assigned the role to spearhead the innovation processes in the 3 cases were a project manager (case A), a home care service manager (case B), and a project manager assisted by trainers (case C). According to Goffman [58], roles are enacted based on available information, the situational context, and the function an actor is expected to perform. When assigned a function such as project manager (case A and C), home care service manager (case B), or trainer (case C), actors face specific expectations from their audience, which they strive to meet or engage in impression management to convey that these expectations are being met. In case B, the role of a home care service manager entailed numerous time-consuming operational responsibilities, which constrained the time and attention available for the implementation process—particularly during the COVID-19 pandemic. The geographical distance also prevented him from shadowing staff and observing their activities firsthand. These conditions made it challenging to enact either a mediator or a service specialist role. Compounding these issues, the home care service manager was new to the organization, starting the position only 2 weeks after the national lockdown in Norway. These circumstances complicated the enactment of a bricoleur role. First, the manager lacked familiarity with the organizational context and staff. Second, not having participated in the planning phase, he had limited background knowledge of the e-lock project's rationale and objectives, as reflected by the following quote: "It was decided before I started working here. So, I'm not entirely sure of the background [of the project], but it's probably to save time on key usage and to increase accessibility and safety for the users" (Respondent 1, home care service manager). Finally, the operational demands inherent in the managerial role overshadowed the implementation process, leaving little opportunity to prioritize it. This contrasts with cases A and C, where project managers were fully dedicated to the implementation process and exempt from other operational responsibilities. Although the project managers were fully dedicated to the innovation process, the way it unfolded varied across the 2 cases. In case A, the project manager and a project coordinator moved into the nursing home during the initial 2 weeks of implementation, providing continuous on-site support and guidance. After this period, they remained available via telephone and email and maintained an office next door to ensure ongoing support and rapid problem-solving. Due to poor collaboration with the ICT department in the municipality, the project manager and coordinator were also compelled to take on responsibilities as ICT specialists. This additional responsibility led the project manager and the coordinator to enact roles of service specialists, which had many advantages for the ongoing process, as expressed by a staff member:

> *I think it would have been difficult without them. It makes the workday easier. We spend less time on frustration, because, well, technology isn't my field, you know. My field is actually healthcare. But having those who are a support function for technology somehow makes my day easier.* [Respondent 2, nurse]

As the patient warning system and digital supervision were implemented directly within the nursing home, the service specialists remained in proximity to the site of action. The continuous presence of the project manager and coordinators, who engaged in shadowing staff and observing daily routines, enabled them to adopt dual roles as both service specialists and mediators gradually. In doing so, they effectively bridged the gap between backstage and the front stage. Drawing on their familiarity with the context and the actors involved, along with their acquired ICT competencies, they gradually enacted roles as bricoleurs—constructing, repairing, and maintaining the health care professionals' performance so they could do their "actual job" (Respondent 2, nurse). The project team also trained a group of superusers, who in turn took on roles as service specialists and actively supported bricolage activities by drawing on their digital competence.

Although the project manager in case C was committed to the innovation process, the physical location—outside the hospital in a separate building—created a spatial distance from the implementation site. Furthermore, the affiliation with a research and innovation unit, rather than the hospital units or the municipality, meant that the project manager lacked an established foothold within the everyday workplace dynamic. These conditions challenged the ability to enact a role as a mediator or service specialist, as the project manager was not embedded in the daily routines of the health care staff and thus had limited access to backstage information, such as training needs and perceptions about the video consultations. Enacting roles as mediators and bricoleurs was also challenging for the unit managers when priorities competed, tasks were incompatible, and responsibilities conflicted. As expressed by a unit manager: "We were a COVID unit, so we already had plenty to just ... work through, so the idea of creating new ideas and having the time to implement new systems ... Well, the staff was also overloaded. You reach a certain limit where you can't take in any more" (Respondent 3, hospital unit manager). However, in some of the units, the trainers were able to step into roles as service specialists and bricoleurs when they were physically present in the hospital to support the setup of video consultations. Their role as trainers granted them access to the backstage where health care professionals prepared for their frontstage performances. This backstage access enabled the trainers to observe real-world challenges and tailor both the training and video consultations to the specific needs of each unit. Drawing on their ICT expertise, they engaged in bricolage, creatively assembling and adjusting tools and practices to support the health care professionals in delivering care. The combination of service specialist and bricoleur roles illustrates how these actors not only facilitated the technical

implementation but also helped maintain the integrity of the health care professionals' frontstage performance. As reflected by the hospital director:

> *Every time we introduce a new ICT or digitalisation product, we turn the experts into novices. They deal with new technology, altering patient-health professional relationships [...]. If the doctor is struggling with an ICT system, they lose some respect in the eyes of the patients. Because then the patient sees them fumbling around and may think they are equally clumsy with all their professional expertise. [...] How can we ensure our healthcare professionals are not novices in ICT but at least able to use it effectively, so they don't come across as incompetent or anything like that? When healthcare professionals experience technical problems, they tend to revert to what they are accustomed to and can handle better.* [Respondent 4, hospital director]

This quote highlights the delicate balance between adopting eHealth solutions and maintaining a professional identity. Trainers who acted as bricoleurs helped preserve this balance by ensuring that health care professionals could maintain confidence and competence in their frontstage roles, even when navigating unfamiliar eHealth solutions.

The 3 cases show that the ability to enact the role of bricoleurs depends on actors' experiential knowledge, proximity to the implementation site, and a dedicated focus on implementation, which makes backstage dynamics more accessible.

Performing Bricolage to Transform Barriers Into Drivers

Goffman [58] distinguishes between 2 models of behavior: the real and the contrived. The real is regarded as a genuine performance, which is not consciously assembled, but an unintended product of an actor's spontaneous reaction to the actual situation at hand. Contrived performances, on the other hand, are regarded as carefully constructed, with each artificial element added one by one, since the behavior is not reacting to any actual situation. How one responds spontaneously to unforeseen events determines whether the performance is characterized by bricolage or a more systematic and planned engineering approach to overcome barriers [57]. Refer to Table 1 for an overview of the drivers and barriers across the 3 cases.

Table . Cross-case synthesis of structural drivers and barriers of bricolage.

Structural factor	Drivers	Barriers
Organizational structure	Colocation and small teams enable rapid feedback and access (A); proximity in small municipalities fosters collaboration (A, B).	Silos and interorganizational differences hinder coordination (A, C); concurrent large IT projects (electronic health records) compete for attention (C); geographic dispersion (A, B, C); role overload in small municipalities (A, B).
Leadership and governance	Supportive management and dedicated project leadership drive progress (A, B, C).	Shifting leadership and lack of clear ownership delay implementation (B, C); operational pressures crowd out strategic work (C).
Political framework	Alignment with local or regional or national priorities; digitalization targets create mandate (A, B, C).	—[a]
Resources	Adequate funding and equipment (A, B, C); stable workforce (A, B); superusers support adoption (A).	Staffing shortages, turnover, and crises (eg, COVID-19, strikes) impede adoption (C); lack of designated superusers (B, C).
Cultural norms and values	Positive work culture (A), and perceived expectations to use technology motivate uptake (A, B, C).	Strong patient-safety ethos and professional identity can slow change (A, B, C); small-community dynamics can amplify resistance (A).
Training and competence development	Needs-based, one-on-one, learning-by-doing, and follow-up (A, B, C) are effective; dedicated trainers also provide support (A, C).	24/7 operations complicate scheduling (A, B, C); generic courses without local tailoring are less effective; trainer distance and high turnover reduce retention (C).
Infrastructure and technology	Technology perceived as applicable or simple supports use (A, B); technology used proximate to superusers or project management supports use (A).	The technology is implemented in settings that lacked proximity to superusers and management (B, C). Technology perceived as surveillance (A), time-consuming (B, C), poorly functioning (C), and not beneficial (B, C) hinders its use. Poor set-up (A, C) and lack of deimplementation (B) create friction.
Communication systems	Multiple channels (meetings, emails, direct access to project leads) aid communication (A, B, C).	Weak interdepartmental and sectoral channels (A, C) and 24/7 staffing patterns (A, B, C) limit the information flow; the existing communication system between sectors hinders the development of a new communication system (C).
Daily relations and collaboration	Colocation and bridging roles (eg, unit management and superusers) improve collaboration (A).	Geographic dispersion (A, B, C) and lack of cross-sector workflows impede collaboration (A, C).
Quality assurance and evaluation routines	Routine monitoring (B, C) and frequent informal evaluation support technology adoption (A).	Monitoring can be perceived as surveillance; the absence of informal feedback loops reduces responsiveness (B, C).

[a]Not applicable.

By being proximate and shadowing the staff, the project manager in case A was present when unforeseen events happened. For example, when a ghost appeared on the patient monitoring system, as elicited by the project manager:

> *We set up [digital supervision] for a user [and] it was supposed to alert us if the person got out of bed. [...] It's nighttime, and the user is restless, so a night shift comes in [...]. She sits on the edge of the bed to calm the patient down. Then she stands up, which triggers an alert for getting out of bed because she's probably been sitting on the bed for too long. Due to our poor Wi-Fi, the signal is delayed. [...] Then, a few minutes pass, and an alert goes off on the mobile phones that the bed is abandoned. An anonymized picture of a man appears. Then, the others panic and rush in, wondering who's here, and they get the idea that this is a ghost [...]. They find out that the woman's late husband is in the room. Because he lived at the nursing home before.* [Respondent 5, project manager]

One of the health care professionals:

> *[...] There's probably much more between heaven and earth than we see, but I'm unsure if it would affect patient monitoring. [...] It's sometimes a profession shrouded in superstition and stories. [...] We are often close to death, right? So maybe it's a bit natural to become a bit superstitious.* [Respondent 2, nurse]

Even though the project manager could not convince the staff that the ghost appeared due to a slow Wi-Fi signal, responding constructively to this event spontaneously required an understanding of the context and the actors involved, as well as technical competence to grasp how cultural and emotional

factors intersect with technological implementation. The project manager also participated in staff meetings to evaluate the use of the patient monitoring system, ensuring that issues were raised and resolved. The training was conducted informally and continuously, based on immediate needs:

> *We simply have to practice. I have to show the staff and test. I don't know how often I've been on the floor to demonstrate a fall. [...] I have to show them and have them try it themselves. We constantly have to repeat, demonstrate, you know ... "Now, I triggered a violence alarm. What do you do then?" And it's like ... recreating scenarios.* [Respondent 5, project manager]

By being present and practicing in the situation, the project manager made it challenging for the staff to conceal actions or project desired impressions. This led the staff to use the patient warning system and digital supervision even when they were not fully confident in operating it. They either invited the project manager backstage for assistance or proceeded without the necessary skills, which created technical challenges and unforeseen events. These events, however, functioned as dramaturgical disruptions that exposed latent vulnerabilities in the performances of health care professionals. Once these issues were made visible, the project manager could implement improvisational strategies using the available resources.

In contrast to case B, where the e-locks were used in service users' homes, this made it difficult for the home care service manager to maintain proximity and shadow health care professionals during their work. Consequently, the home care service manager was not exposed to many unforeseen events caused by technology. The e-lock system log was used to monitor use, but it did not provide sufficient information to facilitate bricolage. As a result, the home care service manager remained unaware of how the staff perceived the e-locks. According to the staff, they only used the e-locks about 50% of the time. One staff member had experienced the e-lock malfunctioning once, so they always carried the regular keys "just in case" (Respondent 6, nurse). Staff members did not convey their experiences and concerns. Consequently, the management remained unaware of these issues. As reflected in the quote from the home care service manager below:

> *It was straightforward and a truly positive thing. It probably hasn't caused many obstacles. Of course, some actors might have hesitated a bit more to carry it out, but it's not like they have rallied others, because it's so simple. So I haven't heard that anyone has really resisted or that there has been noise around this technology. I would have known if there had been something.* [Respondent 1, home care service manager]

This quote reflects that when new or inexperienced leaders are given formal authority over more experienced staff members, the formally empowered actor often enacts a role of symbolic dominance. In contrast, the staff members are the ones who truly run the show [58]. This discrepancy between formal authority and practical influence served as a barrier to performing bricolage. Transforming this barrier to a driver requires strategies to gain backstage access. Because 24/7 operations made formal training difficult, he improvised by installing an e-lock on his office door, allowing health care professionals to practice at their convenience. This arrangement enabled him to remain close to the action and shadow staff during their practice sessions—providing a form of backstage access. These efforts ensured that staff acquired the necessary competencies to operate the e-lock. The staff found the training sufficient for using the e-locks, as remarked: "It wasn't that difficult" (Respondent 6, nurse). However, the staff questioned the usefulness and the functionality of the e-locks, as reflected in the following exchange:

> *Respondent 6, nurse: If [the e-lock] works, it's certainly easier.*
>
> *Respondent 7, nurse: Hmm ... I'm not so sure about that.*
>
> *Respondent 8, nurse: If it works.*
>
> *Respondent 7, nurse: It's very easy just to find the right key and unlock it.*
>
> *Respondent 8, nurse: Yeah, especially if it's raining.*

As such, this performance preparation training facilitated by the home care service manager had a limited effect, as e-locks were still not consistently used in service users' homes. The home care service unit manager emphasized the importance of managing explicit resistance happening on the frontstage: "Those who I thought might give the most resistance, they were actually the first ones I gave training to, and maybe followed up a little extra" (Respondent 1, home care services manager). However, silent backstage resistance might be a barrier more challenging to overcome than explicit frontstage resistance. In case C, many units struggled to implement video consultations for discharge conferences; however, a few units succeeded by engaging in adaptive, improvisational practices. In these units, the technology was not merely adopted as prescribed but reinterpreted and repurposed for alternative use—such as municipal rehabilitation supervision or admission meetings with relatives—illustrating a shift from the scripted "frontstage" plan to context-sensitive enactments. Training similarly moved backstage, taking place within the units rather than in formal classroom settings, fostering unforeseen events and situated learning. The trainers emphasized the importance of readily available support to answer questions and assist with new technology, as stated in the following quote from one of the trainers, highlighting the need for continuous and organized follow-up training in the units:

> *[...] Sometimes I think we could try to be more organised in training in the units. I'm not sure if there should be someone who becomes a superuser or is somehow responsible for it [...]. If one were to mention a missing link, I think it's the transition from having received the training to becoming an integrated part of the unit. That's where we could do something more. [...] It works really well if they have had training with us, and then we have been [in the units]* [Respondent 9, trainer]

The performance of bricolage in these units was facilitated by the trainers' presence backstage, their flexibility, and consistent

availability for support, as well as their provision of ad hoc problem-solving for unforeseen events. As the 3 cases show, responding to unforeseen events in a systematic and planned manner can be challenging. To effectively perform bricolage, it is essential to understand and act upon the context and engage with the involved actors. Understanding the context derives from experiential knowledge, the function assigned, and access to backstage insights. Performing bricolage is not just about creatively navigating unforeseen events using the resources at hand; it is also about being mindful of the interactions and relationships with other actors, ultimately shaping the experience and outcome for everyone involved in the innovation process.

Features of a Bricoleur

Several common features were observed among the actors who performed bricolage. They were familiar with the local work context, able to move fluidly between technical and clinical domains, and demonstrated a readiness to improvise and adapt eHealth solutions to meet the practical needs of health care professionals. As the project leader in case A noted: "Now I am the ICT department. I go into the computer cabinet myself and connect things" (Respondent 5, project manager). Another feature of the bricoleurs was their assigned role, such as project leader or trainer, which required full dedication to the innovation process. This meant they could be consistently available, responsive, and actively worked to meet the expectations of both the leaders and the health care professionals they supported, as emphasized by one of the trainers in case C: "It doesn't matter how much time has passed; I always make myself available" (Respondent 9, trainer). The physical proximity to the implementation site and involved actors enabled frequent, informal interaction that granted them access to backstage areas.

In contrast, actors who lacked the essential features for performing bricolage, such as those who were physically distant from the implementation site or held a position that involved other tasks and responsibilities, struggled to enact roles as bricoleurs. Without embeddedness in the local work context or access to backstage interactions, for example, by being new to the organization, these actors were less able to understand the nuances of everyday practices or respond to emerging needs. For instance, this resulted in staff perceptions of management being "unresponsive to feedback" (Respondent 7, nurse) in case B or feeling surveilled as in case C:

> *[The management] is definitely monitoring whether we are conducting these video consultations. We figured that out. We didn't actually know. But they are keeping an eye on us. [...] What is the reason for that? Well, I think it's because we first tried to say ... "Do we really need this? And should we do it now?" It was very emphatically stated that we should. Also, somewhere between the lines, it says that most consultations should be conducted over video. We have internally determined that as long as we say half/half, we'll have to see if they eventually knock on the door and say "no, no, no, now there are too many physical meetings every day"* [Respondent 10, nurse]

This quote captures the management's attempt to gain backstage access without success, while the nurse and her team strive to protect this backstage area. Consequently, actors without bricoleur features struggle to gain backstage information and are left to resort to more systematically planned approaches, limiting their contributions to, for example, formal training sessions or top-down strategies with limited impact on everyday practices among health care professionals.

Key features of bricoleurs are their familiarity with the local context, the ability to bridge technical and clinical domains, and consistent presence at the implementation site. Together with their dedicated roles and informal access to backstage dynamics, they are enabled to improvise and adapt eHealth solutions to meet practical needs.

Interactions Between Structures and Actors

In all 3 cases, the implementation of eHealth solutions was aligned with local, regional, and national priorities. The initiatives were supported by committed leadership, adequate funding, and a shared perception among actors that the use of eHealth solutions was both expected and necessary. However, these drivers carried limited weight when other structural factors (see Table 1 for an overview of barriers and drivers across cases), such as shortages of health care professionals, posed substantial barriers to implementation, as expressed by a member of the executive hospital management in case C, which was also the case featuring the most complexity:

> *We want to do a lot, but we don't have the resources. [...] We hear: " You get a lot of money; just get started." On the other hand, we simply don't have anyone who can [do it]. We clearly see that there is a need for these things. [...] It creates a vicious cycle spiralling downward, and we need to turn it around somehow.* [Respondent 4, hospital director]

Other barriers to bricolage included organizational silos (case C), interorganizational (case A) differences, shifting leadership (cases B and C), the pressures of 24/7 operations (all cases), high turnover rates (case C), the absence of superusers (cases B and C), and a strong patient-safety ethos (all cases). Additional barriers stemmed from the maintenance of professional identities (all cases), a lack of deimplementation practices (case B), the absence of informal feedback loops, and geographic dispersion among the actors. Technology itself also posed barriers, particularly when it was perceived as a form of surveillance (case A), as time-consuming (cases B and C), or as offering limited benefits to clinical practice (cases B and C). Under such conditions, performing bricolage becomes a challenging task.

Despite structural complexity and barriers, bricolage occurred across all 3 cases. Actors were not merely shaped by these structures; they actively worked within and upon them. Actors performed bricolage, particularly when structural drivers created openings for creative and adaptive problem-solving. While organizational silos, 24/7 operations, and technological infrastructure influenced what was possible, actors leveraged their assigned functions and interactions, using their expertise to adapt, reshape, and, at times, transform these structures. Key drivers of bricolage included colocation and proximity between

actors, which facilitated informal interactions and backstage access. The presence of supportive management, dedicated project leads, and a stable workforce created a foundation for continuity and responsiveness. A high number of superusers, along with tailored training that addressed the specific needs of each unit, enabled health care professionals to engage more confidently with eHealth solutions. Follow-up activities, dual roles (where project leaders also serve as ICT support), routine monitoring, and frequent informal evaluations further supported backstage access and, consequently, adaptive and creative problem-solving.

Discussion

Principal Findings

This study explored how actors involved in implementing and sustaining eHealth solutions enact roles as bricoleurs and perform bricolage to transform barriers into drivers of innovation. Using Goffman's [58] dramaturgical approach and Lévi-Strauss's [57] concept of bricolage, we examined how structural factors and actors' agency interact in complex innovation processes.

This cross-case analysis showed that the ability to enact the role of a bricoleur increased when actors were assigned a function dedicated to the innovation process, thereby being freed from operational demands. For example, being assigned the function of a trainer (case C) provided dedication, but also a mandate and a set of expectations to be fulfilled. Further, the enactment of the bricoleur role depended on actors' experiential knowledge and proximity to the implementation site, which facilitated access to backstage dynamics. The project team in case A is a good example that demonstrates how proximity and presence facilitated backstage access where routines were rehearsed, problems surfaced, and informal knowledge was shared. This backstage access led to a deeper understanding of the everyday challenges faced by health care professionals. Due to the project teams' continuous presence, health care professionals had to use eHealth solutions despite technical uncertainty, which in turn led to genuine performances, flaws, and unforeseen events. These findings resonate with previous research on bricolage [45,47,49] and add to the incomplete understanding of how the bricoleur role can be identified, enabled, and enhanced [26,36,38,49,50].

Bricolage emerged as a spontaneous and improvised response to unforeseen events, as found in previous research [47,49]; however, our research expands the literature by showing that bricolage builds on the bricoleur's experiential knowledge and dual expertise in clinical and technical domains, as was apparent in cases A and C. In these cases, the bricoleurs could transform barriers such as 24/7 operational demands and technological issues into drivers through, for example, ad-hoc, tailored training and by adapting solutions in contextually appropriate ways. Previous research has highlighted that barriers are dynamic and may be transformed into drivers if addressed appropriately [36-40]. We propose that bricolage offers a promising approach for facilitating such transformations.

Without backstage access, actors are left to rely on formal and systematic plans, strategies, and communication, as was the case for the project manager in case C and the home care service manager in case B. In both cases, silent resistance in the form of subtle, unspoken disengagement with the eHealth solutions hindered the implementation. Unlike explicit resistance, silent resistance may be difficult to detect and address, especially when actors lack backstage access. While previous research has emphasized how interactional barriers can hinder innovation processes and underscored the importance of collaboration [25,32,34,36,38,41-43] and boundary-spanning roles [26,31,38,44] in mitigating such barriers, our study adds nuance by demonstrating how bricoleurs can mitigate interactional barriers through backstage access.

Despite structural and contextual constraints, bricolage emerged across all cases. In case A, due to collaboration challenges with the ICT department, the project manager acquired ICT competencies and assumed responsibility for ICT-related tasks, which ultimately proved beneficial to both the staff and the innovation process. Rather than being passively shaped by structural conditions, actors can interact with and actively influence the conditions. This highlights how bricolage is not only resourceful but also interactive and performative, enabled by the interplay between agency and context, offering insight into the previously noted uncertainty regarding how the context facilitates bricolage work [46].

Our findings align with and enrich existing implementation frameworks such as the Non-adoption, Abandonment, Scale-up, Spread, and Sustainability framework [25,68] and Consolidated Framework for Implementation Research [59]. While these frameworks emphasize the importance of context, complexity, and actor engagement, they lack a detailed account of the microlevel improvisations that sustain implementation in practice. We contribute to an underexplored area [24,30,50] by proposing that bricolage offers a complementary mechanism that explains how actors navigate complexity not by eliminating it, but by working within and around it. As such, we suggest that bricolage can be conceptualized as a mechanism that links structural factors with microlevel practices (eg, improvisation, adaptation, and role enactment). This perspective can inform the design of implementation strategies that are more responsive to local contingencies and the agency of actors.

Our study aligns with previous literature on the characteristics of actors driving innovation, highlighting the importance of experience and ICT-related skills [26,35]. However, our study expands the literature by demonstrating that features of a bricoleur also encompass proximity, dedication to the implementation process, dual-expertise, and access to backstage dynamics. These features were most evident in cases A and C. As such, the findings of our study demonstrate that bricolage is not a spontaneous phenomenon or a matter of individual creativity [35]; rather, it is contingent upon various structural factors and interactions with actors. Our contribution offers nuanced, empirically grounded, context-sensitive illustrations that enrich existing understandings of bricolage and its role in innovation processes [45-49]. Although prior studies have conceptualized bricolage [45-49], our research advances the field by identifying the conditions and actors that enable its

practical enactment. Our research advances the field by empirically demonstrating how specific structural and contextual conditions, such as proximity and dedicated roles, enable the positioning of actors to enact roles as bricoleurs. Through detailed cross-case analysis guided by dramaturgy and bricolage, we have identified key features of bricoleurs and demonstrated how backstage access enables them to respond to unforeseen events in real time. This responsiveness creates opportunities to transform barriers into drivers, thereby sustaining innovation processes in complex health care settings.

In times of austerity, bricolage—an approach that uses available resources—may be notably applicable. Specifically, given that public sector innovation processes are often fraught with challenges and have a high failure rate [22-26], and as new approaches to advance, public sector innovation processes are asked for [65-67].

Limitations and Future Research

This study used a qualitative multiple-case design with methodological triangulation. While this approach enabled a rich and nuanced understanding of the implementation of eHealth solutions, the findings are grounded in 3 specific cases in a Nordic welfare context. As such, transferability to other settings may be limited. However, the implementation of eHealth solutions in health care is highly relevant across a wide range of countries. eHealth solutions tend to influence professional roles, interactions, and organizational structures in ways that are difficult to predict and anticipate [32,38,42,43,69]. These dynamics apply regardless of context. While our findings are not intended to be generalized, the conditions that enable successful bricolage—such as proximity and dual expertise—may offer valuable insights across diverse contexts.

Future research could build on this work by using mixed methods designs or larger-scale comparative studies to examine how bricolage unfolds across different health care systems or policy environments. Additionally, further exploration of silent resistance, including its manifestations, consequences, and strategies for mitigation, could deepen our understanding of the subtle dynamics that shape innovation processes in complex health care settings.

Conclusions

This study contributes to the understanding of innovation processes in the public sector by illuminating how actors navigate complex implementation processes through bricolage. By integrating dramaturgy with bricolage, we offer a novel analytical lens that captures both the performative and improvisational dimensions of innovation work. This theoretical pairing enabled us to explore how roles are dynamically enacted and adapted in response to structural and contextual factors, as well as emergent challenges.

Our findings show that actors become bricoleurs not merely by individual traits, but through a combination of contextual knowledge, proximity to the implementation site, and access to backstage dynamics. These conditions enable bricoleurs to improvise, adapt, and sustain innovation efforts in ways that formal strategies alone may not achieve. Our study provides detailed, context-sensitive illustrations that enrich existing theories of innovation and implementation. Recognizing and supporting conditions for bricolage may help design more adaptive, responsive, and sustainable strategies. We demonstrate how bricolage operates as a mechanism that links structural factors with microlevel improvisation, offering a valuable complement to established implementation frameworks. The theoretical pairing further clarifies how social expectations, role performances, and backstage interactions shape the conditions under which bricolage can occur.

Acknowledgments

Abstract

Background: Digital health services are increasingly used in hospital-based outpatient care, offering remote monitoring, patient-reported outcomes, information sharing, and asynchronous communication. While expected to improve self-management, timeliness, and efficiency, the success of digital health interventions relies on patients’ health literacy and digital health literacy. While some research has addressed potential associations between digital health interventions and patients’ health outcomes, research on patients’ experiences remains limited.

Objective: The aim of this study was to explore and gain in-depth knowledge about the experiences of patients with chronic or long-term conditions enrolled in a 6-month digital outpatient care intervention for tailored care and health literacy.

Methods: We conducted an exploratory qualitative interview study with 17 strategically recruited adult patients with cancer, interstitial lung disease, epilepsy, or complicated pain who used a digital outpatient service for 6 months. Individual telephone interviews were conducted using a semistructured guide, transcribed verbatim, and analyzed with thematic analysis to generate codes and themes. Participants had a median age of 62 years (minimum-maximum 36-83 years), with 8 females and 9 males.

Results: The thematic analysis led to 1 main theme “Digital outpatient care as a flexible service supporting patients’ self-management,” informed by 3 subthemes “The ongoing nature of managing a chronic condition and how the digital service meet the patients’ desire for autonomy in their care,” “Digital tools flexibly address the patients’ unique needs, but reliability depends on patient interaction,” and “Digital services enhance the patients’ sense of safety through easy access to a relation with competent healthcare workers.” The themes highlight patients’ appreciation for greater flexibility in their care and their desire to self-manage with the support of easily accessible health care workers, ultimately supporting their health literacy. Patients recognized the importance of actively engaging with the digital solution to fully benefit from its opportunities and emphasized the critical role of health care workers in fostering their sense of security.

Conclusions: Digital outpatient care was experienced as flexible and supportive for patients with long-term conditions. The increased possibility of interacting with health care workers was welcomed by the patients, and the combination of flexibility, self-monitoring, and addressing concerns regarding their self-management may increase the patients experience of autonomy. As health literacy likely plays a role in patients’ ability to effectively engage with digital tools and self-manage their conditions, future research should explore how varying levels of health literacy influence these outcomes. In addition, research should address whether such digital outpatient clinics are positive for a wider range of patients, associated health outcomes, and any positive effects on a health system level.

Introduction

The increasing demand for health care services is not matched by available resources, including workforce shortages [1,2]. To enhance the sustainability of health services, greater flexibility is needed to address the dynamic needs of patients with long-term conditions, aligning with patient-centered care and optimizing resource use. Digital tools have been proposed as a means to achieve this flexibility, offering functionalities such as patient monitoring, self-reporting of objective and subjective data, asynchronous communication, and video consultations [3]. These tools can help identify patients at risk for deterioration or in need of immediate care, while also detecting those stable enough to delay scheduled services. By supporting patient-centered care, digital health solutions may improve attendance at scheduled appointments, enhance symptom management, and empower patients in self-management.

Digital health care services typically enable the subjective reporting of health parameters through patient-reported outcome measures [4]. These measures can aid self-management and support health literacy [5] and facilitate communication between patients and health care workers [6]. Furthermore, digital engagement, self-monitoring, and data sharing offer several advantages for patients [3,7,8]. Recent studies suggest that digital tools in outpatient care for patients with long-term conditions, such as cancer, epilepsy, interstitial lung disease, and musculoskeletal pain, can prevent complications, encourage patient engagement, and increase confidence and autonomy [9-12]. However, research on multicomponent digital solutions—encompassing patient-reported outcome measures, asynchronous messaging, remote monitoring, patient notifications, and video consultations—is limited. In addition, one important prerequisite exists for patients to benefit from digital health services, namely, that the patients use the services as intended. Patients' use of a digital health services might rely on their health literacy and ability to self-manage, and a certain level of digital skills and digital health literacy is also needed [5]. Health literacy provides a theoretical lens for this study, as it is a foundational factor influencing how patients access, understand, and use digital health services. Defined as "the cognitive and social skills that determine the motivation and ability of individuals to gain access to, understand, and use information in ways which promote and maintain good health" [13], health literacy not only affects patients' capacity for self-management but also plays an integral role in their engagement with digital tools. Often, higher health literacy is associated with an increased benefit of digital health interventions [14], while lower health literacy is linked to poorer health outcomes and less digital solution usage [15,16]. Furthermore, adequate health literacy is key to optimizing the use of digital health solutions, as it is suggested to enhance self-management in chronic conditions [5,16-18]. Although several systematic reviews have explored how to define, measure, and understand health literacy and digital health literacy [17,19-24], linking this knowledge to the experience of patients participating in digital health interventions remains scarce. Digital health literacy has been suggested as a super determinant of health comprising more than simply digital literacy and health literacy [25]; thus, exploring the experiences of patients with a digital health intervention supporting flexibility and health literacy might contribute with knowledge on how to research and design more effective, inclusive, and patient-centered digital health solutions that address diverse needs and promote equitable health outcomes.

While research on digital health services expands, research on patients' experiences of participating and making use of integrated digital solutions in outpatient care is lacking. The meaningfulness of a digital health solution depends on factors such as its usability, clinical relevance, convenience, and evidence-based design [6]. Studies on video consultations suggest how they are more convenient and time-saving for patients, but they are not perceived as superior to traditional in-person consultations [26,27]. Thus, despite growing interest in specific features of digital outpatient care and to some extent, the combination of features, previous research remains limited concerning the patients' experiences on a comprehensive model for digital outpatient care. By adopting health literacy as a guiding framework, the aim of this study was to explore and gain in-depth knowledge about the experiences of patients with chronic or long-term conditions enrolled in a digital 6-month outpatient care intervention.

Methods

Study Design

We conducted an explorative qualitative interview study as part of a larger study evaluating the use of digital outpatient care for adults with cancer, interstitial lung disease, epilepsy, or a complex pain condition at 2 university hospitals in Norway [28,29]. The study is reported according to the COREQ (Consolidated criteria for Reporting Qualitative research) guidelines [30].

Setting

The setting for this study was the 4 outpatient services participating in a multicenter controlled trial evaluating digital outpatient services, comprising the Department of Respiratory Diseases, the Department of Neurology, and the Department of Pain Management at Oslo University Hospital, as well as the Department of Cancer at the University Hospital of North Norway [28,29]. All patients included in this trial were living at home, receiving outpatient care, and otherwise managing their own lives.

Eligible participants had been included in the digital outpatient intervention, previously detailed [28,29]. The core focus of the intervention was to improve outpatient service accessibility,

allowing the patients to engage with patient-reported outcome measures, self-monitor parameters, and communicate asynchronously with health care workers. Designated health care workers assessed the patients' responses and parameters and had asynchronous digital contact, aligning with a conceptual model linking health literacy to service access and self-management [31]. Health care workers assigned tasks to patients and set individual thresholds using a traffic light model. Notifications alerted health care workers of deviations such as increased pain, side effects, or uncompleted tasks. Patients received reminders for unfinished tasks. Two-way messaging enabled asynchronous communication for questions, information exchange, and sharing of treatment plans. The digital outpatient intervention was enabled through the Dignio Connected Care platform, allowing personalized patient–health care worker contact [32] (Multimedia Appendices 1 and 2). The platform, including the health care worker's Dignio Prevent system and the patient's MyDignio app, is Conformité Européenne marked, privacy compliant, and globally applied [32].

Recruitment and Study Participants

Patients in the intervention arm of the overall multicenter controlled trial were invited to be interviewed when they completed their 6-month follow-up questionnaire at the end of the digital intervention. One item of the questionnaire asked for their consent to be contacted by a researcher with information regarding the qualitative interviews. An a priori estimation suggested a sample of 12-15 patients from the intervention group [28]. A strategic recruitment among those accepting to be contacted was conducted to ensure a broad sample of interviewees, enabling our aim of collecting rich data on the experiences of using the digital outpatient care intervention. Oral information was given over the phone, prior to written information in a secure digital platform, also allowing for their digital consent. We made use of the secure service "Nettskjema" digital consent in a service for sensitive data (Tjeneste for Sensitive Data [TSD] in Norwegian: the English version is Service for Sensitive Data]) developed at the University of Oslo. TSD is designed for storing and processing sensitive data in compliance with the Norwegian "Personal Data Act" and "Health Research Act." The consent invitations were sent to the participants through the Pretty Good Privacy encrypted version of the University of Oslo web questionnaire service "Nettskjema" demanding a governmental ID portal for login. A total of 91 patients completed their 6-month questionnaire, and of these, 50 agreed to be contacted for a possible interview. A researcher consecutively approached 21 patients, and 18 patients provided their digital consent to be interviewed.

Data Collection

To provide the information most valuable for the study aim, an interview guide was developed based on reviewing previous research in the field, inspired by topics on innovation assessment [33], and by adding items regarding specific factors associated with the current intervention [28]. A draft for the interview guide was developed by the first author and reviewed prior to a satisfactory version for a pilot interview. No changes were made to the interview guide after the pilot interview, and the pilot interview was included in the final analysis. The interview guide (Multimedia Appendix 3) contained an introduction with questions on their use of the digital service in general, before a midpart with more detailed questions on their experience with intervention, and finally some summarizing questions allowing final reflections. The interviewer (HH) has a background as a nurse with a PhD in health service research, without any personal or professional relationship with the participants. She has conducted qualitative research and analysis earlier and led the intervention study in which this substudy arises from.

All interviews were conducted over the telephone. All participants used their private smartphones for the interviews, while the interviewer (HH) used a work-related phone, with only voice. The "Nettskjema" Dictaphone app was used to record all interviews, with 1 main recorder and a backup recorder. All recordings were satisfactory besides one, where the line was interrupted midway through, and a new recording was started. No data were lost in this recording.

All interviews were conducted between 9 AM and 5 PM, with participants offered multiple time slots to ensure convenience. The interviewer called the participants at the scheduled time, and of those consenting, only 1 never responded despite repeated attempts from the researcher. Thus, 17 interviews were conducted with consenting participants, of whom 5 had cancer, 5 had chronic pain, 4 had interstitial lung disease, and 3 had epilepsy (Table 1). All participants were interviewed only once after their 6-month follow-up, and saturation was achieved through the 17 interviews; thus, no participants were added to the interview sample. The median time from the 6-month follow-up questionnaire end to interview was 40 days (minimum-maximum 9-95 days). The interviews lasted from 15 minutes to the maximum of 46 minutes, with a median interview time of 26 minutes. Median age of the interviewed participants was 62 years (minimum-maximum 36-83 years), of whom 8 were females and 9 were males. The participants had some variation in how they had used the digital intervention, and only 1 participant was categorized as a low user (Table 2).

Table 1. Participants, age groups, gender, department, and interview details.

Age groups (years)	N (%)	Sex, female/male	Departments	Minutes of interview, median (minimum-maximum)
31-50	3 (17)	2/1	Neurology and pain management	27 (26-27)
51-60	4 (24)	2/2	Cancer, respiratory diseases, and neurology	24 (16-39)
61-70	6 (35)	2/4	Cancer, respiratory diseases, neurology, and pain management	22 (15-46)
71-90	4 (24)	2/2	Cancer and respiratory diseases	29 (17-33)

Table 2. Use of the digital intervention (N=17).

Intervention	Values
Digital interaction[a]	
Total number of digital interactions	
Mean (SD)	58.8 (55.6)
Median (minimum-maximum)	65 (3-157)
Dichotomized digital interaction[b]	
Low use, n (%)	1 (6)
High use, n (%)	16 (94)
Asynchronous chat messages	
Messages sent from patient	
Mean (SD)	8.4 (9.2)
Median (minimum-maximum)	4 (0-31)
Messages sent from health care worker	
Mean (SD)	8.2 (7.5)
Median (minimum-maximum)	3 (0-20)
Total number of messages	
Mean (SD)	16.6 (16.2)
Median (minimum-maximum)	12 (0-51)
PRO[c] **measures**	
PRO measures sent to patient	
Mean (SD)	23.7 (25.4)
Median (minimum-maximum)	12 (0-82)
PRO measure responses from patient	
Mean (SD)	21.4 (24.7)
Median (minimum-maximum)	11 (0-82)

[a]Total counts were computed for chat messages, video visits, completed PRO measures, and monitoring events.

[b]Low users responded to less than 30% of the expected PRO measures.

[c]PRO: patient-reported outcome.

Data Analysis

All interviews were transcribed verbatim using the F4-transcript software (Audiotranskription.de) in TSD by the first author (HH). Then, the transcripts was analyzed using thematic analysis [34], with the following steps: (1) familiarize with data, (2) generate initial codes, (3) search for themes, (4) review themes, (5) define and name the themes, and (6) produce the report. An inductive approach was used, with the research question at the outset, allowing an analysis on the premises of the data at hand [34]. Both authors read and reread the material and HH generated initial and preliminary codes of the material—interview by interview. These preliminary codes were later reviewed by EF, before they were discussed, reviewed, and refined. Through discussion, the 2 authors (HH and EF) suggested themes to describe and clarify the codes, with particular attention given to exploring how patients' interactions with the digital health intervention may reflect aspects of their ability to access, understand, and use health information and the digital health tool according to health literacy and digital health literacy. A final set of themes, codes, and corresponding quotes was then summarized. All interviews were conducted, transcribed, and analyzed in Norwegian. The quotes have been translated to English and reviewed to assess the intended meaning. Minor alterations were made to ensure anonymity among the participants.

Ethical Considerations

The regional ethical committee in Norway prereviewed the protocol and judged the project as outside its mandate according to the Norwegian Health Research Act (regional ethical committee south-east reference number 252051). The project was approved by the data protection officer at Oslo University Hospital (reference 21/06826) and Northern Norway University Hospital (reference 2021/4942). All participants signed a digital, written informed consent form before participating in the project. This study was conducted in accordance with the Declaration

of Helsinki and all data were deidentified to ensure privacy and confidentiality. No compensation was provided to participants.

Results

Summary of the Themes and Codes

The thematic analysis led to 1 main theme "Digital outpatient care as a flexible service supporting patients' self-management," informed by 3 subthemes (Table 3).

Table 3. Themes and corresponding codes with quotes from the thematic analysis. Theme: digital outpatient care as a flexible service supporting patients' self-management.

Subthemes and codes	Quotes
The ongoing nature of managing a chronic condition and how the digital service meets the patients' desire for autonomy in their care	
Living with a chronic condition necessitates ongoing self-management	• "When you live with a diagnosis like this, it's not something you can easily forget" [P17]. • "I have had some quite big seizures, and little episodes that I don't really know whether are related to these seizures and that worries me" [P19].
Flexible services are required to support self-management	• "It allows me to better track myself and makes me calmer in relation to the disease progression, and I believe it enables me to respond at an earlier stage than I otherwise might have if something were to happen that affects my situation. So, the motivation lies in the ability to cope with a difficult disease, I would say. There's also additional motivation in that I enjoy numbers, apps, and correlations" [P17]. • "My motivation for using the app was the possibility to ask questions, and perhaps add notes to my symptoms, to be able to see some patterns" [P29].
Making use of digital tools for self-management supports autonomy in the patients' role	• "With this app, being able to see that the results sometimes go down a bit, and if you as a patient don't feel particularly worse, you might wait until the next measurement to make contact because you can relate this to your current situation and how you feel then, which is definitely possible with my disease" [P17]. • "Sometimes, I feel I am in bad shape, but the app says I am not, and that makes me happy...because there's so many things affecting my breath, like my state of mind and all" [P11].
Digital tools flexibly address the patients' unique needs but reliability depend on patient interaction	
Digital tools provide new solutions to real needs in a flexible manner	• "I believe that, for my part, the frequency of contact with the healthcare system has decreased since I started using the app" [P17]. • "I find the app to be a part of the entire [outpatient care] system" [P36].
Enabling interaction through communication of unique needs beyond standardized formats	• "The app asked more thorough questions than I remember being asked in person" [P12]. • "You do have specific alternatives to respond to, but perhaps some lines where you could express something? It's useful for the users, but whether it's also useful for you as the recipient, one might question, but maybe just 3-4 lines" [P36].
Making sure digital tools are suitable for the user	• "It is indeed an advantage to have digital contact for those of us who are digital and can use such things. But it is important that the digital solutions do not replace physical attendance and postal mail, but come as an addition, that one can choose" [P6].
Digital services enhance the patients' sense of safety through easy access to a relation with competent health care workers	
Easy and seamless contact with the outpatient clinic	• "But the feeling of safety, the certainty that I could get hold of someone if there was something, that gives a lot of peace of mind for my part" [P32]. • "As I am working full time, it's a hassle to leave work to go to the clinic, and it's adding more stress because I can't do my job properly" [P29].
Digital services facilitate patient access to health care, while supporting the health care workers' workflow	• "It is a reassurance for me if I would need it, and two years ago, I had a question that I didn't know whether was important and it took a month to get an answer. If we could have done it via the app, it would have been faster for both of us instead of having to call repeatedly" [P19].
Building a trustful digital relation to health care workers	• "Yes, I responded twice a week to the nurse and if I didn't respond, I received a message (...) so it worked perfectly (...) but I have never spoken directly with the nurse, which by the way is exceptionally pleasant to communicate with digitally" [P22]. • "I did know the doctor from before, but not the nurse – and not that it matters because now I feel like I know the nurse too, and that gives me a sense of safety" [P37].

The Ongoing Nature of Managing a Chronic Condition and How the Digital Service Meets the Patients' Desire for Autonomy in Their Care

The participants acknowledged the burden of living with a chronic condition. While some felt that they already understood the required self-management, they emphasized that digital follow-up provided a sense of support that lightened the burden, allowing them to focus more on living rather than being ill. One participant remarked, "Because I don't want to spend too much time on my condition, I want to spend my time on life instead, right? If it becomes too much, then it becomes too much concentration on the condition, and I still think that I'm not particularly sick" [P12].

The importance of self-management was highlighted, with some participants noting that this was the first time they had access to a tool that truly supported their self-management effort and the ability to monitor deterioration as highly valuable. The option to send messages, even for minor questions, was particularly appreciated, as these small clarifications provided reassurance: "Even small questions can take up a lot of space" [P34]. This access to advice enhanced their sense of control, and participants found it easier to consult health care workers through the digital platform compared with standard care.

The patients acknowledged their frequent need for health services and the challenges of contacting health care workers in outpatient care. They shared how digital outpatient care addressed this issue by improving communication and accessibility. Patients valued the efficiency and convenience offered by the digital solution, as one participant shared: "So, for me, this worked very well because I don't need to go in just for questions. I wasn't scared of anything, and I didn't have to go anywhere, and I didn't have to spend time calling, so it worked very well for me. Then you can rather go in if you don't achieve your goals with the digital follow-up" [P29]. While the benefits of digital services were valued, the patients emphasized the need for a hybrid model with digital and physical contact. They supported innovation in health services, particularly when it contributed to flexible, individualized care and expressed positivity toward continued digital contact after the project.

Patients found the digital outpatient care tools valuable for tracking health parameters, identifying changes in their condition, thus enhancing their sense of safety. The tools were used less when their condition was stable but became essential when they suspected health changes. Through the app, patients reported gaining an understanding of their symptoms and a reflection on their condition, which they felt had an impact on their health literacy and self-management skills. In addition, the tools facilitated greater involvement of family members, providing an extra layer of support. As one patient shared: "Yes! It's always a big moment every time I take such tests, and the people around me are always interested in how it's going. They always ask how it went when I took these tests" [P17]. This family engagement was described as a motivating factor for using the digital platform. However, some patients noted that their use of the platform was independent of family involvement, reflecting diverse approaches to digital health engagement.

Digital Tools Flexibly Address the Patients' Unique Needs, But Reliability Depends on Patient Interaction

Most patients valued the flexibility offered by digital tools, particularly the convenience of receiving care without traveling to the hospital. This was especially important for those with long travel distances or conditions that made travel burdensome. Digital tools were described as time-saving, stress-reducing, and helpful for minimizing work absences, with the ease of use and sense of security further enhancing their appeal: "If something comes up in the evening, I can enter it and then I get a response in the morning...much more frequent contact than usual" [P37]. Patients appreciated the opportunity for more flexible interactions with health care workers.

Patient-reported outcomes were generally seen as relevant and easy to complete, allowing for more thorough and individualized health reporting than traditional consultations. However, some patients felt that standardized questions and response categories did not fully capture their experiences, expressing a need for more flexibility and individual tailoring. One participant reflected: "For many of the questions I get [through the app], there are some I don't get to elaborate enough on, and it could just be that the information that I have could be valuable to you" [P27]. Suggestions for improvement included displaying scheduled consultations and test results in the app, reducing questionnaire frequency, adding time estimates for completion, and allowing more free-text responses. Patients also expressed trust in the app's data security but emphasized that not all data needed to be shared digitally to minimize risks.

Prerequisites for using digital tools, such as internet access, smartphones, and digital identification, were noted. Most found the app easy to navigate, with minimal training needed, although those using medical monitoring devices appreciated some initial guidance. Initial stress in using the app subsided with familiarity, as one patient noted: "At first, I was a bit stressed by it [the app], when the messages came from the hospital that I had to do these measurements, I felt that I was getting stressed. But why that is, I don't know, it's going well now. I was a bit surprised at myself, like, why is it stressing me, but it has passed now so that's good because now I'm starting to get the hang of it" [P11]. However, digital tools were not universally suitable, with concerns raised about older adult users, individuals with health-related anxiety, and the timing of app prompts for working patients. Despite these concerns, reminders were often described as helpful for completing tasks.

Digital Services Enhance the Patients' Sense of Safety Through Easy Access to a Relation With Competent Health Care Workers

The patients appreciated the sense of security offered by the user-friendly and flexible digital contact with health care workers in outpatient care. The app was seen as supportive rather than burdensome, with some noting that spending a few minutes weekly was a small effort for managing a long-term condition: "It's not like the app reminds you that you have a chronic condition, it's more perceived as a positive element in addition to the treatment you're already receiving" [P17]. Digital reporting was practical and reduced errors, although patients cautioned against relying on technology for false security.

Avoiding phone queues and callbacks saved time and reduced stress for patients, while also improving workflow for health care workers by allowing responses on their schedule. One participant shared: “I liked that I seemed to have better access to the department than normal, it was less burdensome than calling in the limited time the reception is open, and sometimes it rings and rings and rings and rings, and sometimes dealing with less or even unqualified reception workers which I have had problems with before” [P19]. Asynchronous messaging was particularly valued for enabling prompt answers to both urgent and nonurgent questions, fostering a sense of being seen and supported. Even when unused, the messaging function reassured patients that they could reach skilled health care workers if needed.

The competence of health care workers responding to queries was trusted, and while some patients valued consistent interactions with the same person, others prioritized competence over familiarity, especially with nurses. Patients appreciated building relationships through physical consultations before transitioning to digital follow-up but found digital contact effective once trust was established, as one patient elaborated: “And yes, I’ve met them, they know me and I have a face to them, and I think that’s very good. That it’s the same people who follow up. But it’s mostly on the doctor's side that I need to have the same person, whom I trust, and I have met in consultations, who knows me. But with the nurses, I think it’s very good to have two people” [P14]. Administrative workers triaging questions were considered acceptable, provided medical issues were handled by qualified professionals. However, some patients still preferred direct calls to familiar health care workers, especially if they already had access to adequate resources.

Discussion

Principal Findings

The patients experienced digital outpatient care as a flexible service supporting self-management, which fulfilled the patients’ ongoing but unmet need of autonomy in their self-management. The findings suggest that aspects of health literacy, such as the ability to understand, engage with, and act on health information, may have influenced how patients interacted with the digital platform and benefited from the service. To achieve a truly flexible and reliable service, active interaction between patients and health care workers with the digital platform is essential to strengthen the patients’ sense of safety. The patients’ reflections regarding the digital outpatient service in this study highlight key insights worth further discussion.

From the patients’ perspective, a digital outpatient solution offers greater flexibility in health care services than traditional calendar-based approaches, which rely solely on phone calls or scheduled consultations to access the outpatient clinic. Previous research has described how traditional systems are rigid and allow little patient-centered and flexible approaches [35]. If changes in the patients’ clinical status occur, there is little room for a rapid response or to move forward a scheduled appointment to curb the deterioration. However, the digital opportunities include flexibility through asynchronous messaging, monitoring, and patient responses—offering a more patient-centered approach, supporting the patient’s self-management [28]. Furthermore, health literacy is often intertwined with self-management, and both concepts are positively and iteratively influencing each other [16,31]. This highlights how digital outpatient solutions not only enhance the patients’ experience of more flexibility and responsiveness but also foster patient-centered care by supporting self-management and strengthening health literacy in a mutually reinforcing manner.

While our study and similar research highlight the benefits of digital approaches [5,10-12,18], some patients may feel burdened by the added responsibility, potentially threatening their sense of security. One patient described initial anxiety when using the digital platform, fearing mistakes in reporting—a concern echoed in previous studies emphasizing the critical role of usability and adequate digital and health literacy [36,37]. However, with practice, participants gained confidence in self-management and their sense of insecurity decreased. Interaction with health care workers further supported this transition, providing timely guidance and encouragement through digital messaging. This highlights the importance of tailoring support to help reluctant patients build the necessary skills and competencies for digital outpatient care [5,18]. In our study, patients demonstrated health literacy through their engagement with the intervention, responding accurately to patient-reported outcome measures, conducting remote monitoring as instructed, and framing thoughtful questions via the messaging functions, showcasing the integral link between health literacy and effective self-management.

The flexibility and interactive opportunities provided by the digital platform highlight its potential to reduce the traditional asymmetry between patients and health care providers. Unlike calendar-based systems in traditional care, which often overlook individual patient needs, digital outpatient care allows patients to engage with health care workers when changes in their clinical condition occur. Over time, patients became more adept at interpreting the relationship between their symptoms and objective measurements provided by the system, enabling them to make informed decisions and take appropriate actions with guidance from health care workers [28]. In the digital solution, where interactions occurred based on asynchronous messages, the focus of the interaction was more centered on the patients’ input and experiences rather than being primarily driven by the health care workers [6]. The role of the health care worker is also evolving, much like the changes digital solutions bring to the patient’s role. More flexible ways of interacting with patients are shifting the responsibilities of health care workers, often in ways they are not fully prepared for. However, with the necessary competencies in using digital solutions and a clear understanding of their integration into clinical care, health care workers can positively influence patients’ engagement and effective use of digital health solutions to maintain or improve health [38,39]. While processes that strengthen the patient role are well established in patient-centered care [6], their implementations through digital solutions remain underexplored.

Based on our findings, we argue that digital outpatient care can enhance care quality by providing easier and more timely access to health services, saving time and potentially preventing

symptom deterioration through early identification of changes. Patients' trust in the system and providers, their increased self-management, and reduced feelings of burden—both as individuals living with a chronic condition and as users of health care services—further support this claim. However, the impact of digital outpatient care on health outcomes related to patients' conditions remains unclear. While previous research has shown positive but small and low-graded evidence on such effects [5,7,18], further studies are needed to evaluate both health outcomes and the experiences of patients and health care providers using integrated digital health solutions.

Limitations and Strengths

This study is among the few qualitative investigations into integrated digital health solutions in outpatient care, but it has limitations. Participants were recruited from a study evaluating the same digital platform, with tailored interventions based on clinical needs, leading to heterogeneous experiences. All interviews were conducted using telephone with only voice, and thus, potentially relevant data concerning body language and nonverbal communication were not interpreted. To address this, a semistructured interview guide was used, and while data analysis was comprehensive, recurring similar statements were interpreted as having broader relevance. A key finding was that all patients expressed trust in the digital solution and care provided. However, this may introduce bias, as participants were likely those already comfortable with digital solutions, potentially excluding perspectives from less digitally inclined individuals.

Conclusions

In this study, we aimed to explore the experiences of patients with long-term conditions in using a digital outpatient care service for 6 months. Digital outpatient care was experienced as flexible and supportive for patients with long-term conditions. The increased possibility of interacting with health care workers was welcomed by the patients, and the combination of flexibility, self-monitoring, and addressing concerns regarding their self-management seemed to increase the patients' experience of autonomy. As health literacy likely plays a role in patients' ability to effectively engage with digital tools and self-manage their conditions, future research should explore how varying levels of health literacy influence these outcomes. In addition, research should address whether such digital outpatient clinics are positive for a wider range of patients, associated health outcomes, and any positive effects on a health system level.

Acknowledgments

We would like to thank all the participating patients and health care workers at each outpatient clinic. We are grateful to the staff in Dignio for their valuable insight and practical tailoring of their platform, and for a good collaboration, particularly with Anna Hurrød, Meetali Kakad, and Andreas Norling. Furthermore, we would like to thank Anette Winger and Astrid Torbjørnsen for their valuable comments to subsets of the draft in process. Artificial intelligence–assistive technologies have been applied for language editing only.

Funding

This work was initiated by the Oslo University Hospital, financially supported by the Research Council of Norway (grant 316244), internally funded by Oslo University Hospital and UNN to secure staff, and funded by Dignio Connected Care to finance user licenses in the digital platform. The Research Council of Norway and Dignio Connected Care had no role in preparing this manuscript.

Data Availability

The datasets used and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

HH initiated the study, developed the interview guide, and conducted all the interviews and the thematic analysis before she wrote the manuscript. EF collaborated in the project and gave feedback on the interview guide and the preliminary interviews, took part in the thematic analysis, and revised the manuscript. Both coauthors approved the final manuscript. No authors were added or removed during the process.

Abstract

Background: The use of social media platforms, such as Reddit, to seek and share information about disease management and treatment strategies is increasingly common. In the context of asthma—a chronic condition characterized by limiting symptoms and exacerbations that require active patient engagement and adherence to treatment—there is a lack of research describing the content of Reddit posts and the specific topics of interest to patients.

Objective: This study aimed to describe the topics discussed by users on the Reddit asthma forum and identify the sentiments and polarity of the language used in the posts.

Methods: A retrospective observational study of public posts on the asthma subreddit forum (r/Asthma) over a 1-year period (October 2023-October 2024). All posts and related threads were included, subdivided into hot, news, and top, and those voted "up" or "down," those that received "awards," categorized as "golds." The messages were reviewed manually and excluded if they were not related to asthma. A mixed methods analysis was conducted, comprising (1) analysis using text lemmatization, (2) structural topic modeling to identify topics based on word frequency, and (3) sentiment and polarity analysis. This approach aimed to identify the most frequently used topics on Reddit, detect positive and negative sentiments based on the words used, and acceptance or rejection (polarity) based on the language used in the asthma subreddit. Statistical analyses were performed using R software (version 4.1.3; R Foundation for Statistical Computing), with a significance threshold set at $P<.05$.

Results: After removing duplicates, 7806 posts were identified. The suitability of the chosen analysis model was confirmed, as it presented the best balance between exclusivity and semantic coherence. Clusters of 25 topics were identified and distributed according to their weight. The topics with the highest weight were Topic 7 (Symptoms and severity of asthma attacks) and Topic 18 (Causes of asthma). No significant differences were found in the evolution of emerging topics throughout the year except in Topic 20 (Seeking advice from people with asthma; $P=.04$), Topic 21 (Medical tests that should be reviewed periodically; $P=.04$), and Topic 22 (Times of year when attacks occur; $P=.03$). The proportion of feelings and emotions showed a stable trend throughout the year. Discrepancies in feelings and emotions were identified depending on the dictionaries used. Thus, a higher probability of positive feelings was confirmed in the AFINN lexicon. Meanwhile, negative feelings were significant in the Stanford Natural Language Processing, Bing, and National Research Council Canada lexicons.

Conclusions: These results can serve as a guide to identify hidden patient needs and help professionals develop specific interventions on topics relevant to patients.

Introduction

Asthma is one of the most prevalent chronic respiratory diseases, affecting over 300 million people globally [1]. The intermittent onset of bronchospasm attacks causes symptoms such as wheezing and dyspnea, and is characterized by airway inflammation, hyperresponsiveness, and mucus hypersecretion, leading to airflow obstruction [1]. The clinical manifestation of asthma varies across individuals, with distinct phenotypes [2], influencing treatment of the disease [3].

The introduction of novel clinical biomarkers (such as sputum and blood eosinophils, serum immunoglobulin E (IgE), and fractional exhaled nitric oxide) [2] has facilitated the development of treatments tailored to each patient's individual phenotype [4,5], specifically monoclonal antibodies. However, these drugs are limited to the most severe forms and certain phenotypes [3,4]. Treatment for most patients with mild to moderate forms of the disease is based on the use of inhalers; however, despite the ongoing development of educational programs, significant issues remain in relation to adherence [6] and inhalation technique [7], both of which have critical implications for disease management and the frequency of exacerbations.

Another key aspect in the treatment of asthma is the shared perspective between prescribing physicians and patients diagnosed with asthma on the impact of the disease on daily life [8,9]. Previous studies [8,9] show that there are differences in perspective on the management and control of the disease, resulting in an underestimation of the impact of asthma on the patient's life by the physician, reducing disease and symptom control [8].

One of the responses among patients is to seek help to cope with symptoms, apply strategies, and share their experiences with other patients [10,11]. In this regard, the use of social media for health reasons has increased over the last decade [10,11], having a major impact on patients' understanding of the disease, the acquisition of habits, the decision-making process, and health outcomes [12-18]. In addition, widely shared or viral content significantly influences the adoption—or rejection—of health behaviors [10], largely due to its ability to elicit strong, activating emotions, whether positive or negative [19].

Reddit is a large-scale online platform that hosts more than 130,000 individual communities, known as subreddits. It attracts around 500 million visits per month and engages approximately 73 million unique users each day [20]. With over 270 million active users each month [21], Reddit allows individuals to share personal experiences related to illness and health care. Users frequently post firsthand accounts, respond to others with shared experiences, and exchange advice on symptoms, medical conditions, and treatments [10,22]. The platform allows registered users (known as Redditors) to post content (text, images, and videos) to moderated boards, which are voted on by other users. Posts on Reddit are visible to the broader community, and their prominence within a subreddit is shaped by user voting—either upvotes or downvotes [23]. Subreddits are organized by topic, and users, known as Redditors, can subscribe to those that match their interests, allowing them to curate the content displayed on their personalized front page [24]. Additionally, some subreddits follow a question-and-answer format, with popular examples including r/AskReddit and r/AMA, which features the interactive "Ask Me Anything" style. Discussions on Reddit are public (unless specifically designated as private), allowing for passive data collection. Furthermore, for an internet user seeking information on a specific topic, Reddit is a useful starting point due to its topic-centric organization [10].

To the authors' knowledge, there are no studies that have shown the use of Reddit by patients with asthma and described the topics they consult. The questions that guided this study were: "What were the most consulted and discussed topics by patients with asthma on Reddit?" and "Was the language used on Reddit positive and negative? The objectives of this study were (1) to describe the topics discussed by patients in the asthma subreddit (r/Asthma) and (2) to identify the sentiments and polarity of the language used by patients with asthma on Reddit.

This study may help identify unknown and unmet needs of patients with asthma and improve medical care.

Methods

Design

An observational study was conducted, consisting of a retrospective analysis of public posts on Reddit over a 1-year period, from October 2023 to October 2024. Also, we used the subreddit forum asthma (r/Asthma) [25]. This study adhered to the Reporting Guidelines for Social Networks in Health Research [26], which are incorporated within the EQUATOR (Enhancing the Quality and Transparency of Health Research) initiative [27].

Data Collection

Posts that included general comments were identified and subdivided into hot, news, and top. Similarly, posts that were voted "up" or "down" were identified, as well as those that received "awards," categorized as "golds," and cross-posted posts. r/Asthma posts were obtained with the R library *RedditExtractoR* [28]. This library allows for extracting up to

1000 main posts by each category (hot, top, and new posts) and all generated threads. Only posts in the English language were used to facilitate the analysis.

All posts from the r/Asthma forum and all threads derived from the conversations were included, as r/Asthma is a subreddit forum dedicated specifically to asthma, so the objective of the study is to determine what topics interest the users of this forum without establishing any specific selection criteria a priori.

In addition, the main topic, secondary topics, number of votes obtained, number of responses, and subresponses obtained were included. Also, all information related to asthma, such as symptom management, treatment, follow-up consultations, risk behaviors, healthy habits, professional care, adherence (or nonadherence) to treatment and medical recommendations, education, use of inhalers, etc, was incorporated into the study and analyzed. Messages were reviewed manually and systematically excluded if they were not related to asthma use.

Statistical Analysis

Overview

Statistical analyses were performed using R software (version 4.1.3; R Foundation for Statistical Computing) [29]. The significance level was set at $P<.05$. The Kolmogorov-Smirnov test with Lilliefors correction was used to test the distribution of the variables. The variables were described with mean (SD), median (IQR), or with absolute and relative values, that is, n (%).

In this study, a mixed methods analysis was carried out that included three types of analysis: (1) text lemmatization analysis, (2) structural analysis using models based on topics identified by their frequency of appearance, and (3) sentiment and polarity analysis. This allowed us to identify the most frequently used topics on Reddit, identify positive and negative sentiments based on the words used, and determine acceptance or rejection (polarity) based on the language used to discuss asthma in Reddit posts.

Analysis Using Text Lemmatization

First, the text of the posts was lemmatized for analysis. Lemmatization is a linguistic process that involves identifying the base or lexicon form of a word—known as the lemma—from its inflected variants (eg, plural forms, gendered adjectives, verb conjugations). The lemma is the canonical form under which all inflected versions of a word are grouped. For example, in traditional dictionaries, nouns are typically listed in their singular form, adjectives in the masculine singular, and verbs in the infinitive.

Structural Topic Modeling Analysis

Second, a structural topic model analysis was conducted to examine the emergence of topics across user comments. This method also allows the incorporation of metadata, such as the time period of each comment, as a covariate in the model. The selection of the optimal number of topics was carried out in 2 phases: first, the range of topics with the best values of held-out likelihood and lower limit of stability of convergence between iterations of the models and with the lowest value in the residuals was evaluated; in a second phase, the ratio between semantic coherence and exclusivity between the selected models was analyzed. Exclusivity evaluates whether the main words of the topics also appear as main words of other topics, while semantic coherence shows whether the words most associated with a topic occur equally or not within the documents; in both cases, higher values are better [30-32].

Sentiment and Polarity Analysis

Finally, a sentiment analysis was performed using the Bing [33], AFINN [34], National Research Council Canada (NRC) [35], and Stanford Natural Language Processing (Stanford NLP) [36] dictionaries. All 4 dictionaries are based on unigrams or individual words that assign scores for positive or negative feelings. In addition, the NRC lexicon classifies words into 8 emotional categories of anger, anticipation, disgust, fear, joy, sadness, surprise, and trust. While the Affin lexicon assigns words a score ranging from –5 to 5, with negative values indicating more negative feelings and positive values indicating more positive feelings. Stanford NLP classifies positive into 5 categories: very negative, negative, neutral, positive, and very positive. Similarly, sentence polarity was analyzed using the Bing lexicon, incorporating modifiers such as amplifiers, decrementers, and negators as proposed by Halliday [37]. The integration of these 4 dictionaries facilitates a detailed and comprehensive analysis of the emotions and feelings conveyed in the texts shared by Reddit (r/Asthma forum) users. This methodological approach enables an emotional profiling of the analyzed content, contributing to a deeper understanding of the affective dimensions embedded in user-generated discourse. Furthermore, this combination of dictionaries allows for a multiangle analysis, providing a comprehensive analytical framework that encompasses the analysis of positive and negative emotions, ranging from –5 to 5 with the AFINN dictionary or from very negative to very positive with the Stanford NLP dictionary, as well as assessing 8 more complex emotions with the NRC dictionary. Moreover, the simultaneous use of these 4 dictionaries allows for a cross-validation and complementarity strategy; the combination of results can lead to a more robust and reliable analysis [38,39].

The presence of significant differences in the proportion of the categories of feelings and emotions or the average score of each lexicon and its temporal evolution was analyzed using a regression model. The assumption of linearity between the dependent variables and the quantitative predictors was tested by evaluating the effective degrees of freedom (EDF) with a value greater than 1 as a nonlinearity cut-off point. A generalized additive mixed model (GAMM) or a linear mixed model (LMM) was applied depending on the EDF value. Since these were time series, the correlation structure was modeled by comparing, using a likelihood ratio test (LRT), the models without this structure, with an autoregressive structure with lag 1 (AR1), and with an autoregressive moving average structure (ARMA) evaluated by means of an ARMA analysis of the residuals of the previous AR1 model. In the GAMM models, the fulfillment of the assumptions of v for the smoothed terms was tested, eliminating those with a value greater than 0.8, and the adequacy of the number of basic functions was checked using the K index ($P>.05$ as a selection criterion). The fulfillment of the

assumptions in the residuals was checked with the Kolmogorov-Smirnov tests with Lilliefors correction (normality) and Breusch-Pagan (heteroscedasticity). Since these were not met in the GAMM models, the robust sandwich-type standard errors were calculated in the LMM model with the Stanford NLP lexicon using a bootstrap.

Ethical Considerations

This study does not require approval from the Ethics and Clinical Research Committee of the University Hospital of Salamanca because the information is publicly available. The same considerations have been applied in previous studies that analyzed the use of Reddit by patients to share and search for information on topics related to health and disease [40-42]. In addition, institutional review board and research ethics committee approvals were not required nor sought because the research did not meet the requirements for needing ethical approval per section 1.3 of the European Pharmaceutical Market Research Association guidelines [43]. The ethical principles established by the Declaration of Helsinki were respected. In addition, Reddit offers a comprehensive application programming interface that grants access to much of the platform's information. In strict compliance with the rules and ethical guidelines of each subreddit, we only collect data from subreddits that explicitly allow research activities. Furthermore, to protect user privacy, we only record the comment ID without including any user information or the content of the comment itself, ensuring that no personally identifiable information or data that could lead to reidentification is collected. Furthermore, in the posts selected as illustrative examples for this study, all identifying information, including authorship and publication dates, was removed, and the content was summarized to preserve and emphasize the essential information.

Results

Descriptive

A total of 7806 posts were collected from the r/Asthma thread between October 2023 and October 2024 after removing duplicates, of which 454 generated a total of 6046 response threads. Since Reddit does not allow the extraction of more than 1000 posts, different filters were used to maximize the search for primary comments, from which an unlimited number of response threads could be obtained (Table 1).

Table 1. Reddit r/Asthma posts' characteristics between October 2023 and October 2024.

Post characteristics	2023			2024

[a]Hot: Comments with the highest popularity rate based on their age and number of positive votes are the most active and popular discussions in real time.

[b]Not available.

[c]New: New comments generated in a given period of time.

[d]Top: Comments with the highest number of net upvotes (upvotes minus downvotes) in a given time period.

[e]Score: Net positive votes (positive votes minus negative votes).

[f]Upvotes: Positive votes.

[g]Up ratio: Quotient of positive and negative votes in percentage.

[h]Cross-posts: Comments linked from other subreddits. Generated comments: comments not written by humans.

Analysis of Thematic Models

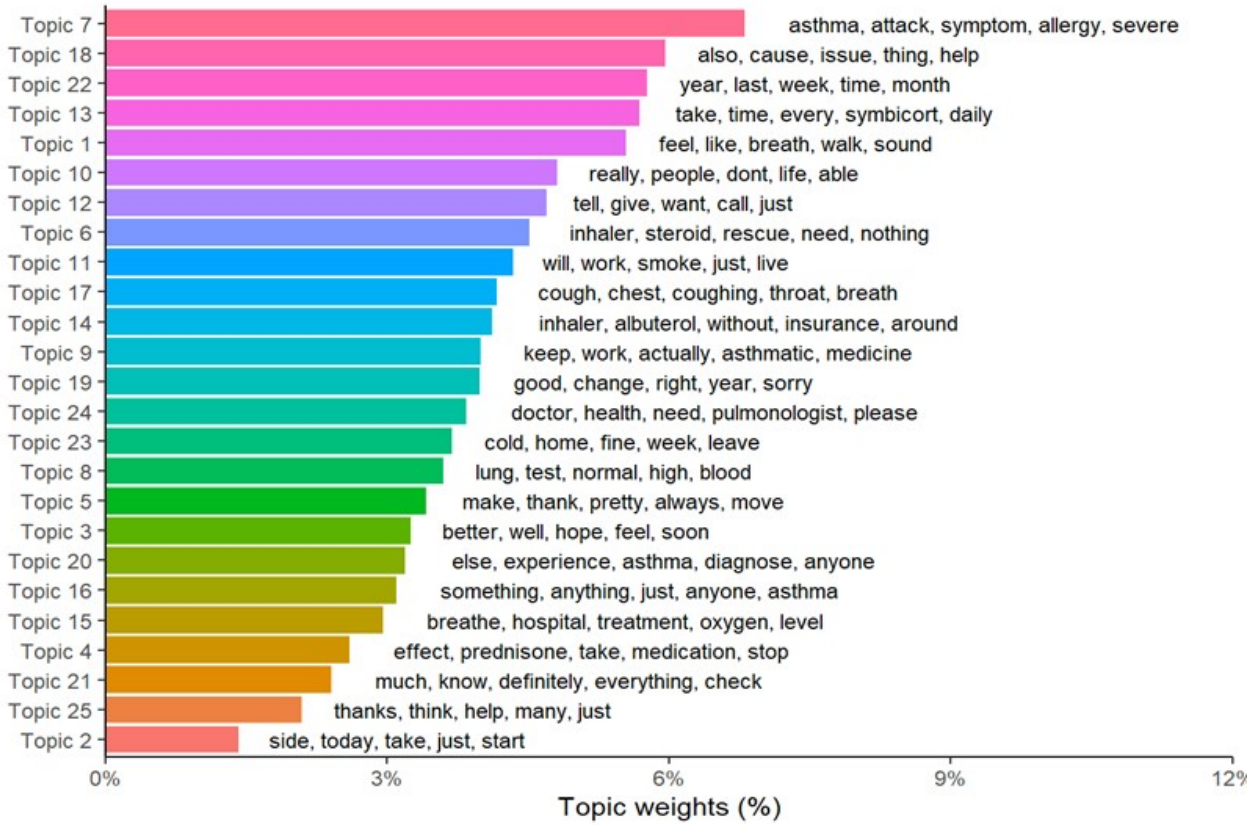
By determining the best held-out likelihood values among the models, it was determined that the optimal number of topics was 15 and 25 (Multimedia Appendix 1). Subsequently, the model with 25 topics was found to have the best balance of exclusivity versus semantic coherence, and therefore, the model with 25 topics was adopted (Multimedia Appendix 2). Table 2 shows the 25 topics hypothesized after the development of the model.

Table 2. Reddit r/Asthma posts topics identified.

Topic	Description
Topic 1	Influence of respiratory problems on the ability to walk.
Topic 2	Timing of attacks.
Topic 3	Hopes for rapid improvement.
Topic 4	Adverse effects of Prednisone that may justify stopping its use.
Topic 5	Gratitude for improvement.
Topic 6	Use of inhaled steroids as rescue medication.
Topic 7	Symptoms and severity of asthma attacks.
Topic 8	Medical tests to be monitored.
Topic 9	Influence of respiratory problems on work activity.
Topic 10	Influence of respiratory problems on quality of life in general terms.
Topic 11	Influence of tobacco.
Topic 12	Need for information.
Topic 13	Budesonide spray dosage.
Topic 14	How to access Albuterol inhalers for wheezing without medical insurance.
Topic 15	Hospitalization with oxygen therapy in case of acute exacerbation.
Topic 16	Search for any asthma-related therapy.
Topic 17	Influence of respiratory symptoms such as coughing.
Topic 18	Causes of asthma.
Topic 19	Symptom change throughout the year.
Topic 20	Request for advice to people who have asthma.
Topic 21	Medical tests that should be checked periodically.
Topic 22	Times of the year when attacks occur.
Topic 23	Change in symptoms at times of the year when temperatures are cooler.
Topic 24	Need for specialized medical care.
Topic 25	Gratitude for the assistance received.

Subsequently, each topic was classified according to the weight of its frequency, together with the most frequent words used in each topic (Figure 1 shows the weighted topics).

Figure 1. Weighted topics.



The topics with the greatest weight were Topic 7 (Symptoms and severity of asthma attacks) and Topic 18 (Causes of asthma).

Regarding the annual analysis of the topics, there were no significant differences in the evolution of the emerging topics throughout the year, except in 3 topics. These were Topic 20 (Request for advice from people with asthma; *P*=.04), Topic 21 (Medical tests that should be checked periodically; *P*=.04), and Topic 22 (Times of the year when attacks occur; *P*=.03; Table 3).

Table 3. Evolution of each topic throughout the period of time analyzed.

Topic and time period	Coefficient (SE)	*t* statistic	*P* value[a]

[a]Significant $P<.05$.

Multimedia Appendix 3 presents examples of texts and narratives shared by users in the Reddit r/Asthma forum, organized by each identified topic.

In addition, a clustering and correlation of all topics was observed, except topics 3, 6, and 13 (Hope of getting better soon; Use of inhaled steroids as rescue medication; and Dosage of Budesonide aerosol; respectively) referring to the use of steroids and Budesonide to accelerate the improvement of symptoms; and topics 17, 20, and 23 (Influence of respiratory symptoms such as cough; Asking for advice from people who have asthma; and Change of symptoms at times of the year when temperatures are lower; respectively) related to asking for advice from those who have already experienced asthma on the management of respiratory symptoms such as cough, especially at times of lower temperatures (Multimedia Appendix 4).

The graphs with the model predictions show how, over the year, the probability of posts containing topics 20 (Request for advice to people with asthma*)* and 22 (Times of the year when attacks occur) appear in autumn 2024, decreasing over 2024. In the

case of Topic 22, they increase again in the autumn of 2024. Conversely, Topic 21 (Medical tests to be checked periodically), increases especially in the summer-autumn of 2024 (Multimedia Appendix 5).

Analysis of Feelings and Polarity

The proportion of feelings and emotions and scores showed a stable trend throughout the year (Multimedia Appendix 6). In addition, a nonnormal distribution in polarity was confirmed ($P<.001$).

In relation to the contrast of the hypotheses, the significant LRT indicated that the ARMA model is the one that presented the best fit, except in the NRC lexicon of emotions, which presents better results in the AR1 model. Meanwhile, in polarity, the best-fitting model was the model without autocorrelation structure (Multimedia Appendix 7).

Significant differences were confirmed in the proportion of categories appearing in each of the dictionaries used versus the reference category. In contrast, time has no significant effect on the proportion of feelings and emotions or polarity (Multimedia Appendix 8).

Sentiment and emotion analysis produced varying results depending on the lexicons applied. For instance, categorical analysis showed a higher likelihood of positive sentiments and score values of 2 using the AFINN lexicon. In contrast, the Stanford NLP, Bing, and NRC lexicons highlighted significant negative sentiment. Additionally, the NRC lexicon revealed notable associations with the emotions of anticipation, fear, and trust (Multimedia Appendix 9).

The following lines present excerpts from Reddit posts in which both negative and positive emotional expressions are identified. Each example is accompanied by the date of publication. One post describes a near-death experience due to worsening asthma symptoms:

> *I expressed my feelings towards the limitation that asthma brings to me…well, 2 days ago, I almost died…I had an asthma attack after minimal exercise.*

Another post reflects intense frustration caused by the progression of the disease:

> *My asthma has been flaring up more frequently than usual. It's stopped me from seeing friends, working, and made me lose sleep. This is causing me a significant amount of stress and anxiety, too, which I know also makes it worse.*

A third example illustrates how an asthma crisis can complicate air travel:

> *Had an asthma attack at the beginning of a long international flight…it was really scary being trapped in that confined space, not being able to breathe.*

On the other hand, positive experiences were also identified:

> *No doctor wanted to diagnose me as asthmatic, but the only thing that controlled my coughing attacks was corticosteroids…I am grateful to the doctor who agreed to prescribe me.*

Discussion

Principal Findings

The analysis of Reddit's r/Asthma forum has made it possible to identify and classify user-generated topics based on their weight and relevance. The most prominent topics include the causes of asthma and the symptoms and severity of attacks, followed by seasonal patterns of exacerbations and corticosteroid inhaler dosing. Posts display a wide range and intensity of emotions, with a noticeable tendency toward the use of negative language when discussing asthma.

Comparison With Previous Work

The analysis of social networks (including Reddit) and their ability to influence risk behaviors, and the construction of people's opinions, grew during the COVID-19 pandemic [44-46] because of their use as tools for obtaining and cross-checking information, sharing knowledge and as a source of help in dealing with diseases and applying strategies or treatments [47-50]. However, the use of online health information carries significant risks related to the acquisition of reliable knowledge [51-55]. To obtain trustworthy, evidence-based medical or scientific information, users must navigate through a vast amount of misinformation and poor-quality content, including posts that promote unhealthy practices or unproven treatments [52,54-56]. As a result, individuals may make decisions that could potentially harm their health [52-54]. A key factor in acquiring reliable and safe online health information is enhancing the digital literacy and search skills of lay users [57]. Moreover, several recommendations have been proposed to support safe and informed health information searches online, including (1) using trustworthy websites with official domains such as .gov, .edu, or .org; (2) verifying authorship and sources, and prioritizing content reviewed by scientific societies, health organizations, or accredited institutions; (3) avoiding personal testimonials as clinical evidence, since anecdotal narratives do not substitute scientific knowledge; and (4) consulting health care professionals before making any medical decisions [51,54,58,59].

In the field of pulmonology and respiratory diseases, the Reddit social media platform has previously been used to identify unmet needs, sentiments toward areas of interest, shared patient concerns, and the adoption of (unhealthy) behaviors related to e-cigarette use during the COVID-19 pandemic [60], lung cancer [61], vaping use [62], and respiratory lesions [63,64]. However, no previous work from Reddit's analysis has been found for people with asthma. Asthma carries a significant burden on patients' lives, with an important impact on their quality of life and health loss burden, measured by disability-adjusted life years, years of life lost, and years lived with disability [65]. Ten Have et al [66] showed that there are 4 asthma symptoms that, due to their impact, need to be prioritized in their resolution: fatigue, sleep disturbance, impairment of physical activity, and work-related symptoms. Moreover, our results do not show posts with relevant weight on fatigue or sleep disturbances, but on walking ability (topic 1, the fifth by weight, see Figure 1), and on work activity (topic 9, the 12th by weight). Our results revealed posts and comments from patients with Asthma on

Reddit discussing the onset of asthma attacks, changes in symptoms throughout the year, and seasonal variations linked to colder temperatures (topics 2, 19, and 23). This interest aligns with previous studies showing that extreme temperatures—both hot and cold—can trigger asthma attacks and worsen symptoms [67,68].

The strategy for asthma prevention and remission of the European Forum for Research and Education in Allergy and Airway Diseases Consensus Statement [69] adopts a phenotype-centered approach aimed at improving clinical outcomes and preserving health-related quality of life. This strategy moves away from the current "one-size-fits-all" concept, which focuses on symptom-oriented treatment strategies. In addition, there is growing support among experts for including nonpharmacological and interdisciplinary interventions—such as breathing exercises and multicomponent services—in the asthma management "toolbox." These approaches aim to help manage clinical symptoms, improve patients' quality of life, reduce health care costs, and address unmet needs [70]. This would help to decrease the discordance between compliance rates reported by patients with asthma and physicians [71].

Additionally, another aim would be to avoid loss of adherence to treatments. Thus, Amin et al [72] described how denial of the disease and of the need for long-term treatment, along with poor physician-patient communication, suboptimal knowledge of asthma medication (lack of understanding of the distinction between maintenance and reliever inhalers), suboptimal inhaler technique, and the high cost of asthma medication, were key factors in poor medication adherence. Access to pharmacological treatment, its correct use, identification of adverse effects, and use of other therapies appear in our results in six topics (Topics 4, 6, and 13-16), with special consideration of inhaled treatments as a means of administration.

At this point, patient participation is key to treatment adherence and adoption of healthy behaviors. Kang et al [73], in their systematic review and meta-synthesis of qualitative studies on shared decision-making, highlight that patients with asthma engage in shared decision-making when they have the opportunity (ie, environmental factors such as social, cultural, and institutional conditions that either facilitate or hinder individual behavior). The capability (skills, knowledge, and abilities required for individuals to engage in a particular behavior), and the motivation (internal psychological factors that drive individuals to choose specific behaviors based on their motivations and goals. The authors of this study believe that Reddit could be a tool used by patients with asthma to gain more capacity and opportunity to manage the disease, its symptoms, and treatments.

Another possible explanation for the use of Reddit as a source of information, obtaining medications and guidelines for the use of pharmaceutical products and drugs, may be related to the price of health care provided by professionals (doctors) and the cost of drugs [72,74,75]. Zhang et al [65], in their study on health loss and the economic burden of asthma in China, described an annual direct cost of between US $348 and US $1187 per capita, indirect costs of US $7 to US $1195, and hospitalization costs of US $177 to US $1547, influenced by the frequency and severity of acute exacerbations, comorbidities, and treatment adherence. Each country has different health systems with their own models of resource organization (public vs private), which could influence access to health care, medical information and recommendations, and pharmacological treatments for people with asthma [75].

Our results revealed a range of emotions and sentiments, with notable differences between the positive sentiment scores found using the AFINN lexicon and the negative sentiments identified through the Stanford NLP, Bing, and NRC lexicons. This variability in both positive and negative emotions also appears in the study by Volpato et al [74], where patients with uncontrolled asthma experienced a wide range of emotions that impacted their daily lives. Fear and anxiety appeared alongside the unpredictability of asthma attacks, while frustration and hopelessness accompanied the symptoms [74].

Limitations and Strengths

Among the limitations of this study is the inability to confirm an asthma diagnosis in the users who participated in the r/Asthma forum on Reddit, as well as the inability to determine other sociodemographic data of the forum participants [40]. However, the anonymous and private nature of social media would allow users to share questions, doubts, embarrassing topics, and make comments without restrictions that they would not make in other contexts [10]. Another limitation is that there was no uniformity in the comments, with some posts providing more information and content than others. This limitation was resolved by including all possible response threads derived from the posts in the study. The third limitation is that no keywords or combinations were used to search for and include posts in this study. In our study, since there were no previous studies on Reddit content related to asthma, all posts and threads generated during the study year were included. Finally, the reliability of the information shared on Reddit and other online social media platforms is essential for fostering trust in such content, promoting healthy behaviors, and protecting users' health [54]. In this initial study conducted within the Reddit r/Asthma forum, we presented the thematic content and types of information shared by users, as well as the emotional expressions and polarity of their language. Based on this preliminary work, further research would be justified to investigate the credibility and reliability of the information shared in thematic posts, and to explore potential relationships or associations between specific emotional states and the quality of the information provided.

In relation to strengths, social media analysis (Reddit) can provide key information compared to other data collection methods, such as traditional surveys, without being limited by issues such as sensitivity or taboos surrounding certain topics [10,40]. Conversely, among all available online social media platforms, only Reddit was used due to its structure based on thematic forums or communities (subreddits), where users share content and engage in discussions focused on specific topics or interests. This structure contrasts with other platforms, such as Instagram or X, which are primarily oriented toward following individuals. Moreover, content visibility on Reddit is determined

by user evaluations—either positive or negative—rather than by algorithms that prioritize virality or engagement metrics. Reddit also enables extensive discussions without restrictions on character count, image format, or source type, unlike other platforms that impose limitations based on character length (X), visual format (Instagram), or social network boundaries (Facebook). This would allow for the collection of valuable insights into users' motivations and the nature of the content they share. Furthermore, another strength of Reddit analysis for understanding patient feelings and behaviors is that large volumes of data can be obtained in a short period of time, and user-generated content can be processed quickly [76,77]. In addition, social media generates and shares a large amount of varied information on health and disease topics, allowing patients and their families to learn about different aspects of health care, such as diagnostic processes, treatments, coping strategies, professional advice, etc.

Conclusions

These findings can help uncover hidden needs and challenges faced daily by forum users and may assist health care professionals in developing targeted interventions aimed at improving knowledge around key topics. Identifying the most frequently shared thematic content (weighted topics) is relevant for health care professionals, as it may not reflect their clinical priorities. It also enables the assessment of information quality and the detection of potentially risky behaviors that are not supported by scientific evidence. In future research, it would be necessary to examine the scientific quality of the information shared in posts within Reddit's r/Asthma forum and its relationship to emotional state when sharing posts.

Acknowledgments

This study would not have been possible without the support of the Sociedad Castellanoleonesa y Cántabra de Patología Respiratoria (Spanish and Cantabrian Society of Respiratory Pathology).

Funding

This research was funded by Sociedad Castellanoleonesa y Cántabra de Patología Respiratoria (Spanish and Cantabrian Society of Respiratory Pathology). The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Data Availability

The datasets generated and analyzed during this study is not publicly available; although Reddit posts are publicly available and anonymized by username, Redditors did not consent for their content to be shared publicly in a curated dataset. The dataset is available from the corresponding author on reasonable request for research purposes.

Abstract

Background: Thrombolysis and mechanical thrombectomy represent the most successful stroke innovations over the last 30 years. Quantifying innovation in stroke is essential for identifying productive research lines and prioritizing funding, but health care lacks validated methods for measuring innovation.

Objective: This study aimed to systematically evaluate the relationship between stroke-related patents and publications, demonstrate the feasibility of using large language models (LLMs) in this process, and identify the most rapidly advancing innovations in stroke care by mapping them to a theoretical innovation life cycle.

Methods: The Open Patent Services (European Patent Office) and PubMed databases were searched between 1993 and 2023 for "stroke OR cerebrovascular." In this bibliometric patent-publication analysis, a 13 billion–parameter Llama LLM was trained to identify patents related to stroke disease, as opposed to other references to the word "stroke," on a manually labeled subset of 5000 patents and assessed using 5-fold cross-validation. The LLM filtered irrelevant results, and the resulting patent codes were grouped into innovation clusters. For each cluster, annual patent and publication counts were normalized to adjust for global trends. Cluster-specific growth curves were plotted to analyze the rates and characteristics of growth. The innovation life cycle stage for each innovation cluster was estimated by fitting a sigmoid curve to the patent and publication data consistent with the diffusion of innovations theory by Rogers.

Results: The cross-validated accuracy of the LLM was 99.2%, with a sensitivity of 96.5% and a specificity of 99.6%. An initial bibliometric search retrieved 237,035 patents and 486,664 research publications. A manual review of a random sample of patents before filtering revealed that only 11.2% (56/500) were relevant to stroke. After LLM filtering, of the 237,035 patents, 28,225 (11.9%) stroke-related patents remained. These were grouped into 7 innovation clusters: pharmacological treatment, alternative medicine, rehabilitation devices, medical imaging, diagnostic testing, surgical devices, and artificial intelligence (AI) methods. Patent and publication counts were strongly correlated across clusters (Spearman r_s=0.65-0.92; P<.006) except for pharmacological treatment (r_s=0.09) and alternative medicine (r_s=0.55). Pharmacological treatments were the top-performing cluster over the last 30 years, accounting for 49.3% (36,005/73,094) of all patents, but patent activity in this area has plateaued since the late 2000s. AI methods, rehabilitation devices, and medical imaging exhibited exponential rates of patent growth, with annual normalized increases of 39.2%, 15.9%, and 5.8% compared to 16.9%, 5.3%, and 2.2% for publications, respectively.

Conclusions: Applying an LLM to publicly available patent and publication data provides a scalable way to quantify innovation in stroke. Pharmacological treatment appears to have entered a saturation phase, whereas AI methods, rehabilitation devices, and medical imaging remain in rapid growth, highlighting areas of greatest traction for future research and investment.

Introduction

Turning points in stroke treatment occurred in 1995 and 2015 with the introduction of thrombolysis and mechanical thrombectomy, respectively [1,2]. Such shifts are rare and, in a more formal context, can be considered innovations: a term defined as a process that ushers in new technologies or techniques that induce a substantial change in practice [3,4]. Quantifying innovation in stroke care is vital as it helps discern which lines of research are productive, such as revascularization therapies, perfusion imaging, and decompressive surgery, as opposed to those that have been less successful, such as neuroprotective and neurorestorative therapies. Measures of innovation output aid in research strategy planning, prioritizing, and assessing the effectiveness of research funding. However, while the study of innovation is well established in other fields [5], health care has relatively few validated methods for quantifying innovation outputs, which can limit progress [6].

Prior evaluations of innovation in stroke have been limited, consisting largely of qualitative reviews [7-9] or conventional bibliometric analyses that track academic trends [10]. While valuable for tracking academic discourse and research activity, such bibliometric approaches have inherent limitations for measuring tangible innovation. Metrics based on citations and publications tend to reflect academic impact over practical implementation, and they do not readily distinguish incremental advances from transformative breakthroughs. Consequently, these methods primarily measure research inputs and academic outputs, not the development of novel, practical solutions.

An alternative approach, originally applied to surgery [4], leverages original patents as a benchmark of technological innovation by comparing the cumulative quantity of patents for a specific innovation with that of related peer-reviewed publications. This method has the advantage of drawing on a comprehensive repository of inventions that have been independently evaluated for novelty and utility; these are generally sufficiently mature and practical to have attracted the funding resources required for patent filing. However, patent analysis relies heavily on the precise interpretation and determination of relevant patents, a task complicated by the broad and often ambiguous language of patent documents, making it labor-intensive and time-consuming. The difficulty of this task is particularly magnified in the context of stroke-related patents given that the term “stroke” could denote a disease as well as multiple engineering concepts and mechanical action of engines, clocks, and other mechanisms. Conventional search engines such as Google are liable to confound stroke terms as they lack the specialized filtering and context awareness needed for precise medical searches.

In this regard, recent advancements in artificial intelligence (AI), specifically large language models (LLMs), hold tremendous potential. They have exhibited remarkable proficiency in textual tasks, making them invaluable in this context [11]. Essentially, LLMs are statistical models trained on vast datasets enabling them to learn intricate relationships between words and phrases. While training LLMs from scratch might pose considerable difficulties and financial burden, the recent availability of open-source trained LLMs to the public has mitigated these challenges [12].

Therefore, the aims of this study were 3-fold: first, to evaluate systematically the relationship between stroke-related patents and publications over the last 3 decades; second, to demonstrate the feasibility of using LLMs to assist in this process; and, finally, to identify the most rapidly advancing innovations in stroke care.

Methods

Although this was not a clinical study, the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines [13] were adhered to where appropriate. The methodology was based on the work by Hughes-Hallett et al [4], with adaptions for stroke-related innovation.

Data Collection

The Open Patent Services web service, provided by the European Patent Office [14], was used to obtain patent application data from more than 80 different countries. The period from 1993 to 2023 was chosen to capture the modern era of stroke care, beginning shortly before the pivotal 1995 National Institute of Neurological Disorders and Stroke trial that established thrombolysis as a standard treatment [1]. Patents filed between 1993 and 2023 were downloaded if either their title or abstract matched the following Boolean search: “stroke OR cerebrovascular.” A PubMed (National Library of Medicine) search was also conducted using the same strategy to extract publication data for the same period.

Data Filtering

The collected patents were randomly sampled, and a subset of 5000 was manually annotated by a single author (AM), who is a medical professional, as either related or unrelated to stroke. A second, random unfiltered sample of 500 patents and 500 publications matching the search terms “stroke” or “cerebrovascular” was also manually labeled by the same annotator (AM). Annotations from the 5000-patent subset were used to provide ground truth for model fine-tuning, whereas the second sample was used to verify the accuracy of the search strategy, especially for PubMed results. Patents were considered stroke related if their primary content was directly relevant to stroke management or pathophysiology. Publications were considered stroke related if they contributed to the understanding of stroke, including basic science suitable for stroke journals and clinical studies with stroke as an end point.

A 13 billion–parameter Llama model (Meta AI) [12], a state-of-the-art open-source LLM trained on web data, was then fine-tuned using low-rank adaptation (LoRA) [15] to classify stroke-related patents. Fine-tuning was performed using PyTorch (version 1.13; Meta AI) on a machine equipped with a 2.80-GHz AMD EPYC 7543P central processing unit and an NVIDIA RTX A4500 20-GB graphics processing unit. The hyperparameters, which are listed in Table 1 and were based on standard values from the original LoRA paper [15], were chosen to ensure stable training while preventing overfitting. In particular, the LoRA rank was set to 8 to keep model adaptation minimal and efficient. The prompt template is provided in Figure 1. To assess prompt sensitivity, alternative phrasings were trialed on a development subset during fine-tuning. The model's performance was evaluated using 5-fold cross-validated binary classification metrics and compared to that of the base model before the final model was used to analyze the unlabeled patents and filter out those unrelated to stroke. The model was not used for classifying publications.

Table 1. The hyperparameters used for fine-tuning the Llama model using low-rank adaptation (LoRA).

Parameter	Value
Batch size	128
Number of epochs	10
Learning rate	0.0003
Optimizer	Adam
Maximum gradient norm	1
LoRA rank	8
LoRA alpha	16
LoRA dropout	0.05
LoRA target modules	Query and value projection

Data Normalization

Across all fields, the number of patents and publications has risen exponentially. To adjust for this increase, both counts were normalized using the formula outlined by Hughes-Hallett et al [4]:

In this formula, II_i denotes the innovation index, defined as the number of patents or publications within a particular field; C_i is the innovation constant; and t_i is the total number of patents granted or publications indexed on PubMed for a given year i. For example, if a field had 50 patents in a year when 100,000 patents were granted and the maximum number of patents in any year during the study period was 200,000, then C_i = 100,000/200,000 = 0.5, and the normalized innovation index would be 50/0.5 = 100.

Identifying Innovation Clusters

The process of identifying innovation clusters involved a 2-stage method to ensure comprehensive coverage. Initially, the top 100 most frequent International Patent Classification (IPC) [16] codes from the filtered, stroke-related patent dataset were extracted. These codes, assigned by patent examiners, offer a standardized way of categorizing the technological domains of inventions. Focusing on the top 100 codes provided a quantitative starting point, representing the most concentrated areas of patent activity while avoiding the sparsity and noise of the long tail of less frequent codes.

These top 100 codes were then manually grouped into preliminary innovation clusters by 2 authors (AM and GL-T).

This grouping was based on the descriptive content of the IPC codes and their relevance to distinct areas of stroke care. Interrater reliability was assessed using the Cohen κ, and any disagreements regarding this grouping were resolved by a third author (PB).

To capture relevant patents and publications that may not have fallen into these top 100 codes, a second stage was implemented. Expanded, cluster-specific Boolean search strategies were developed as listed in Table 2 and performed on both the patent database and PubMed. The keywords for these searches were also determined by 2 authors (AM and GL-T), with a third author (PB) resolving any disagreements. For clusters such as alternative medicine, broader search terms such as "food" and "herbal" were intentionally used. This was necessary to capture innovations described in nonclinical or lay terms, which is common in patent applications for complementary therapies that may lack standardized medical terminology. The final dataset for each cluster comprised all documents identified through either the initial IPC code grouping or the subsequent expanded Boolean search. Finally, this entire 2-step methodology was repeated for patents and publications from the last decade (2013-2023) to allow for the determination of more recent innovations.

Table 2. PubMed and European Patent Office database search strategies.

Innovation cluster	Search strategy
AI[a] methods	(AI OR "artificial intelligence" OR "deep learning" OR "machine learning" OR "neural network") AND (stroke OR cerebrovascular)
Alternative medicine	(food OR tea OR coffee OR beverage OR herbal OR acupuncture OR aromatherapy OR reflexology OR "holistic therapy") AND (stroke OR cerebrovascular)
Diagnostic testing	("diagnostic testing" OR "diagnostic tools" OR "clinical tests" OR "screening tests" OR "blood tests" OR "laboratory tests" OR "genetic testing") AND (stroke OR cerebrovascular)
Medical imaging	(imaging OR angiography OR angiogram OR ultrasound OR CT OR MRI OR PET OR "computed tomography" OR "magnetic resonance" OR "positron emission tomography") AND (stroke OR cerebrovascular)
Pharmacological treatment	(thrombolysis OR aspirin OR clopidogrel OR warfarin OR DOACs OR alteplase OR tPA OR "tissue plasminogen activator" OR "thrombolytic therapy" OR "pharmacological treatment" OR "pharmaceutical composition" OR "drug therapy" OR "secondary prevention" OR "direct oral anticoagulants") AND (stroke OR cerebrovascular)
Rehabilitation devices	(rehabilitation OR neurorehabilitation OR exoskeleton OR "training device" OR "brain-computer interface") AND (stroke OR cerebrovascular)
Surgical devices	(thrombectomy OR embolectomy OR "clot removal" OR "clot retrieval" OR "catheter device" OR "surgical device" OR "endovascular treatment" OR "endovascular therapy") AND (stroke OR cerebrovascular)

[a]AI: artificial intelligence.

Statistical Analysis

All statistical analyses were performed using Python (version 3.11.3; Python Software Foundation) and the *statsmodels* [17] package. Permutation testing with Bonferroni correction was used to calculate *P* values adjusted for multiple tests. The relationship between patent and publication data was visualized using scatterplots to assess the nature of the association. On the basis of this visual inspection, an appropriate correlation coefficient was selected: Pearson (r) for linear relationships and Spearman rank (r_s), a nonparametric method, for monotonic but nonlinear relationships. To model the technology diffusion life cycle, innovation life cycle progression was derived by fitting sigmoid curves to the patent and publication data, a method consistent with the diffusion of innovations theory by Rogers [18]. To quantify the uncertainty in these estimates, 95% CIs were calculated using nonparametric bootstrapping, which involved repeatedly resampling the data and refitting the curve.

Results

Data and Filtering Performance

The initial search retrieved 237,035 patents and 486,664 publications. In a random, unfiltered sample of 500 patents and 500 publications matching the search terms "stroke" or "cerebrovascular," 11.2% (56/500) of patents and 74.2% (371/500) of publications were stroke related. The remaining patents typically referred to "stroke" in nonclinical contexts, including mechanical travel (eg, stroke length in pistons), engine cycles (eg, 2-stroke engines), lightning discharges, and line rendering in handwriting or graphics. These examples formed the negative class for model fine-tuning. An LLM was then fine-tuned to classify whether a patent was stroke related, achieving a cross-validated accuracy of 99.2% with a sensitivity of 96.5% and specificity of 99.6% and significantly outperforming the base model across all metrics listed in Table 3 (all $P<.001$). The receiver operating characteristic curve is shown in Figure 2 [19]. Prompt sensitivity was also evaluated during model fine-tuning using alternative phrasings; this had a negligible impact on classification outcomes. After filtering using the model, of the 237,035 patents, 28,225 (11.9%) stroke-related patents remained. Figure 3 illustrates the annual

increase in these patents filed by geographic region, with the largest proportion originating from China. The original and normalized counts of patents and publications related to stroke are shown in Figure 4. Normalized patent counts reached a peak in 2010, whereas normalized publication activity continues to grow.

Table 3. Five-fold cross-validated performance of the fine-tuned Llama model compared to the base model for classifying whether a patent was stroke related. *P* values are from 2-tailed paired t tests across the 5 folds.

Measure	Fine-tuned estimate (95% CI)	Base estimate (95% CI)	*P* value
AUROC[a]	0.990 (0.988-0.992)	0.654 (0.605-0.703)	<.001
Accuracy (%)	99.2 (99.0-99.5)	66.8 (66.3-67.3)	<.001
Sensitivity (%)	96.5 (94.8-98.2)	54.5 (48.3-60.7)	<.001
Specificity (%)	99.6 (99.4-99.7)	68.2 (67.6-68.7)	<.001
PPV[b] (%)	96.1 (94.8-97.4)	16.5 (13.9-19.1)	<.001
NPV[c] (%)	99.6 (99.4-99.8)	92.9 (92.2-93.7)	<.001
F_1-score (%)	96.3 (95.1-97.5)	25.2 (21.6-28.9)	<.001

[a]AUROC: area under the receiver operating characteristic curve.

[b]PPV: positive predictive value.

[c]NPV: negative predictive value.

Figure 2. Receiver operating characteristic curve illustrating the cross-validated performance of the fine-tuned Llama model compared to the base Llama model in classifying stroke-related patents. The shaded area represents the 95% confidence region determined via the fixed-width band technique [19]. AUC: area under the curve.

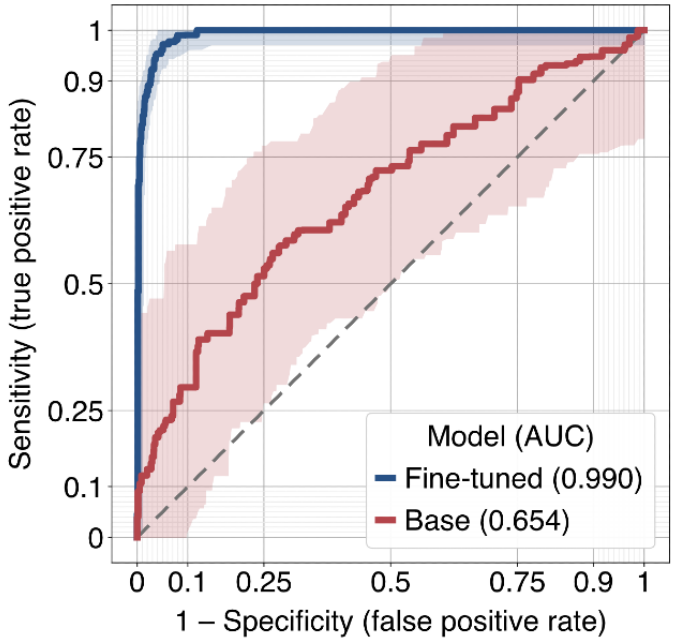

Figure 3. Stroke-related patents filed between 1993 and 2023 categorized by geographic coverage as defined by patent filing jurisdiction and route (China: China National Intellectual Property Administration; United States: US Patent and Trademark Office; Japan: Japan Patent Office; South Korea: Korean Intellectual Property Office; Canada: Canadian Intellectual Property Office; Europe: European Patent Office; worldwide: Patent Cooperation Treaty or World Intellectual Property Organization; other regions: other national or regional offices).

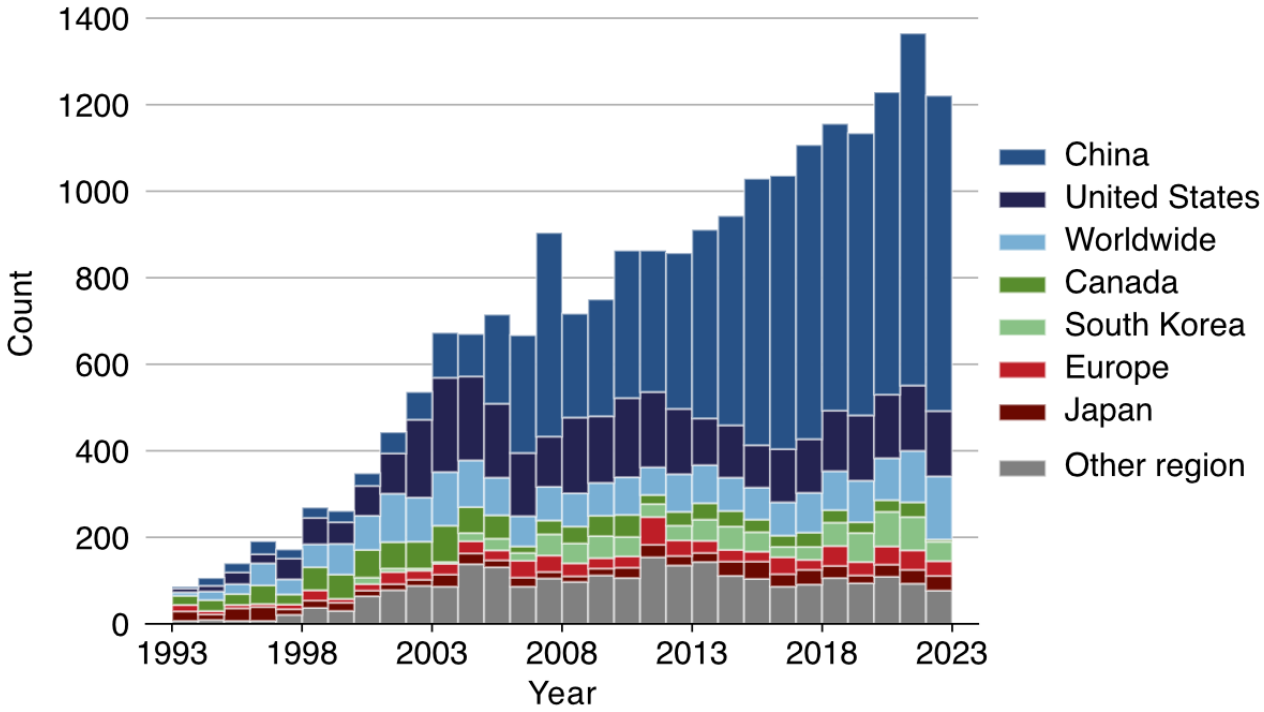

Figure 4. Overview of the (A) counts of patents and publications related to stroke over time and (B) year-on-year normalized patent and publication counts for each innovation cluster. Normalized counts were calculated by dividing the annual number of stroke-related patents or publications by the total number of patents or publications in that year, scaled to the maximum annual total across the study period. In both cases, the dashed lines depict exponential fits with the associated coefficients of determination (R^2) given per plot. AI: artificial intelligence.

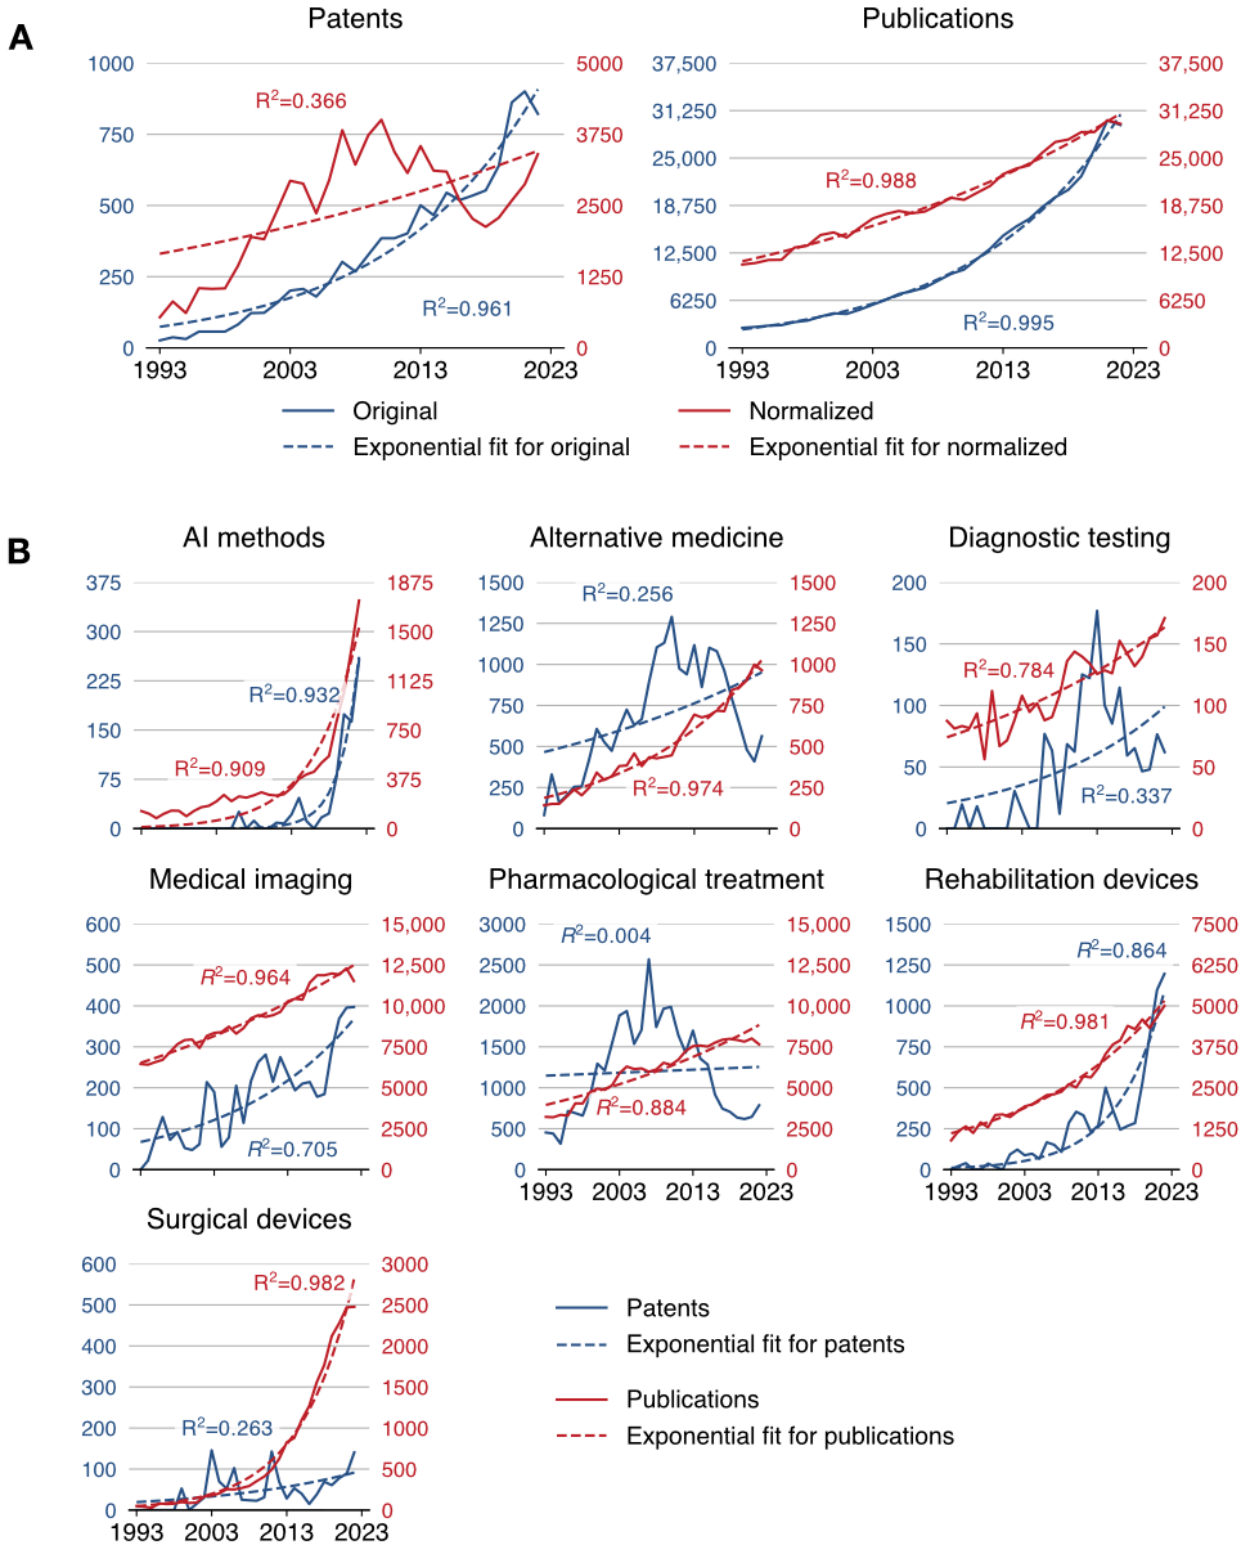

Leading Innovation Clusters

There were 7 top stroke-related innovation clusters identified over the last 30 years; interrater reliability between the 2 authors was high (Cohen κ=0.871). To address potential overcapture in the alternative medicine cluster due to broad search terms, a sensitivity analysis of 100 randomly sampled patents was performed, verifying that 97% were stroke related. The performance of these clusters, as measured using patents, is summarized in Table 4, with the allocation of patent codes provided in Multimedia Appendix 1. Pharmacological treatment was the largest cluster, accounting for 49.3% (36,005/73,094)

of the patents filed over the study period. To ensure the stability of these findings, a sensitivity analysis was performed confirming that cluster rankings held without normalization (data not shown). Within the last decade, only AI methods increased in rank, with the relative ordering of the other top-performing clusters remaining constant. Although not reflected in a change in order, the proportion accounted for by pharmacological treatments fell to 33.7% (9391/27,870), whereas all the other clusters increased their shares.

Table 4. Comparing the top-performing stroke-related innovation clusters by cumulative normalized patent counts over the past 30 years and the last decade. Artificial intelligence (AI) methods were the only cluster to increase in rank.

Rank	Innovation cluster	Normalized patent count, n (%)
1993-2023 (n=73,094)		
1	Pharmacological treatment	36,005 (49.3)
2	Alternative medicine	20,291 (27.8)
3	Rehabilitation devices	7777 (10.6)
4	Medical imaging	5331 (7.3)
5	Diagnostic testing	1448 (2.0)
6	Surgical devices	1397 (1.9)
7	AI methods	845 (1.2)
2013-2023 (n=27,870)		
1	Pharmacological treatment	9391 (33.7)
2	Alternative medicine	8005 (28.7)
3	Rehabilitation devices	5569 (20.0)
4	Medical imaging	2668 (9.6)
5	AI methods	791 (2.8)
6	Diagnostic testing	834 (3.0)
7	Surgical devices	612 (2.2)

Statistical Analysis

Figure 4 and Table 5 show the relationship between normalized patent and publication counts over time for the top-performing innovation clusters. There were strong associations (r_s>0.6; P<.006) between patent and publication rates for all clusters except pharmacological treatment (r_s=0.094; P=.99) and alternative medicine (r_s=0.546; P=.01). These 2 clusters showed normalized patents peaking in the late 2000s, with a continued shallow rise in publications. This trend is further illustrated by the normalized patent-to-publication ratio over time for each innovation cluster, as detailed in Multimedia Appendix 2. Plots of the data on AI methods show a rapid rise similar to that of other emerging clusters. To quantify this concurrent growth, the temporal correlation between the AI cluster and other leading clusters was assessed. AI patent activity was strongly correlated with patent activity in rehabilitation devices (r_s=0.767; P=.004) and medical imaging (r_s=0.662; P=.004). Similarly, AI publication rates correlated strongly with publication rates in rehabilitation devices (r_s=0.963; P=.004) and medical imaging (r_s=0.962; P=.004). These clusters all exhibited a strong exponential fit for both patent and publication data supported by coefficient of determination (R^2) values exceeding 0.7, as shown in Table 5. The rates of exponential growth for AI methods were the highest (39.2% per year for patents; 16.9% per year for publications), followed by rehabilitation devices (15.9% per year for patents; 5.3% per year for publications) and medical imaging (5.8% per year for patents; 2.2% per year for publications). The diffusion dynamics for each innovation cluster, approximated by fitting sigmoid curves to the patent and publication data, are shown in Figure 5 [18] and contextualized within the phases of the diffusion of innovations theory by Rogers [18], highlighting their positions in the innovation life cycle. The estimated progression through the innovation life cycle based on patent data was highest for pharmacological treatment (97.5%), followed by surgical devices (82.9%), nutritional and complementary therapies (71.4%), diagnostic testing (52.2%), AI methods (41.6%), medical imaging (30.5%), and rehabilitation devices (16.5%).

Table 5. Comparing the association between the normalized patent and publication counts for each innovation cluster along with the equations of the associated lines of the best exponential fit.

Innovation cluster	Patents		Publications		Association	
	Equation for the line with the best exponential fit	R^2	Equation for the line with the best exponential fit	R^2	r_s	*P* value
AI[a] methods	$3.7E\text{-}343e^{0.392x}$	0.932	$2.7E\text{-}146e^{0.169x}$	0.909	0.776	.001
Alternative medicine	$7.3E\text{-}20e^{0.025x}$	0.256	$2.2E\text{-}49e^{0.059x}$	0.974	0.546	.02
Diagnostic testing	$9.1E\text{-}47e^{0.054x}$	0.337	$1.9E\text{-}22e^{0.027x}$	0.784	0.645	.006
Medical imaging	$5.8E\text{-}50e^{0.058x}$	0.705	$2.6E\text{-}16e^{0.022x}$	0.964	0.767	.001
Pharmacological treatment	$8.5E\text{-}1e^{0.003x}$	0.004	$3.8E\text{-}21e^{0.028x}$	0.884	0.094	>.99
Rehabilitation devices	$9.1E\text{-}138e^{0.159x}$	0.864	$1.6E\text{-}43e^{0.053x}$	0.981	0.916	.001
Surgical devices	$5.2E\text{-}46e^{0.053x}$	0.263	$3.8E\text{-}120e^{0.140x}$	0.982	0.649	.001

Discussion

Principal Findings

To the best of the authors' knowledge, this study provides the first rigorous quantification of innovation in stroke management. By using a scientifically validated framework, along with a novel application of an LLM, publicly available patent and publication data were analyzed. Among the top stroke-related innovation clusters identified, pharmacological treatment was found to be the most dominant over the past 30 years, accounting for nearly half (36,005/73,094, 49.3%) of all patents filed. AI methods, followed by rehabilitation devices and medical imaging, exhibited the highest rates of patent and publication growth, suggesting that these emerging innovation clusters are taking on increasingly important roles.

The diffusion of innovations theory by Rogers [18] describes the adoption curve of technology as a sigmoid function. This arises from the natural variation in the attitudes of individuals, ranging from early adopters to laggards, toward a new innovation. Previous studies have shown that this curve can also be applied to specific clusters themselves [4,20], indicating different phases of innovation: the incubation phase, where seminal work occurs and which is reflected by the initial rise in patenting and publication activity; the growth phase, where industry and clinicians drive innovation and which is associated with an exponential rise in patent and publication counts; and, finally, the saturation phase, which occurs when manufacturers refine the technology to maintain their competitive edge while continuing to pursue patents, leading to a plateau in both patent and publication activity. While these curves provide a model for technology diffusion, we acknowledge that this is a simplification. Real-world adoption in health care is complex and is further influenced by external factors such as regulatory approvals, reimbursement policies, and the development of clinical guidelines, which were not modeled in this study.

Applying this theory to this study, there was an exponential rise in the number of patents and publications for AI methods. This

study's novel quantification of this trend demonstrates that the patent growth rate for AI methods is approximately 2 to 7 times greater than that for the other key growth clusters of rehabilitation devices and medical imaging. This suggests that these clusters are all in the growth phase but that AI is accelerating at a substantially faster rate. There was a significant inflection point for AI methods observed in 2018, coinciding with the regulatory approval of the first AI software developed by Viz.ai [21]. Subsequently, the market has experienced a proliferation of commercially available software platforms designed to interpret and triage radiological data [22]. Therefore, the concurrent rise in medical imaging is to be expected given that these AI platforms, and indeed the main applications of AI in stroke [23-25], relate to analysis and interpretation of medical images. Similarly, while rehabilitation systems for stroke have yet to receive the same level of attention, there has been growing interest in full automation, with AI methods actively being researched [26].

The pattern for surgical devices presents a less clear trajectory: patent counts are leveling off, whereas publications continue to increase. This divergence could suggest that surgical device innovation remains at a nascent, exploratory stage: scholarly output continues to rise, whereas commercial patenting momentum has yet to follow. Alternatively, this pattern may relate to a limitation of the innovation discovery method used in this study in that patents for generic technologies that do not explicitly state stroke management may be incorrectly excluded. Thus, many patents for mechanical thrombectomy, being applicable to multiple diseases, may not be seen to parallel the rise in stroke thrombectomy publications.

Pharmacological treatments, alternative medicine, and diagnostic testing all experienced peaks in patent activity during the 2000s and have since plateaued, indicating that these sectors are now in the saturation phase. This finding for pharmacological treatments is particularly notable and perhaps unexpected given recent high-profile trials of novel drug classes. The rise in pharmacological treatments can be traced back to 1995 following the groundbreaking National Institute of Neurological Disorders and Stroke tissue-type plasminogen activator trial [1]. However, despite extensive efforts, the development of new therapeutics has become more challenging [27], and thus, a relative decrease in the number of patents and publications is perhaps unsurprising. Notably, this decline coincided with a decoupling between research output and patent activity (r_s=0.09; P=.99), suggesting that ongoing research in pharmacology increasingly focuses on avenues less amenable to patenting. Similarly, alternative medicine, despite seeing increased enthusiasm, particularly in addressing poststroke depression [28], is a well-established field whose roots predate orthodox medicine [29]. Diagnostic testing is also mature, with many of the key technologies, such as electrocardiogram and blood pressure monitors, able to be traced back to the 19th century [30,31]. As such, the observed trends appear in line with expectations.

The varying patent coefficient of determination (R^2) values across the innovation clusters provide insights into the reliability of their respective innovation trajectories. For AI methods (R^2=0.932), rehabilitation devices (R^2=0.864), and medical imaging (R^2=0.705), the high values signify a consistent and predictable exponential growth, reinforcing the conclusion that these are emerging technologies in a strong growth phase. In contrast, the lower values for patent trends in pharmacological treatments (R^2=0.004) and alternative medicine (R^2=0.256) suggest that an exponential model is less descriptive. This lower reliability is not a limitation of the data but rather an indicator that these fields have likely reached a saturation phase in which innovation, as measured via patent filings, is no longer accelerating at a consistent exponential rate.

The observed rise in AI-driven platforms, many of which operate on medical imaging data, has been linked to faster treatment times in acute stroke care. For example, a single-center study reported that the introduction of the Viz.ai software, which uses automated image interpretation to triage stroke cases, was associated with a 30-minute reduction in median door-to-needle time, alongside improvements in door-to-imaging and door-to-puncture intervals [32]. Similarly, innovations in rehabilitation devices, including robotic-assisted gait and upper-limb training, have demonstrated clinically meaningful improvements in motor function and activities of daily living in randomized controlled trials [33]. This demonstrated clinical value arguably provides a powerful mechanism that drives the investment, research, and patenting activity observed in this study. Taken together, these examples suggest that the observed growth in patents and publications within emerging innovation clusters reflects not only conceptual progress but also improvements in patient care and clinical workflows.

Comparison With Other Studies

There has been limited prior work evaluating innovation in stroke, with those studies focusing only on specific areas and generally being qualitative [7-9]. Martinez-Gutierrez et al [7] conducted a narrative review of developing technologies in the prehospital space in which they identified emergency medical service detection and triage of stroke as important areas for future advancements. The study also supported the potential of AI algorithms in these domains, aligning with the findings of our study. Recently, Ji et al [10] conducted a bibliometric analysis using Web of Science specifically for perioperative stroke over the past 20 years and found rapid growth in research publications addressing antiplatelet and antithrombotic therapy, cardiovascular surgery, and thrombectomy, among others. One notable difference between this study's results and those of our study is that the former identified pharmacological treatments and surgical devices as leading research areas. However, this discrepancy may be due to their use of absolute rather than normalized publication counts and their restriction to a narrow type of stroke as opposed to all causes, as in this study.

Within the field of health care more generally, Tran et al [34] performed a survey of health AI publications using Web of Science between 1977 and 2018 and found stroke to be a leading application area. The approach used in the aforementioned study has also been applied to neurosurgery [16] and surgery [4] as a whole. In both instances, and in keeping with the work presented in this paper, trends in patents and publications were consistent with the diffusion of innovations theory.

Strengths and Limitations

A key strength of this study lies in its use of a data-driven and quantitative framework to evaluate innovation in stroke management. This approach moves beyond traditional qualitative analyses by incorporating an LLM. This was critical for enabling the study's scale, as the manual filtering of 237,035 patents, of which a sample review found only 11.2% (56/500) to be relevant, would have been prohibitively labor-intensive. By enabling a detailed and extensive search across the breadth of stroke research fields, this study comprehensively quantified the current popularity and productiveness of innovation clusters and, by plotting changes in these metrics over time, can estimate where along the trajectory of innovation diffusion each cluster currently lies. Our results identify emerging technologies and may be useful metrics to inform policy and grant funding strategies. Our results also build on previous work [4,16] that underscores the value of using patent and publication data in the assessment of innovation. Despite their value, patent data have remained largely underused and underinvestigated [4].

Although this study used a novel approach to quantitatively evaluate innovation in stroke management, it is not without limitations. First, the methodology relied on patents as an indicator of technological innovation, potentially overlooking the output from individuals or organizations who lack the resources to apply for patents or choose not to for ethical or other reasons. Second, emerging or small-scale innovation clusters were unlikely to be identified through the method used, as they may be concealed within larger, more mature clusters. Third, patents for generic technological innovations that did not explicitly state their application to stroke were excluded from the analysis, even though they could still be applicable to stroke management. Fourth, it is possible that some inventors may deliberately delay academic publication until a patent has been granted, leading to an underestimation of recent innovations. Fifth, bias could be introduced due to the imperfect filtering of patents by the LLM, which was trained on a single-annotated dataset. Such limited annotation may have introduced misclassification errors, potentially overrepresenting clusters that use terminology closely aligned with the training labels while underrepresenting those that rely on novel or nuanced language. This may have affected both the sensitivity and specificity of cluster assignment. Future work building on this methodology should prioritize creating a ground-truth dataset with multiple, independent annotators to validate labels and further improve model generalizability. Sixth, the normalization method based on the work by Hughes-Hallett et al [4] is sensitive to the maximum value within the time series, which may introduce instability in the normalized metrics if future volumes differ substantially. Finally, the findings of this study were not validated against external clinical data. Such a validation would be a valuable next step to confirm whether the identified trends in patenting activity correlate with tangible improvements in stroke care and patient outcomes.

Conclusions

This is the first study to systematically use patent and publication data to quantitatively evaluate innovation in stroke care. Seven influential innovation clusters were identified over the 30-year study period, and their respective growth characteristics were found to be explainable by the diffusion of innovations theory. Looking ahead, the results suggest that AI methods, rehabilitation devices, and medical imaging are undergoing exponential growth and are forecasted to have a greater impact on stroke management. Furthermore, the methodology used in this work, particularly the novel use of an LLM, could be applied to assess more specific clusters and assist in decision-making for future research and funding.

Acknowledgments

The research team gratefully acknowledges the support and resources provided by the BioMedIA laboratory and Imperial College London. Generative artificial intelligence was not used in the creation of the manuscript text, figures, or tables. The large language model (Llama) discussed in this paper was an object of study and a tool for data filtering as described in the Methods section; it was not used to generate any part of this research paper.

Funding

This work was supported by the following grants and programs: the UK Research and Innovation Centre for Doctoral Training in AI for Healthcare [35] under grant EP/S023283/1, The Graham-Dixon Charitable Trust, the UK National Institute for Health and Care Research Invention for Innovation Programme under grant II-LA-0814-20007, he Imperial College Biomedical Research Centre, and the Economic and Social Research Council London Interdisciplinary Social Science Doctoral Training Partnership Collaborative Awards in Science and Engineering studentship.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the terms and conditions of the Open Patent Services web service but are available from the corresponding author on reasonable request.

Authors' Contributions

AM and PB were responsible for the conceptualization of the study. AM, GL-T, and PB developed the methodology. AM conducted the formal analysis and data curation. AM wrote the original draft of the manuscript. All authors contributed to the writing, review, and editing of the final manuscript. PB and DR provided supervision.

Conflicts of Interest

PB is a cofounder of GripAble Ltd, a spin-out company from Imperial College London. All other authors declare no other conflicts of interest.

Abstract

Background: In today's digital era, the internet plays a pervasive role in daily life, influencing everyday activities such as communication, work, and leisure. This online engagement intertwines with offline experiences, shaping individuals' overall well-being. Despite its significance, existing research often falls short in capturing the relationship between internet use and well-being, relying primarily on isolated studies and self-reported data. One major contributor to deteriorated well-being is stress. While some research has examined the relationship between internet use and stress, both positive and negative associations have been reported.

Objective: This study aimed to identify the associations between an individual's internet use and their stress.

Methods: We conducted a 7-month longitudinal study. We combined fine-grained URL-level web browsing traces of 1490 German internet users with their sociodemographics and monthly measures of stress. Further, we developed a conceptual framework that allows us to simultaneously explore different contextual dimensions, including how, where, when, and by whom the internet is used. We applied linear mixed-effects models to examine these associations.

Results: Our analysis revealed several associations between internet use and stress, varying by context. Increased time spent on social media, online shopping, and gaming platforms was associated with higher stress. For example, the time spent by individuals on shopping-related internet use (aggregated over the 30 days before their stress was measured via questionnaires) was positively associated with stress on both mobile (β=.04, 95% CI 0.00 - 0.08; *P*=.04) and desktop devices (β=.03, 95% CI −0.00 to 0.06; *P*=.09). In contrast, time spent on productivity or news websites was associated with lower stress. Specifically, in the last 30 days of mobile usage, productivity-related use showed a negative association with stress (β=−.03, 95% CI −0.06 to −0.00; *P*=.04). In addition, in the last 2 days of data, news usage was negatively associated with stress on both mobile (β=−.54, 95% CI −1.08 to 0.00; *P*=.048) and desktop devices (β=−.50, 95% CI−0.90 to −0.11; *P*=.01). Further analysis showed that total time spent online (β=.01, 95% CI 0.00 - 0.02; *P*<.001), social-media usage (β=.02, 95% CI 0.00 - 0.03; *P*=.02), and gaming usage (β=.01, 95% CI 0.00 - 0.02; *P*=.02) were all positively associated with stress in high-stress Perceived Stress Scale (PSS>26) individuals on mobile devices.

Conclusions: The findings indicate that internet use is associated with stress, and these associations differ across various usage contexts. In the future, the behavioral markers we identified can pave the way for designing individualized tools for people to self-monitor and self-moderate their online behaviors to enhance their well-being, reducing the burden on already overburdened mental health services.

KEYWORDS

online behavior; stress; internet use; web browsing traces; sociodemographic differences; longitudinal design

Introduction

Stress is an unavoidable part of human life, arising from the demands and challenges we face daily. It is a significant factor in health issues such as cardiovascular disease, weakened immune function, and mental health challenges [1,2]. The internet, now an integral part of modern life, has sparked debates about its impact on stress levels and psychological well-being [3,4], as well as whether this influence is predominantly positive or negative. As our online and offline lives become increasingly interconnected, understanding the relationship between internet use and stress has gained considerable attention.

While the internet offers numerous advantages, such as enhanced connectivity and easy access to information, excessive or problematic use has been linked to various stress-related factors [3,5,6]. For example, heavy internet use has been associated

with higher levels of anxiety [5], while the amount of time spent online has been linked to sleep loss and withdrawal [6]. On the other hand, past research suggests that not all forms of internet use are detrimental; certain online activities have been associated with reduced stress and improved psychological well-being [7-9].

Despite the internet's widespread influence, research on psychological well-being, including stress, has primarily focused on offline activities, leaving a critical gap in understanding how online behaviors impact stress and well-being [10]. For instance, a comprehensive review of 99 commonly used psychological well-being scales identified 196 dimensions, yet none explicitly addressed online activities or behaviors [10]. Moreover, studies on online engagement have often faced limitations, including short study durations, small sample sizes, and an over-reliance on questionnaires to capture internet use patterns. These approaches can introduce biases and fail to provide a complete picture of the connection between online and offline experiences [11,12].

In this paper, we first review previous research on the association between internet use and stress and examine the methodologies used in these studies. We then outline our longitudinal multimodal study design, which integrates actual internet usage data with monthly questionnaires to measure stress, and discuss our study's potential impact.

Conflicting Findings on Associations Between Stress and Internet Use

The relationship between internet use and stress is complex, with previous research showing contrasting associations depending on the type and context of digital engagement, as well as individual characteristics. High levels of internet and smartphone use have been linked to increased stress [13,14], often due to digital overload (ie, the cognitive strain caused by constant notifications and an endless stream of information) [15,16]. In contrast, internet use through computers has been associated with less burnout compared to smartphone use [17]. However, these associations are not consistent. For instance, age influences the impact of digital multitasking: younger users report higher stress than older adults when handling multiple digital tasks, yet they appear less affected by communication overload [15]. Experimental evidence shows that multitasking increases perceived stress levels in both younger and older adults, with no significant differences between the age groups [18]. Other studies have shown no association [19] or even a negative association between time spent online and stress, particularly in young adults [20].

Moreover, the type of online activity plays a crucial role in stress outcomes. Social networking and entertainment-related use have been associated with higher stress levels, while internet use for work-related tasks has been linked to greater life satisfaction in the middle-aged population [21]. Research also indicates that communication overload from emails and messages is positively associated with perceived stress in the age group of 50 - 85 years [15]. Studies on social media show similarly nuanced findings. While Pew Research found no association between social media use and stress in men, a negative association was observed in women [22]. A large-scale study also showed slightly higher perceived stress among high social media users than nonusers [23]. Other digital behaviors, such as problematic news consumption [24] and adult content addiction [25], have also been linked to heightened stress and emotional distress. Similarly, concerns such as cyberbullying, online harassment [26], work-life boundary erosion [27], and data privacy issues [28] have been widely documented as stress-inducing. Further studies have found positive associations between stress and various digital behaviors, such as online shopping addiction in young people [29], negative information seeking [30], interpersonal communication in older adults [7], misinformation sharing [31], and excessive gaming in adolescents [32,33].

Conversely, the internet can also act as a buffer against stress [20], offering access to supportive communities [9], relaxation tools, and leisure activities [7]. Online entertainment and social interaction, in particular, have been shown to reduce stress and enhance well-being among older adults [7,8,34]. In addition, internet use has been recognized as a coping mechanism. Several online activities, including social media [35], entertainment [36,37], shopping [38], and gaming [35,39], have been identified in previous studies as strategies for managing stress.

User Characteristics Shape the Relationship Between Online Activity and Stress

Studies show that age, gender, income, and baseline stress levels influence how online activities relate to stress [15,18,22]. Social media use has been negatively associated with stress among females [22], though females overall report higher stress than males [40,41]. Older adults tend to report lower stress than younger groups but experience stronger associations between communication load, frequent messaging, and stress [42,43]. Higher income is generally linked to lower stress levels [44], though findings differ by context—for instance, higher income was associated with fewer mental health issues in Germany but with more issues in China [45]. Social media use has also been linked to slower recovery from real-world stressors, suggesting possible stress maintenance in already stressed individuals [46].

Methods for Identifying Connections Between Internet Use and Stress

Past research on internet use and stress has used various methodologies. Many studies rely on cross-sectional designs and self-reported surveys [7,15,16,21,24,32]. These studies often focus on specific populations, such as university or medical students [13,14]. Some have used larger samples [23,24,32] but still rely on questionnaires to capture internet use. A smaller number of experimental studies are available [30,46], and some have adopted alternative approaches, such as analyzing social media data to infer psychological states [31]. Studies using actual web browsing data [20,47] are limited and tend to capture general metrics, such as total time spent online [20], and are based on relatively small samples (92 and 107 participants), indicating how difficult it is to conduct such studies.

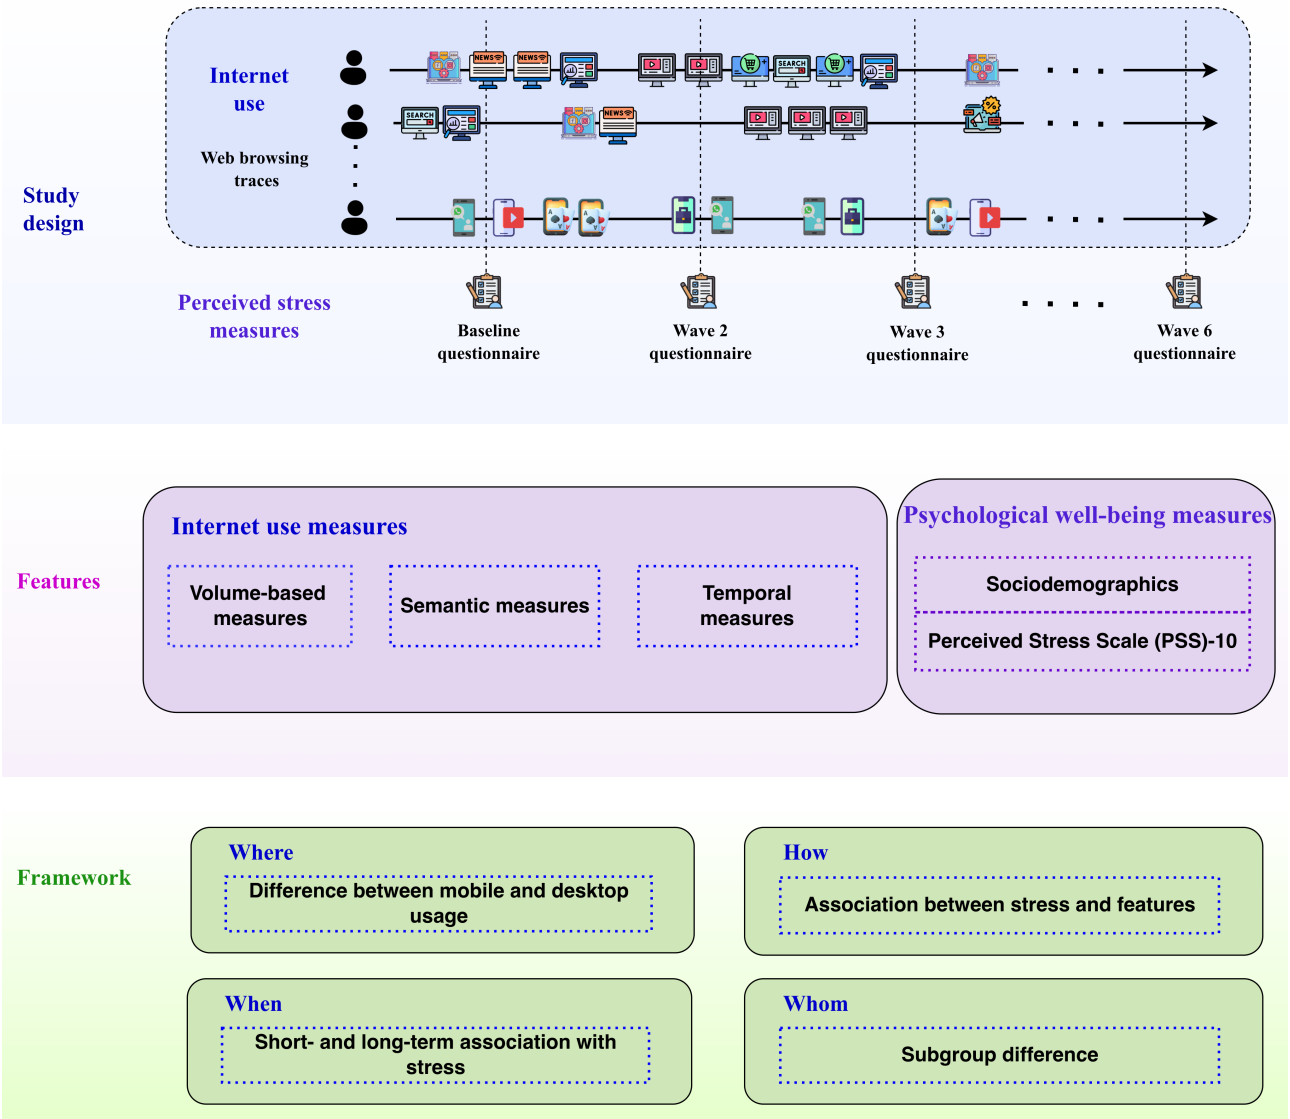
Contributions and Impact of Our Study

Previous research on the relationship between internet use and stress has shown mixed findings, revealing both negative and

positive associations depending on the type of internet activity. However, much of this evidence remains fragmented, as previous studies have largely relied on self-reported internet use data (which often lacks granularity) and have focused on limited aspects of internet use.

To address these limitations and to provide a more comprehensive understanding of how internet use relates to stress, we conducted a longitudinal multimodal study involving 1490 internet users in Germany over 7 months. Our study integrates fine-grained, passively collected web trace data from both desktop and mobile devices with participants' monthly responses to a validated stress scale (refer to Figure 1). Using objective behavioral data, we move beyond subjective self-reports and introduce a data-driven framework for revealing long-term usage patterns and identifying digital markers of stress.

Figure 1. Overview of the study design and contextual dimensions. The top panel shows our longitudinal study design combining desktop and mobile web ‐ trace data with monthly stress questionnaires. The middle panel depicts the internet use and well-being features extracted from web browsing traces and monthly questionnaires. The bottom panel shows the contextual dimensions we consider for examining associations between internet use and stress.



Building on existing research, we further identify 4 key dimensions that shape the relationship between digital behavior and stress:

1. How: the type and pattern of internet behaviors—such as usage volume [14,48], temporal rhythms [49], and content categories (eg, social media, productivity, entertainment, or shopping)—may influence stress in different ways [21,50-52].
2. Where: the device context plays a significant role. Previous research suggests that desktop use is often more goal-oriented and structured, whereas mobile use tends to be more fragmented and reactive [53].
3. When: the timing of online behaviors in relation to stress assessments is important, as short-term engagement with digital content may have immediate effects on stress responses [54,55].
4. By whom: individual differences—such as age, gender, income, and baseline stress levels—can moderate the impact of digital engagement on stress, with some groups being more susceptible than others [40-44].

By adopting this multidimensional perspective, our study seeks to bring coherence to the scattered evidence in existing research and provide a more thorough understanding of the link between digital behaviors and stress. In addition, identifying behavioral markers of stress in internet use may inform the design of future tools for real-time stress monitoring, complementing traditional self-reported measures. This approach contributes to a deeper understanding of digital well-being and supports the development of targeted interventions for healthier online behaviors.

Methods

In this section, we describe our study design, participants, collected data, extracted features, and analysis models that allowed us to overcome the challenges of previous work described in the "Contributions and Impact of Our Study" section.

Study Design

We conducted a longitudinal multimodal study over 7 months that combined passively collected fine-grained web browsing traces with repeated monthly online questionnaires (as provided in Figure 1). The web browsing traces for desktop users included URL-level traces, while for mobile users, both URL-level and application-level traces were included (throughout the paper, we will use "app" to mean mobile app). We measured the perceived stress of our panelists using the validated Perceived Stress Scale (PSS)-10 in 6 monthly waves. In the first wave, we also collected the sociodemographic characteristics of the panelists, including age, gender, and income.

Participants

The study was conducted on a sample of German internet users, recruited through a General Data Protection Regulation–compliant panel company (Bilendi GmbH), which provided access to participants who had already installed tracking software on their devices to capture their internet use. The company also managed survey coding and distribution, sending email notifications to relevant participants each time a survey was launched. Participation was voluntary; panelists were informed about the study and chose to take part. Compensation ranged from €1 - €3 (US $1.10-US $3.30) US $3.30) per month, depending on the number of devices tracked, plus an additional amount based on the company's standard rate (€6/h or US $6.60/h) for each survey completion. All currency values in this study are reported in euros. The exchange rate at the time of the study was €1=US $1.10. All panelists from the company were invited via email for the first wave of questionnaires, yielding 1490 completed responses. In the subsequent 5 waves, which were approximately 1 month apart, all these 1490 respondents were invited via email to participate in each wave. Across all waves, the average range between the earliest and latest survey completion dates was 15 days, and the average completion time for the baseline survey was about 37 minutes (90% CI 32.7-42.3), while for the remaining 5 waves, it was approximately 19.6 minutes (90% CI 17.8-21.5). Table 1 reports the number of participants with completed responses for each wave that we retained for further analysis. We excluded 1 panelist who reported their gender as nonbinary and 52 panelists who reported their income as "other," because these categories had too few respondents. The sample for Wave 1 is therefore 1437. We observe that about 23% of the panelists dropped out by the sixth wave. In Table 1, we also depict the distribution of the panelists across age, gender, and income for the 6 waves of questionnaires.

Next, we examined how closely our sample's sociodemographic distributions match the German population margins for gender, age, and income (provided in Table 2). We observe that our sample's gender distribution matches closely with that of the German population (Destatis [56]). However, for both age and income, the middle ranges are overrepresented in our sample, while the extremes are underrepresented.

Table . Descriptive characteristics of participants across 6 survey waves. The table presents the number of participants, gender distribution, age groups, income categories, and mean perceived stress scores (with SDs) for each wave. Percentages are shown in parentheses for categorical variables.

Wave	1	2	3	4	5	6
Participants (n)	1437	1314	1212	1198	1205	1107
Gender, n (%)						
Male	738 (51.35)	688 (52.36)	639 (52.72)	635 (53.01)	628 (52.12)	593 (53.57)

>€4170 (>US $4587)	22.6 (27.1)

Data Collection

The panelists of the panel company had already consented to install tracking software on their desktops or mobile devices. Some participants consented to install it on both devices. Through this tracking software, the company provided fine-grained traces of visited URLs and mobile apps, including the time of visit and duration of each visit. During the 7 months, we recorded 47,100,701 URL visits from both desktop and mobile users, covering 236,955 unique web domains. For mobile apps, we captured 13,553,645 app visits across 13,476 unique apps.

Data Cleaning and Preprocessing

First, we removed the bottom 20% of panelists in each wave, ranked by total time spent browsing, since they did not have sufficient data to extract meaningful internet use patterns. Second, we identified a group of panelists who appeared to be "professional survey takers," spending more than 25% of their online time on survey domains. To focus on users with more typical internet use, we excluded these individuals from the sample. Notably, applying the above time threshold to their nonsurvey activities would have led to the removal of more than 29% of these panelists. Finally, to ensure that our internet use measures accurately capture user behavior, we only included panelists for whom we could categorize at least 80% of their web visits (refer to the "Data Enrichment" section for details). Table 3 summarizes the number of participants excluded at each step, resulting in a set of distinct panelists across waves comprising 656 mobile users and 526 desktop users. Table 4 presents the sociodemographic characteristics of the remaining users included in the analysis. In the mobile data, the proportion of users aged 31 - 45 years increased compared to the baseline questionnaire, as provided in Table 3. In the desktop data, the proportion of males and users aged 46 - 60 years increased, while the proportion of users aged 31 - 45 years decreased relative to the baseline questionnaire.

Table . Overview of panelists with matched passive web data from desktop and mobile devices across 6 survey waves. The table shows the number of users before and after data cleaning for both device types. The final row indicates the total number of distinct users retained in the cleaned dataset.

Survey wave	Number of panelists	Desktop users	Desktop users (cleaned)	Mobile users	Mobile users (cleaned)
1	1437	981	359	907	519
2	1314	848	321	806	470
3	1212	762	284	728	426
4	1198	717	257	717	418
5	1205	714	265	697	399
6	1107	656	227	649	368
Total distinct users	__[a]	—	526	—	656

[a]Not applicable.

Table . Sociodemographic characteristics of users included in the analysis after data cleaning for both mobile and desktop datasets.

Characteristic	Mobile (n=656)	Desktop (n=526)
Gender, n (%)		
Male	334 (50.91)	289 (54.94)
Female	322 (49.09)	237 (45.06)

>4000 (Tier V)	164 (25)	131 (24.9)

Data Enrichment

To understand "how" the panelists are using the internet, we categorized their online visits into semantic categories. The goal was to group domains, subdomains, and apps based on their primary function into categories such as "social media" (eg, facebook.com [Meta Platforms, Inc] and TikTok app [ByteDance]) and "productivity" (eg, Gmail [Google LLC] and calendar.google.com [Google LLC]). We derived the set of categories (provided in Table 5) by combining categories used by app stores and web domain classification services such as Webshrinker.com. For platform domains such as google.com, we also categorized their subdomains. For instance, google.com was categorized as "search," while mail.google.com was

classified as “productivity.” Table 5 provides the complete list of semantic categories we considered, along with some examples. Two researchers from our team first independently annotated the categories for all domains and apps that constituted around 85% of web visits made by our panelists. Later, disagreements were resolved collaboratively. We observed a substantial interannotator agreement with a Cohen κ agreement [57] score of 0.7, based on annotations for a random subset of 200 domains. Following this process, we classified 3777 domains and 989 apps into semantic categories, capturing 85% of visits from mobile devices and 84% from desktops.

Table . Categorization of web domains and mobile apps based on semantic usage type. The table lists representative examples of domains and apps across various categories, grouped separately for desktop web domains and mobile apps.

Category	Example of domains, subdomains, and apps in the category
Domains	
Entertainment	youtube.com, twitch.tv, disneyplus.com, and netflix.com
Shopping	amazon.de, ebay.de, kleinanzeigen.de, and temu.com
Social media	facebook.com, twitter.com, and instagram.com
Messaging	whatsapp.com, knuddels.de, and fdating.com
Productivity	mail.google.com, outlook.live.com, navigator.web.de, and docs.google.com
Games	gameduell.de, anocris.com, forgeofempires.com, and spielaffe.de
Adult	pornhub.com, xvideos.com, xnxx.com, and romeo.com
News	bild.de, focus.de, welt.de, and wunderweib.de
Apps	
Entertainment	YouTube (Google LLC), Netflix (Netflix, Inc), and Spotify Music (Spotify Technology)
Shopping	Amazon Shopping (Amazon.com, Inc), eBay (eBay, Inc), Vinted.fr (Vinted Group), and Lidl Plus (Schwarz Group)
Social media	Facebook (Meta Platforms, Inc), Instagram (Meta Platforms, Inc), and Twitter (X Corp), TikTok – Make Your Day (ByteDance)
Messaging	WhatsApp (Meta Platforms, Inc), Facebook Messenger (Meta Platforms, Inc), and Telegram (Telegram FZ-LLC)
Productivity	Gmail (Google LLC), GMX Mail (Global Mail eXchange), WEB.DE Mail (United Internet Group), and Google Calendar (Google LLC)
Games	Candy Crush Saga (King), Coin Master (Moon Active), Royal Match (Dream Games), and Pokémon GO (Niantic)
News	n-tv Nachrichten (RTL Group), kicker online (Olympia -Verlag GmbH), AOL – News (AOL Media LLC), and BILD: Immer aktuell informiert (Axel Springer SE)

Measures

As described in the “Study Design” section, we combined repeated monthly stress questionnaires with web browsing data. Perceived stress was measured through PSS-10 questionnaire responses, and internet use features were derived from passively collected web traces. For each panelist in each survey wave, we calculated internet usage features based on their activity during the period “T” preceding the stress measurement (ie, the time of questionnaire response). To address the question of “when” the internet is used, we extracted features for either 30 or 2 days to examine both long-term and short-term effects. The resulting measures were then used to examine the associations between internet use and stress.

Measures From Web Traces

To measure “how” individuals use the internet, we created features that span from coarse- to fine-grained measures, as provided in Table 6. We captured overall web activity at the coarse-grained level, such as total time spent online. We also accounted for the time of the day when panelists were browsing the web by including the difference between the time spent online during daytime (6 AM-6 PM) and nighttime (6 PM-6 AM) hours. At a finer granularity, we analyzed how panelists distributed their time across online activities such as social media, entertainment, and news. For each survey wave, if a participant completed the survey on a given date (eg, July 31), we summed their time spent on each activity over the period (T=30 or 2 days; eg, July 1 - 30 or July 29 - 30) preceding the day of completing the survey. For instance, time spent on news represents the aggregated time on news domains (desktop) and news domains and apps (mobile) during that period. Each participant had up to 6 time points, 1 per wave.

Table . Features and their descriptions. Time spent online is measured in hours in the period T (30 days or 2 days) before the measurement of stress. These features are computed for online activity on each device (desktop or mobile) separately.

Features	Description
Coarse-grained	
• Total time spent online	Total time spent online in period T
• Daytime nighttime difference	Difference of time spent online during daytime (6 AM-6 PM) and nighttime hours (6 PM-6 AM)
Fine-grained	
• Time spent on entertainment • Time spent on social media • Time spent on messaging • Time spent on news • Time spent on adult content • Time spent on games • Time spent on shopping • Time spent on productivity	Time spent on different semantic classes of online activities. For instance, time spent on entertainment domains or apps such as YouTube.com or Amazon Prime is classified as entertainment use.
Control variables	
• Gender • Age • Income • Survey wave	Sociodemographic characteristics of individuals and seasonality

Measures From Questionnaires

We used the PSS-10 [58] in our monthly questionnaires to measure the stress levels of our panelists. The PSS-10 is a widely used, validated scale designed to assess how stressed individuals feel. It captures aspects such as the unpredictability of life, perceived control over situations, and general stress levels over the past month. Participants rate their responses on a scale from 0 (never) to 4 (very often), producing a total score between 0 and 40 across the 10 items. Higher scores indicate greater perceived stress, with scores typically grouped into 3 levels: 0 - 13 (low stress), 14 - 26 (moderate stress), and 27 - 40 (high stress) [59,60]. In addition, we collected each participant's self-reported sociodemographics, including age, gender, and income, in the first wave of the questionnaires.

Statistical Analysis

We used linear mixed-effects models (LMMs) [61] to examine the relationship between internet use and stress. We chose LMMs for analyzing data from our longitudinal study since they account for repeated measurements of individuals and incorporate fixed and random effects. Fixed effects included internet use features provided in Table 6. Random intercepts were added to account for individual-specific differences in baseline stress levels across participants.

We formally describe the models as follows. For an individual i at questionnaire wave j∈ {1,2...6}, we denote Yij as the variable of interest, xij as the covariate, and the intercept for the random effect as uj. Therefore, we consider the following LMM:

$$Yij=\beta0+\beta1xij1+\beta2xij2+\ldots+\beta nxijn+uj+ ij$$

where:

- Yij is the perceived stress level of the individual i measured at the questionnaire wave j.
- β0 is the fixed intercept.
- β1,…,βn are the fixed effect coefficients for each covariate xijn.
- xij1=(total time spent online, xij2=daytime-nighttime difference, xij3=time spent on entertainment ... xijn=survey wave), where xijn corresponds to each feature provided in Table 6.
- uj is the random effect for individual i, capturing individual-level variability.
- ij is the residual error term for the individual i at wave j.

We conducted model diagnostics to validate the assumptions of LMMs, including checks for multicollinearity (Variance Inflation Factor (VIF) <2.0). All statistical analyses were implemented using Python's statsmodels package (version 0.14.1; Python Software Foundation) [62].

To understand whether the granularity of the extracted features affects model performance and the associations identified, we developed 2 models. The first model (Model 1) focused on coarse-grained measures of internet use such as total time spent online and daytime-nighttime difference. The second model (Model 2) extended the first model and also incorporated finer-grained measures of internet use across semantic classes. For Model 2, we dropped the total time spent online feature to avoid multicollinearity.

Previous work has shown that both sociodemographics [40-44] and seasonal variations [63,64] can significantly influence individuals' stress levels. Accordingly, we included the sociodemographics and seasonality measures as control variables for both models, as provided in Table 6.

Ethical Considerations

Our study was approved by Aalto University's Research Ethics Committee (approval ID D/894/03.04/2023). Data collection was conducted via a General Data Protection Regulation–compliant European company, and informed consent was obtained from participants for both the surveys and web-trace datasets, with the option to withdraw consent at any time during or after the study. To protect participants' privacy, we implemented strict data privacy measures. The web dataset was anonymized by the panel company by removing personal information such as email addresses and usernames to prevent participant identification. In addition, the dataset was stored and analyzed solely on the university's secure server, with access restricted to the research team. We will make the anonymized data and code available to support the open-source community and to spur further research at the intersection of internet use and well-being.

Results

Overview

Our study examined various internet use behaviors associated with stress, and in this section, we present our results across 4 key contextual dimensions (as outlined in the "Contributions and Impact of Our Study" section). We first analyzed "how" internet-based features relate to stress. We then explored the remaining dimensions: device-based differences (where) by comparing desktop and mobile usage, temporal patterns (when) using internet activity from the 2 days before the survey, and individual differences (by whom) through subgroup analyses based on age, gender, income, and baseline stress levels.

Behavioral Patterns (How)

To understand how internet usage is associated with stress, we ran LMMs on 2 sets of features, progressing from coarse-grained (amount and timing of usage) to fine-grained (also including semantic category usage) measures. An ANOVA test was conducted to determine whether the more complex model explained significantly more variance than the simpler model. The results showed no statistically significant improvement when using the more complex model, although the more complex model provided important information on the nuanced relationship between internet use and stress.

Analysis of 30-day mobile data (number of panelists, N=656) and observations, n=2600), as provided in Table 7, revealed that Model 2—which includes both timing and semantic category usage—identified significant associations with stress. Specifically, shopping-related usage was positively associated with stress (β=.04,, 95% CI 0.00 - 0.08; *P*=.04), while productivity usage showed a negative association (β=–.03, 95% CI −0.06 to −0.00; *P*=.04). In contrast, Model 1, which included only total usage and timing, did not show any significant associations.

Table . Results from linear mixed-effects models for all participants, based on 30-day mobile data. Model 1 includes coarse-grained features, while Model 2 incorporates fine-grained usage categories (described in the "Statistical Analysis" section). Estimates, CIs, and *P* values are reported for each predictor. Statistically significant *P* values are in bold.

[e]Not applicable.

In addition, sociodemographic factors such as age, gender, and income consistently predicted stress across both models. Age (β=–1.57, 95% CI −2.16 to −0.99; *P*<.001) and income (β=–1.08, 95% CI −1.47 to −0.69; *P*<.001) were negatively associated with stress, while women reported higher stress levels (β=1.68, 95% CI 0.68 - 2.68; *P*=.001).

Device Matters (Where)

To observe device differences, we analyzed 30-day desktop data. For desktop data (N=526 and n=1713), the results are shown in Table 8. Model 2, which incorporates semantic and temporal features, showed a weaker positive association between shopping usage and stress (β=.03, 95% CI −0.0 to 0.06; *P*=.09). As observed with mobile data, the simpler Model 1 did not reveal any significant associations with internet usage features. Similarly, the sociodemographic results were consistent with those observed in the mobile data.

Table . Results from linear mixed-effects models for all participants, based on 30-day desktop data. Model 1 includes coarse-grained features, while Model 2 incorporates fine-grained usage categories (described in the "Statistical Analysis" section). Estimates, CIs, and *P* values are reported for each predictor. Statistically significant *P* values are in bold. Random effects, intraclass correlation coefficient (ICC), number of participants (N), and total observations are also provided.

Predictors	Model 1[a], estimate (95% CI)	*P* value	Model 2[b], estimate (95% CI)	*P* value

Time Period of Data (When)

To investigate the relationship between short-term versus long-term internet usage patterns and stress, we analyzed associations between various online activities performed on mobile and desktop devices in 2 time periods—30 days and 2 days—and individual stress levels. We used the same features and models as in our previous 30-day data analyses. Here, we specifically focused on web activity recorded during the 2 days immediately preceding the PSS-10 survey.

For both mobile and desktop data (as provided in Tables S1 and S2 in Multimedia Appendix 1), news usage showed a negative association with stress (β=–.54, 95% CI −1.08 to 0.00; *P*=.048) and (β=–.50, 95% CI −0.90 to −0.11; *P*=.01), respectively, in Model 2. In addition, in desktop data, messaging usage demonstrated a weak negative association with stress (β=–.59, 95% CI −1.24 to 0.06; *P*=.07) in model 2.

Individual Differences (By Whom)

To explore how internet usage varies by individual characteristics, we conducted subgroup analyses, running models separately for categories such as gender (male and female) to understand how associations differ based on these characteristics. In the following subsections, we first examined the relationship between internet use and stress based on baseline stress levels by analyzing high-stress and low-stress groups. We then explored differences by gender, age, and income categories.

Stress Levels

We identified 2 groups of panelists from our data—high-stress and low-stress—based on their reported PSS-10 scores in the online questionnaires. Panelists who scored more than 26 in any wave they participated in were included in the high-stress group, and panelists who scored below 14 in any wave were included in the low-stress group.

For the high-stress population (PSS-10 score > 26), several notable results were observed (as provided in Tables S3-S6 in Multimedia Appendix 1). In the 30-day mobile data, time spent (β=.01, 95% CI 0.0 - 0.02; *P*<.001) in Model 1, and social media usage (β=.02, 95% CI 0.0 - 0.03; *P*=.02), and gaming usage (β=.01, 95% CI 0.0 - 0.02; *P*=.02) in Model 2 were positively associated with stress. In the 2 days of data, the daytime-nighttime difference showed a weak positive association (β=.11, 95% CI −0.01 to 0.23, *P*=.08) in Model 1. For desktop data, no significant variables, including sociodemographics, were found to be associated with stress in the high-stress subgroup.

In the low-stress population (PSS-10 score <14 in the baseline survey), as provided in Tables S7-S10 in Multimedia Appendix 1, adult-content usage was negatively associated with stress in 30-day desktop data (β=–.02, 95% CI −0.04 to 0.0; *P*=.07). Similarly, for the low-stress group, in the 2 days data, time spent (β=–.07, 95% CI −0.14 to 0.0; *P*=.04) was significant for desktop, while gaming usage was weakly significant for mobile data (β=.08, 95% CI −0.01 to 0.17; *P*=.1).

When analyzing the 30-day data for all participants, sociodemographic factors were strongly associated with stress in both mobile and desktop settings. However, within the high-stress group, income was the only sociodemographic variable that remained significant in mobile data, showing a negative association with stress in both the general population (β=–1.08, 95% CI −1.47 to −0.69; *P*<.001) and the high-stress subgroup (β=–.52, 95% CI −0.91 to −0.12; *P*=.01). In contrast, gender and age—which were significant predictors in the overall population—did not show statistical significance in the highly stressed subgroup for either mobile or desktop data.

Gender Differences

Subgroup analysis by gender revealed distinct patterns in feature significance for both desktop and mobile data. In the 30-day mobile data (as provided in Table S11 in Multimedia Appendix 1), shopping usage (β=.07, 95% CI 0.01 - 0.14; *P*=.02) and productivity features (β=–.05, 95% CI −0.09 to −0.01; *P*=.02) were significant only for male users (N=334 panelists and n=1334 observations) in Model 2. In contrast, these features were not significant for female users (N=322 panelists and n=1266 observations) as provided in Table S12 in Multimedia Appendix 1. No features were significant for males and females in the 30-day desktop data.

In the 2-day data (as provided in Tables S15-S16 in Multimedia Appendix 1), news consumption was negatively associated with stress for males in both desktop (β=–.52, 95% CI −1.02 to −0.01; *P*=.04) and mobile (β=–.58, 95% CI −1.23 to 0.07; *P*=.08) data. For females, in mobile data, daytime-nighttime difference (β=.10, 95% CI −0.0 to 0.21; *P*=.06) and messaging (β=.23, CI −0.02 to 0.48; *P*=.08) were weakly positively associated.

Age Differences

Subgroup analysis by age revealed distinct patterns in web-based associations. For the 30-day mobile data (as provided in Tables S19-S22 in Multimedia Appendix 1), shopping was positively associated with stress in age groups of 18 - 30 years (β=.12, 95% CI −0.02 to 0.25; *P*=.09) and older than 60 years (β=.01, 95% CI 0.02 - 0.19; *P*=.02). In the age group of 30 - 45 years, weak positive associations were found for entertainment (β=.02, 95% CI −0.00 to 0.04; *P*=.08) and messaging (β=.03, 95% CI −0.00 to 0.06; *P*=.07), whereas productivity was negatively associated (β=–.08, 95% CI −0.14 to −0.02; *P*=.007). In the older than 60 years group, time spent (β=.01, 95% CI 0.00 - 0.03; *P*=.03) and messaging (β=.05, CI −0.00 to 0.09; *P*=.06) were positively associated, while the daytime-nighttime difference (β=–.03, 95% CI −0.05 to −0.01; *P*=.01) and shopping (β=.10, 95% CI 0.02 - 0.19; *P*=.02) were negatively associated.

In the 30-day desktop data (as provided in Tables S23-S26 in Multimedia Appendix 1), adult content usage was negatively associated in 18 - 30 years (β=–.87, 95% CI −1.77 to 0.03; *P*=.06) and older than 60 years (β=–.19, 95% CI −0.38 to 0.00; *P*=.06) age groups. In addition, in the 18 - 30 age group, the daytime-nighttime difference (β=.07, CI −0.00 to 0.14; *P*=.06) was positively associated, while news usage (β=.026, CI −0.42 to −0.10; *P*=.002) was negatively associated. Shopping was positively associated in the age group of 45 - 60 years (β=.04, 95% CI −0.00 to 0.09; *P*=.06).

For the 2-day mobile data (as provided in Tables S27-S30 in Multimedia Appendix 1), news was negatively associated in both the 30 - 45 years (β=–1.01, 95% CI −2.22 to 0.19; *P*=.10) and 45 - 60 years (β=–.85, 95% CI −1.76 to 0.06; *P*=.07) age groups. In addition, in the age group of 30 - 45 years, the daytime-nighttime difference (β=.14, 95% CI 0.02 - 0.25; *P*=.02) and entertainment usage (β=.22, 95% CI 0.01 - 0.43; *P*=.04) were positively associated, whereas shopping was negatively associated (β=–.54, 95% CI −1.08 to −0.0; *P*=.05). In the older than 60 years of age group, time spent on gaming (β=.26, 95% CI 0.01 - 0.50; *P*=.04) was positively associated.

Similarly, for the 2-day desktop data (as provided in Tables S31-S34 in Multimedia Appendix 1), messaging was negatively associated in the 45 - 60 years age group (β=–.78, 95% CI −1.48 to −0.07; *P*=.03), but positively associated for the older than 60 years age group (β=7.63, 95% CI 0.39 - 14.87; *P*=.04). In the age group of 18 - 30 years, entertainment (β=1.14, 95% CI −0.18 to 2.46; *P*=.09) was positively associated, and social media (β=1.22, 95% CI 0.15 - 2.29; *P*=.03) was positive for the 30 - 45 age group. In addition, time spent (β=–.14, 95% CI 0.28 - 0.0; *P*=.06) and news usage (β=.46, 95% CI −0.96 to 0.04; *P*=.07) were negatively associated in the older than 60 years age group.

Income Differences

For the 30-day mobile data (as provided in Tables S35-S39 in Multimedia Appendix 1), messaging (β=–.06, 95% CI −0.12 to −0.01; *P*=.03) was negatively associated with stress in participants earning less than €1000 (US $ 1100) per month (Tier I). In the €2001-€3000 (US $2201.10-US $3300) income group (Tier II), productivity (β=–.05, 95% CI −0.10 to 0.0; *P*=.06) and news usage (β=–.10, 95% CI −0.20 to 0.01; *P*=.08) were both negatively associated. Time spent (β=.01, CI 0.0 - 0.02; *P*=.02) and shopping (β=.08, 95% CI 0.01 - 0.16; *P*=.02) were positively associated with stress for participants earning €3001-€4000 (US $3301.10-US $4400; Tier IV). No other significant internet-based features were observed for other income categories.

For the 30-day desktop data (as provided in Tables S40-S44 in Multimedia Appendix 1), news usage was positively associated with stress in Tier I income group (β=.28, 95 CI 0.05 - 0.50; *P*=.02), while productivity was negatively associated (β=–.07, 95% CI −0.13 to −0.01; *P*=.03). For participants in Tier III income, news usage (β=–.13, 95% CI −0.25 to 0.0; *P*=.06) was negatively associated. For participants in Tier IV income, shopping was positively associated with stress (β=.08, 95% CI 0.02 - 0.15; *P*=.02). For Tier V participants, social media use was positively associated with stress (β=.06, 95% CI 0.01 - 0.12; *P*=.03), while news use (β=–.16, 95% CI −0.25 to −0.07; *P*<.001) and time spent were negatively associated

(β=–.01, 95% CI −0.03 to 0.0; *P*=.03). No significant associations were identified for other income categories.

For the 2-day mobile data (as provided in Tables S45-S49 in Multimedia Appendix 1), gaming (β=.21, 95% CI −0.02 to 0.43; *P*=.07) was positively associated in the Tier II income group and negatively associated (β=–.19, 95% CI −0.37 to 0.0; *P*=.047) in the Tier V income group. News use was negatively associated in the Tier III (β=–.75, 95% CI −1.58 to 0.09; *P*=.08) and Tier V (β=–.74, 95% CI −1.60 to 0.12; *P*=.09) income groups. In addition, messaging (β=, 95% CI 0.14 - 0.82; *P*=.006) was positively associated in the Tier III income group, and daytime-nighttime difference (β=.18, 95% CI 0.0 - 0.36; *P*=.04) was positively associated in the Tier IV income group.

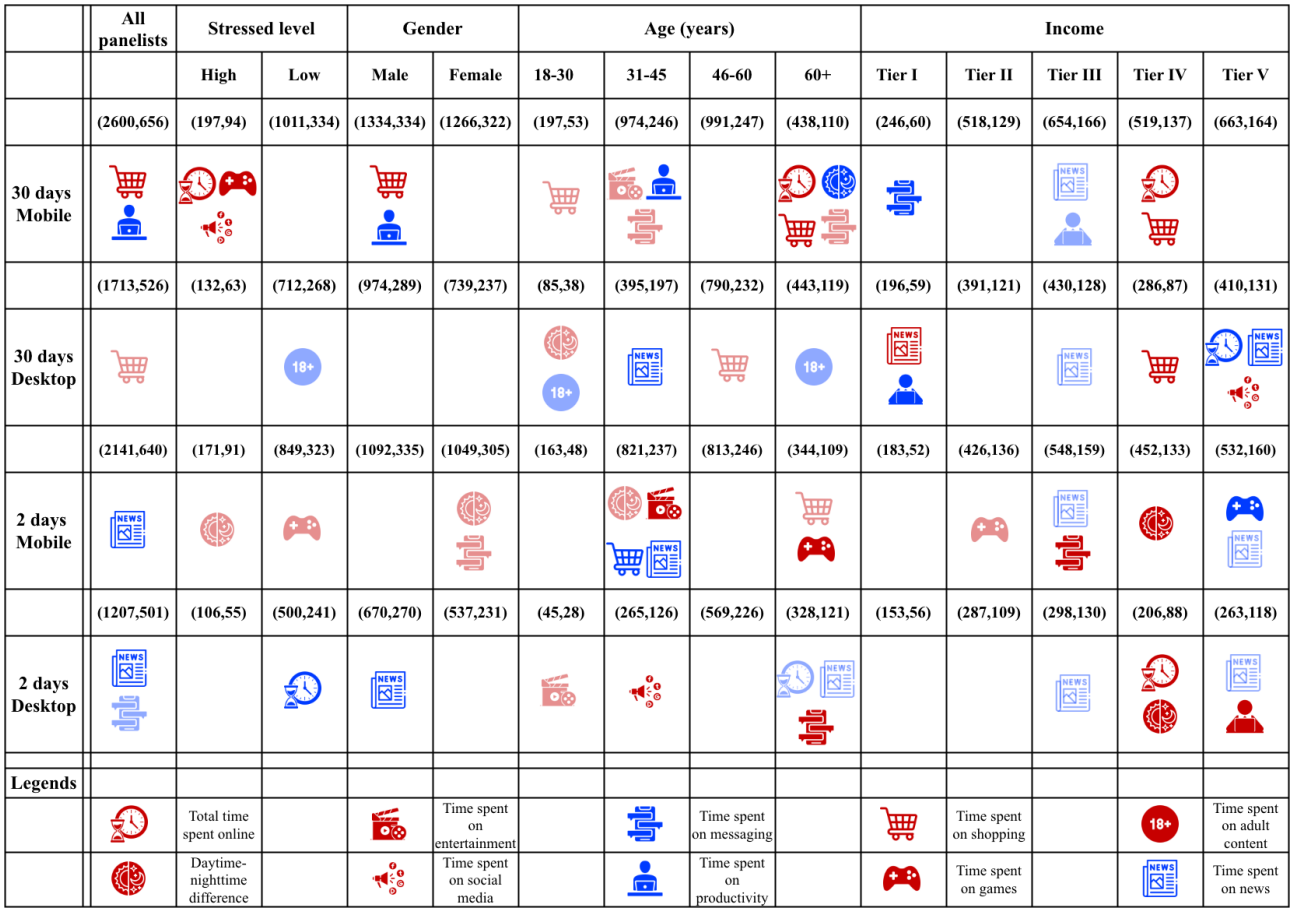
For the 2-day desktop data (as provided in Tables S50-S54 in Multimedia Appendix 1), news usage was negatively associated in the Tier III income group (β=–1.13, 95% CI −2.33 to 0.06; *P*=.06) and the Tier V income group (β=–1.04, 95% CI −1.76 to −0.32; *P*=.005). In addition, in the Tier V income group, productivity (β=.64, 95% CI 0.07 - 1.21; P=.03) was positively associated with stress. In the Tier IV income group, time spent (β=.23, 95% CI 0.04 - 0.42; *P*=.0192) and daytime-nighttime difference (β=.23, 95% CI −0.00 to 0.46; *P*=.05) were positively associated.

Discussion

Principal Findings

Our results show that various internet usage behaviors are associated with stress, both positively and negatively. These associations differ across device type, time frame, and sociodemographic groups. Figure 2 summarizes these patterns and their variation across panelist subgroups. In the following sections, we discuss the internet use features that have shown positive (social media, entertainment, shopping, games, and time of internet use), negative (adult content, productivity, and news), and mixed (messaging and screen time) associations with stress.

Figure 2. Overview of significant internet usage behaviors across various contextual dimensions. The icons represent different internet use features. The rows correspond to a combination of the time frame (30 days or 2 days) and device type (desktop or mobile), and the columns correspond to factors pertaining to individual differences (stress levels, gender, age, and income). Red icons denote positive associations, blue icons indicate negative associations, and empty cells show no significant internet features. The intensity of the color reflects the strength of the significance, with lighter icons denoting weak significance (*P*=.05 to *P*<.10) and darker icons representing high significance (*P*<.05).



Positive Associations

Social Media

People spend a substantial portion of their time online on social media platforms [65]. In our dataset, social media accounted for approximately 23% of total usage in mobile data and 15% in desktop data. Therefore, understanding social media's relationship with stress is increasingly important as it continues to occupy a large share of individuals' internet activity.

Previous research shows that social media can contribute to stress, act as a resource, or function as a coping tool [50]. Factors such as fear of missing out [66], appearance-related pressure [67], and communication overload [68] have been linked to increased distress. At the same time, other studies have highlighted its potential to buffer stress and offer social support in specific contexts [22,35,69].

In our results, when significant, social media was consistently positively associated with stress across subgroups and device types. This association was significant for the high-stress subgroup in the 30-day mobile data, the Tier I income group in the 30-day desktop data, and the 30 - 45 age group in the 2-day desktop data (Figure 2). Although we cannot definitively determine whether social media contributes to or alleviates stress, these patterns suggest that it may be used as a coping strategy for these groups.

Previous work has identified social media as a space for various coping mechanisms [35]. Our findings in the middle-aged group potentially reflect this pattern, aligning with earlier research [70], possibly due to the support accessed through these platforms. This is consistent with studies linking social media use, particularly Facebook, to support-seeking behavior [71].

Overall, our results highlight the role of social media in shaping stress experiences. While our study, combining fine-grained web data with a longitudinal design and contextual framework, strengthens this interpretation, further research is needed to disentangle the causal directions of the observed associations and social media's role—whether as stressor, resource, or coping tool.

Entertainment

According to a recent survey in Germany, people spend an average of 203 minutes per day watching content online [65]. In our data, entertainment usage accounted for 9% of total usage on mobile devices and 14% on desktop devices.

Previous studies have reported a positive correlation between entertainment usage and stress [21,72-74]. Further, activities such as watching content or listening to music have also been identified as common coping strategies for managing stress [36,37,75]. In our findings, entertainment usage was positively associated with stress in both desktop and mobile data. For mobile users, this association was consistent across both the 30-day and 2-day periods for the 30 - 45 age group. In the 2-day desktop data, a weak positive association was observed for the age group of 18 - 30 years.

These results suggest that entertainment usage (similar to social media) may serve as a coping mechanism, especially among younger users in our data, compared with older individuals. Previous research indicates that younger individuals are more likely to engage in binge-watching as a way to regulate emotions [36]. However, there is a lack of detailed research on this association [74], and future studies should further explore the types of content consumed and their relationship to mental health.

Online Shopping

Online shopping has grown substantially in recent years, particularly with the rise of smartphones, which now account for 80% of all retail visits [76]. Previous studies have linked compulsive buying-shopping disorder to higher levels of stress [29,38,52,77-79]. At the same time, shopping has also been identified as a way to relieve stress [80,81].

In our results, shopping was predominantly positively associated with stress across mobile and desktop data, in various time frames and subgroups (refer to Figure 2), aligning with previous findings. A negative association was observed only for the age group of 30 - 45 years in the 2-day mobile data, suggesting that, for this group, shopping may serve as a short-term stress reliever, or that individuals under stress may avoid shopping. The latter behavior aligns with previous research showing that, in middle-aged adults, stress can lead to increased saving behavior [82].

This association was more pronounced in mobile data, suggesting that people may use mobile phones to cope with stress due to their easier accessibility. It was also consistent across both mobile and desktop data for the Tier IV income group, supporting earlier findings that higher-income individuals may use shopping as a way to cope with stress [38]. In the 30-day mobile data, this positive association was observed among male participants but not among females. Previous studies show that males are more likely to experience negative emotions related to shopping [83], while some studies report no gender differences in online shopping addiction tendencies [29].

These findings highlight how shopping has become embedded in daily life and its potential influence on stress levels. Future research should explore different types of shopping (hedonic vs utilitarian) and their impact on mental health. Another direction could be to examine the time spent on shopping compared with actual purchases completed after the payment process, and how these different shopping behaviors are associated with stress levels.

Gaming

Gaming has become a widespread daily habit, with the global market projected to reach US $522.46 billion by 2025 [84]. Previous research presents mixed findings: while gaming has been positively linked to stress and lower psychosocial well-being, with stress being a known precursor to pathological gaming [32,33,85]. It has also been identified as a stress reliever and coping mechanism [39,86-88].

In our results, gaming usage was positively associated with stress in the 30-day mobile data for the high-stress subgroup. In the 2-day mobile data, positive associations were observed for the low-stress group, users aged older than 60 years, and those in the Tier II income range. A negative association was found for the Tier V income group. These findings align with previous research suggesting that gaming may intensify stress in already stressed individuals [89], whereas older adults often use gaming as a way to relieve stress [90]. The contrasting patterns across income groups may reflect differences in usage

intensity, as lower-income individuals tend to engage more frequently in gaming than those with higher incomes [91].

We did not find any significant associations in the desktop data, which may be due to lower gaming activity on desktop browsers compared with mobile apps—gaming accounted for only 4.7% of desktop usage versus 16.8% in mobile data. Future research should examine the type of gaming, such as games that require active cognitive engagement (eg, first-person shooter games) versus low cognitive requirement arcade games, and how these different types of games relate to stress.

Timing of Online Activity

Individuals tend to have preferences for the timing of both online and offline activities throughout the day [92,93]. Previous research has shown that increased nighttime smartphone use is linked to higher perceived stress [49]. Nighttime use has also been associated with reduced sleep duration [48,94] and poorer sleep quality [95,96], both of which are shown to impact mental health negatively [97-99].

In our results, the daytime–nighttime difference feature was mainly positively associated with perceived stress across various groups. A negative association was observed only in the age group of older than 60 years in the 30-day mobile data. Positive associations were more common in the shorter time frame, particularly in the 2-day mobile data, for groups including high-stress individuals, females, those aged 30 - 45 years, and the Tier IV income group (refer to Figure 2).

Our results indicate that daytime internet use, compared with nighttime use, is positively associated with stress, contrasting with earlier studies that reported a stronger link between nighttime use and stress in young adults [49]. Longitudinal research has shown that it is sleep loss due to time spent online, rather than internet use itself, that is associated with poorer mental health outcomes [6]. Internet use patterns can also be influenced by individuals' chronotypes, which in turn will affect preferred active hours [100]. Moreover, future studies could investigate panelists' bedtime and examine postbedtime usage, as previous studies have shown that postbedtime use—rather than nighttime use in general—has the most harmful effects on sleep quality [95]. The negative association observed in the age group of older than 60 years may suggest that older individuals are more sensitive to late-night use and its link to stress. Further research is needed to better understand how daily temporal patterns of internet use relate to stress, particularly by considering users' chronotype and bedtime.

Negative Associations

Adult Content

A recent study estimates that around 90 million people may be affected by problematic adult content usage [101]. Research has shown that problematic adult content consumption can impact mental health, including associations with higher stress [102,103].

In our results, however, adult content consumption was negatively associated with stress levels. This negative relationship was observed in the low-stress group (PSS score < 14), and in the age groups of 18 - 30 years and older than 60 years within the 30-day desktop data. Some studies have reported no significant link between adult content use and psychological health [104], while others suggest it is often consumed as a form of leisure [105]. Our results may suggest that adult content serves as a stress buffer for our participants, as previous research has indicated stress and stress relief as common motivations for its use [106,107]. Another possible explanation is that users with lower stress levels might engage in this activity as a form of leisure or a means to alleviate boredom [105]. Previous research has identified boredom proneness and its positive association with the frequency of pornography use [108]. However, the positive associations observed in past studies were tied to problematic adult content consumption or addiction. This implies that while limited consumption may offer stress relief, excessive use could have detrimental effects. Future research should explore both the positive and negative impacts of adult content consumption on mental health, particularly in relation to the amount of consumption.

Productivity

Information and communication technology has become a central part of daily work and study routines, particularly in the 21st century. Most of the work we do on information and communication technology devices is connected to the internet, and their use for work and productivity has been linked to improved workplace efficiency [109,110]. However, the effects of internet use on psychological health and stress are dual in nature. While it has been associated with increased productivity, higher internet use for work-related tasks has also been linked to higher stress levels [51,111-114]. Some interventional studies report no significant effects [113], while others suggest that using the internet for work and study can have a positive impact on mental health [6].

In our results, increased use of productivity-related apps and domains was generally associated with lower perceived stress. In the 30-day mobile data, negative associations were observed among all participants, as well as within the male subgroup, the age group of 31 - 45 years, and the Tier III income group. In the 30-day desktop data, a similar negative association was found in the Tier I income group. A positive association appeared only once—in the 2-day desktop data for the Tier V income group.

Our findings suggest that stressed individuals may avoid productivity-related tasks by shifting their focus to other activities. This is supported by previous research showing a positive relationship between perceived stress and avoidant coping styles [115]. Previous research has reported a negative relationship between work-related online tasks and stress among middle-aged adults [21]. At the same time, communication overload from emails and messages has been linked to higher perceived stress in adults aged 50 - 85 years [15]. In our results, we found a similar negative association between productivity-related use and stress in the age group of 31 - 45 years, suggesting that increased productivity use may be linked to lower stress in this group. However, no significant association was observed in the older age group. For higher-income groups, the observed positive association may reflect greater work

responsibilities that are more difficult to avoid, contributing to increased stress.

Overall, our findings highlight the need for further research into how productivity-related internet use influences stress. As previous studies have shown, avoidance behaviors can increase the risk of prolonged stress and other mental health challenges [116]. Future studies should explore how online interventions can effectively help users mitigate stress.

News

Informed citizens are a cornerstone of a well-functioning democracy and good governance. However, recent studies suggest that news, especially news with highly negative content, can adversely affect mental health and increase stress levels [24,117-119].

Our findings reveal a counterintuitive relationship between news engagement and stress: participants who spent more time-consuming news tended to report lower stress levels. This association was more pronounced in the 2-day data for both mobile and desktop users, and overall, it was stronger in desktop data across both time periods. One possible explanation is that individuals experiencing stress may avoid the news altogether in the short term. Previous research supports this, showing that people under stress often disengage from news consumption [120-122]. Other studies have found no significant link between news consumption and stress [123,124], while some suggest that positive and soft news content may improve mood [30] and well-being [125].

Since our news category includes a range of sources, such as entertainment, sports, and politics, it is important to consider how different types of news relate to stress in the future. Future studies could examine the effects of specific news genres, as well as the influence of low-quality news sources and misinformation on mental health. Examining how consistent exposure to different news categories, sources, and misinformation influences stress responses over time could provide insights into mental health risks and how media consumption habits shape psychological well-being.

Mixed Associations

Messaging

In 2021, an estimated 3.09 billion mobile phone users accessed the top messaging apps for communication, with this number projected to reach 3.51 billion by 2025 [126]. The younger generation, in particular, remains connected with friends and family through messaging apps such as WhatsApp (Meta Platforms, Inc) and Telegram (Telegram FZ-LLC). Research has shown that messaging apps can be both positively associated with stress [7,127-130] and serve as stress reducers [131-134].

In our results, messaging usage was mostly positively associated with stress in mobile data. It was positively associated in the age groups of 30 - 45 years and older than 60 years and negatively associated in the Tier I income group in the 30-day mobile data. In the 2-day mobile data, it was positively associated with females and those in the Tier III income group. In the 2-day desktop data, it was negatively associated with all participants and the age group of 45 - 60 years, while it was positively associated with the age group of older than 60 years.

The key finding is that messaging use was predominantly positively associated with stress in mobile data and more negatively associated in desktop data. Previous research suggests that "checking behavior" (ie, brief and repeated usage sessions) is more common in mobile use compared to desktop devices [53], and perhaps this type of repeated checking on mobile devices adds to the stress. We found that in the age group of older than 60 years, messaging was positively associated with stress in both mobile and desktop data, which aligns with previous studies showing that older individuals experience higher stress from interpersonal communication [7]. In the Tier I income group for mobile data, messaging was negatively associated with stress. Studies show that people in lower-income groups tend to send more messages [135]. Previous research has also shown that messaging can be an effective tool for reducing depression, particularly among low-income individuals [136]. Finally, in the 2-day mobile data, messaging was positively associated with stress in females but not males, reflecting previous research suggesting that frequent messaging is linked to mental health symptoms (externalizing and inattention) in females, but not in males [137].

Our results highlight how messaging can have a dual impact on stress, depending on the device, time period, and individual differences. Future work could examine how messaging with friends and family, interactions with strangers in chatrooms, and repeated checking behavior on mobile devices relate to stress, loneliness, and overall well-being.

Screen Time

The internet plays a pervasive role in our daily lives, and the amount of time we spend online may have a detrimental impact on stress levels [48,138]. Research has shown that smartphone addiction is significantly linked to higher stress [139,140], and the amount of time spent online is positively associated with stress [48] and other mental health issues [141,142].

In our results, total time spent online was positively associated with stress in the 30-day mobile data, aligning with previous studies [48,139,140]. This association was significant for the high-stress group, individuals older than 60 years, and those in income Tier IV. However, the relationship was mainly negative in both the 2-day and 30-day desktop data across different groups, with the exception of a positive association for the Tier IV income group in the 2-day desktop data, which mirrored the mobile data results.

Our findings suggest that increased time spent online on mobile devices may amplify stress in different contexts. For high-stress individuals, extended mobile phone usage is positively associated with stress, likely due to the constant accessibility of smartphones, making it harder to disconnect from them. Previous studies have also found that smartphone users tend to experience higher levels of digital burnout compared to those using desktops or laptops [17]. In addition, older individuals in our study showed an increase in stress with more time spent online, consistent with previous research [141].

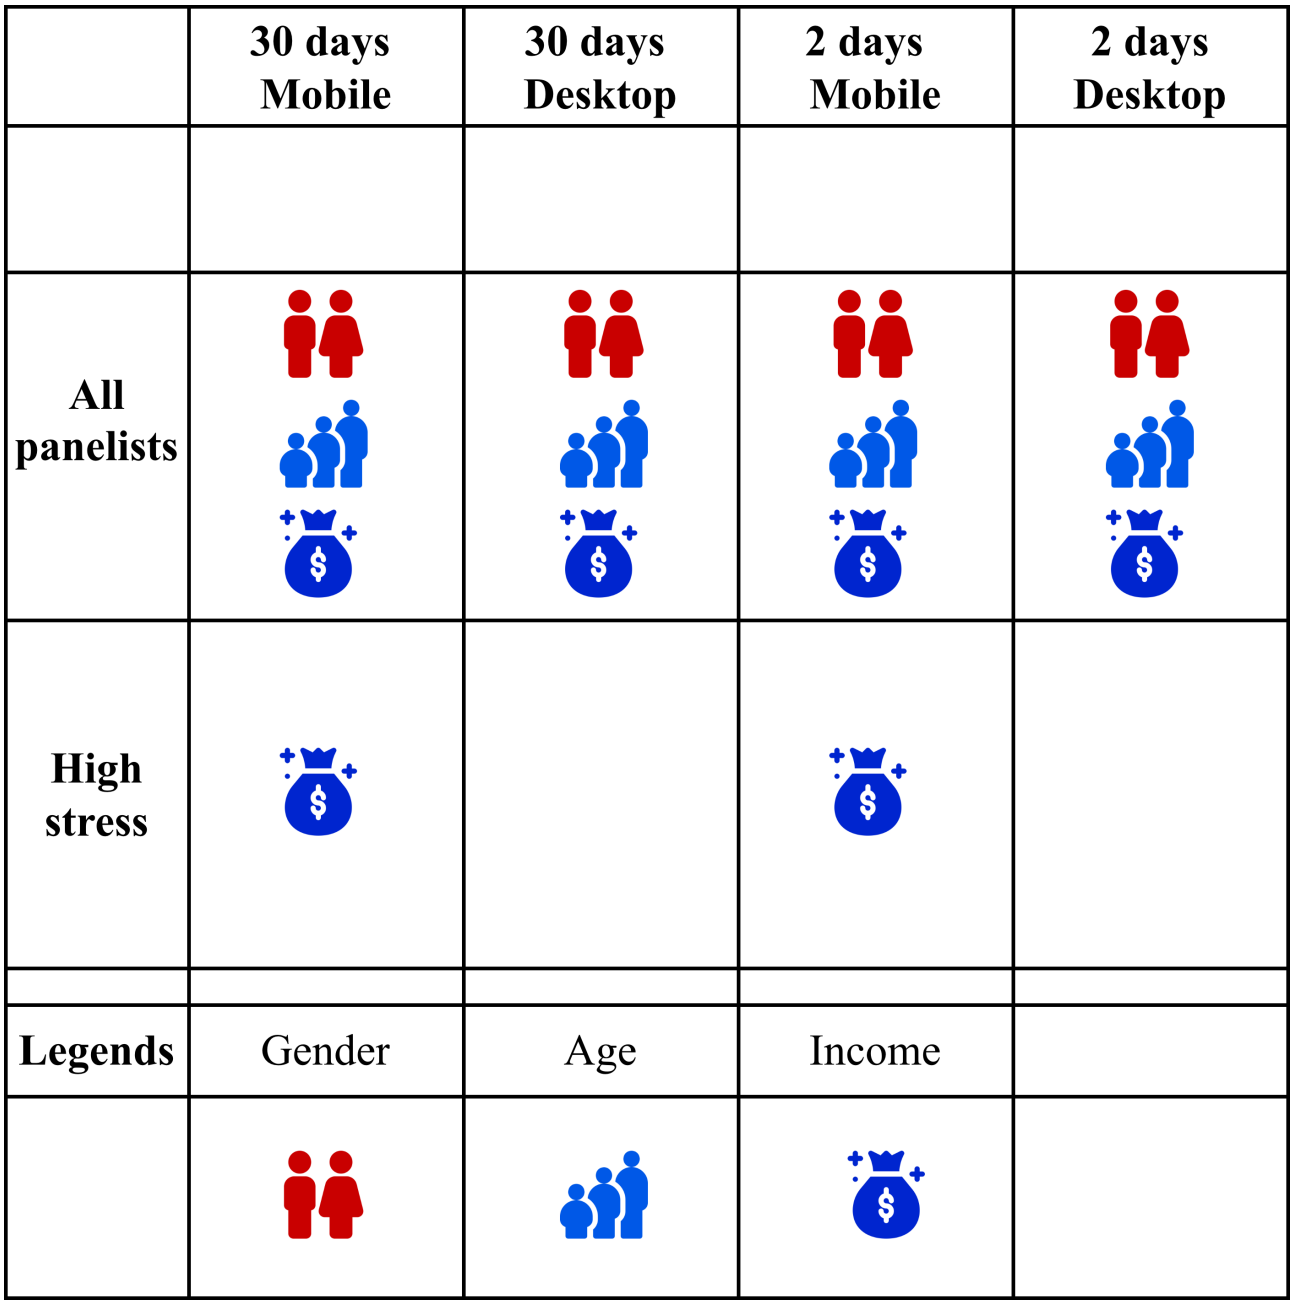
In contrast, desktop usage generally showed negative associations with stress, which may be due to the differences in accessibility of smartphones and desktop devices. Our data show that time spent on desktop devices has higher variability, as reflected by the higher SD (71.43 for desktop vs 66.86 for mobile) and coefficient of variation (desktop: 0.97, CI 0.93 - 1.02 vs mobile: 0.70, CI 0.67 - 0.73), compared to time spent on mobile devices.

Future research should further investigate device differences and the role mobile devices play in predicting stress levels.

User Characteristics and Stress

User characteristics such as gender, age, and income influence both stress levels and their association with internet use, as provided in Figure 3. In our results, female users reported significantly higher stress than males across both mobile and desktop data and for both the 30-day and 2-day periods (refer to Figure 3). Age and income showed consistent negative associations with stress across contexts. Similar findings have been reported in earlier research on sociodemographics and stress [40-44]. Interestingly, in our analysis, income was the only sociodemographic factor significantly associated with stress in the high-stress group for mobile data, while no other sociodemographic features were significant across platforms or time frames. Previous research also suggests that income, rather than age or gender, shows the strongest association with stress [45]. This highlights the need for further investigation into the role of income in stress, as such insights can inform policies aimed at reducing income-related health disparities. Future studies should also incorporate measures to incorporate resilience of individuals (trait stress measures) [143] and personality traits alongside sociodemographics to better understand these associations.

Figure 3. Overview of significant sociodemographic associations across time frames (30 days vs 2 days) and device types (mobile vs desktop). Rows distinguish model results between all participants and high-stress participants. Red icons indicate positive associations, blue icons indicate negative associations, and empty cells denote no significant effects.



Implications

Building on these findings, it is important to consider the implications for various stakeholders, including digital platform designers, health care professionals, and end-users.

For digital platform designers, these findings suggest opportunities to promote healthier use patterns. Features such as reminders to take breaks, tools to visualize usage habits, and reduced notifications during evening/nights could help users avoid stress-inducing behaviors. In addition, adaptive designs that encourage daytime work engagement over late-night use could be particularly effective. Finally, different design considerations may be needed for mobile versus desktop devices to encourage healthier internet use.

For health care professionals, understanding how digital behaviors relate to stress could offer new ways to support patients. For example, excessive gaming on mobile devices might indicate elevated stress. Health workers could include questions about internet habits in assessments and recommend tools that encourage healthier online behaviors. Notably, the low cost and high availability of web data could provide efficient tools to complement traditional monthly surveys for monitoring stress, helping to alleviate the burden on the already strained health care sector.

For individuals, these findings emphasize the importance of timing and purpose in digital habits. Being mindful of potentially stress-inducing activities, such as excessive shopping or gaming, can foster a healthier balance. Tools that track and suggest

healthier patterns of internet use could assist users in managing their habits.

Overall, the relationship between stress and internet use is influenced by factors such as the type of activity, timing, and individual circumstances. This suggests that small, intentional changes in digital habits can help manage stress effectively.

Limitations

The panelists we collected data from are gig workers who regularly participate in surveys, which may lead to behavioral differences compared to the general population. To address this issue, we used rigorous preprocessing steps, including removing users who spent more than 25% of their time on survey websites and excluding the bottom 20% of users based on time spent. Moreover, browsing data from these panels has been shown to prominently feature the most visited domains in Germany [144]. Another limitation is that users may change their online behavior when they are aware of being tracked. However, previous work has demonstrated that the privacy attitudes of web-tracked panelists are comparable to those of nonweb-tracked panelists in Germany [145], though they may vary across countries. These findings support the reliability and suitability of the web-tracking data for capturing individuals' internet usage behavior. In addition, due to budget constraints, all panelists were from a single country, which may limit the generalizability of our findings because of cultural and behavioral differences. Previous research has demonstrated differences in cultural, social, and technological access contexts, variations in usage patterns, and mental health prevalence across countries [146,147]. Replicating this study in other countries or with a larger and more diverse sample could help further improve the generalizability and provide a broader cultural context. Further, 23% of participants dropped out between the first and final survey waves. To mitigate this attrition, we initially used a larger sample and invited all panelists from the panel company to participate in our baseline survey. Furthermore, since our tracker only tracks browsing behavior through the browser, we lack complete data on desktop usage through desktop apps, which may limit our ability to fully capture differences between mobile and desktop use. Finally, we used a validated self-report measure to assess stress, as inviting all participants to a lab setting was not feasible. Alternative approaches, such as physiological or real-time assessments, could provide more objective and detailed measures of stress.

Conclusion

Our study examines the relationship between internet use and perceived stress through a novel contextual framework that considers how, where, when, and by whom the internet is used. The findings indicate that internet use is associated with stress, and these associations differ across various usage contexts. Specifically, engagement with social media, online shopping, entertainment, and gaming is positively linked to higher stress levels. Notably, these activities have been identified in previous research as common coping mechanisms for stress, highlighting the need for future studies to examine whether such coping strategies alleviate stress or, possibly, exacerbate it over time. In contrast, productivity-related activities, news consumption, and adult content use are negatively associated with stress, suggesting they may either function as stress buffers or indicate avoidance behavior. Associations inferred from desktop data across different contextual dimensions are weaker than those inferred from mobile data, indicating that device type plays an important role. In the short term, news consumption is negatively associated with both mobile and desktop data. For individuals already experiencing high stress, increased time online on mobile phones—particularly on social media and gaming—is correlated with higher stress levels. In addition, sociodemographic factors, especially income, have significant associations with stress. These findings have important implications for the design of digital platforms, the development of mental health interventions, and the formation of healthier online habits. Future research should focus more specifically on particular web-based behaviors, such as news consumption and online shopping, and their effects on psychological well-being. It should also aim to establish causal links between internet use and stress and further investigate the mechanisms underlying sociodemographic differences in these associations.

Acknowledgments

This work was supported by the Helsinki Institute for Information Technology (HIIT). We would like to thank Yajing Wang for her help with data annotation and Emilia Marchese for her help with the data collection process. In addition, we acknowledge the computational resources provided by the Aalto Science-IT project.

Funding

This work was supported by the Helsinki Institute for Information Technology (HIIT). The funder had no involvement in the study design, data collection, analysis, interpretation, or manuscript writing.

Authors' Contributions

JK, MB, and TA led the conceptualization of the study. JK, MB, and TA were responsible for data curation and methodology development. MB and NL contributed to software implementation and validation. The investigation was conducted by JK, MB, NL, and TA, and data analysis was performed by MB and NL. JK and MB prepared the original draft, and JK, MB, NL, and TA contributed to reviewing and editing the paper. Visualizations were created by MB and NL. JK and TA provided supervision, acquired funding, and secured the necessary resources for the project.

Conflicts of Interest

None declared.

Abstract

Background: Whether the benefits of identical physical activity (PA) patterns for adults with high blood pressure (BP) vary according to an individual's characteristics has not been adequately studied.

Objective: This study aimed to investigate whether an individual's characteristics modify the associations between PA patterns and mortality rate.

Methods: Four PA patterns were derived from accelerometer-based data: active weekend warrior, active regular, active light PA, and baseline PA. The main outcome was all-cause mortality. A machine learning model to predict the optimal PA pattern for individual patients was trained in the UK Biobank (UKB) cohort and externally validated in the National Health and Nutrition Examination Survey cohort, which was subsequently integrated into a web-based application. The potentially optimal PA pattern within patients was identified as the one leading to the highest predicted survival probability. Multivariable Cox models were used to estimate hazard ratios and 95% CIs for all-cause mortality corresponding to the inconsistency of the current PA pattern with the predicted optimal PA pattern.

Results: A total of 71,637 UKB adults and 5104 National Health and Nutrition Examination Survey individuals were enrolled. External validation demonstrated that the area under the receiver operating characteristic curve of our model for predicting mortality at 10 years of follow-up was 86.4% (95% CI 85.1% - 87.7%). The predicted optimal PA patterns in the UKB cohort were active regular PA for 26,643 (37.2%) participants, active light PA for 22,606 (31.6%) participants, and active weekend warrior for 21,749 (30.4%) participants. Stroke history, age, sex, BP class, and antihypertension medication were key factors driving heterogeneity in individuals' optimal PA patterns. Cox regression analysis suggested that individuals in the UKB cohort whose current PA patterns were inconsistent with the predicted optimal patterns may be associated with a 28% increase in all-cause mortality risk on average (hazard ratio 1.28, 95% CI 1.20 - 1.38) compared to those with consistent patterns.

Conclusions: Our findings may help patients with high BP obtain individualized recommendations for PA patterns based on their specific characteristics, thereby improving their prognosis.

KEYWORDS

hypertension; physical activity pattern; machine learning; mortality; precision medicine

Introduction

According to the latest report from the World Health Organization, the global population of adults with hypertension has more than doubled between 1990 and 2019, rising from 0.65 billion to 1.3 billion [1,2]. In 2019, high blood pressure (BP) was responsible for 10.8 million deaths worldwide, primarily due to cardiovascular diseases and chronic kidney disease [1,2]. Timely and effective interventions are therefore critical to mitigating this burden. International hypertension management guidelines universally endorse physical activity (PA) as a first-line nonpharmacological intervention for BP control [3,4]. Furthermore, PA offers distinct advantages over antihypertensive medications, including cost-effectiveness and a reduced risk of adverse effects [5,6].

As outlined by Dzau and Hodgkinson [7], patients with hypertension should receive individualized management that accounts for patients' unique genetic and environmental factors,

namely, *precision hypertension*. This perspective highlights the heterogeneity in treatment response among hypertensive individuals and underscores the need for tailored PA strategies. A major challenge in advancing precision hypertension is to move beyond the estimation of average associations and address the variability in individual responses to PA. This variability depends on factors such as personal characteristics, baseline risk profiles, and differential sensitivity to PA interventions [8]. Therefore, conducting studies on the heterogeneous associations between PA and health outcomes and identifying key factors driving this heterogeneity is essential for precision hypertension management.

PA patterns (defined by frequency, duration, and intensity of PA) and their associations with mortality have caught significant attention in recent research [9-11]. Furthermore, these studies on the heterogeneous associations between PA and mortality rely on subgroup analyses [12,13]. For example, Ji et al [13] studied the heterogeneous association between PA and mortality using prespecified gender subgroups. However, such traditional subgroup analyses require prespecification of potential subgroup variables, which limits their exploratory value [14]. Furthermore, one-variable-at-a-time analyses may produce false positives due to multiple testing and false negatives due to limited statistical power in small subgroup samples [15]. The burgeoning field of machine learning (ML) holds promise in estimating heterogeneous treatment effects, potentially offering significant support in addressing this concern [7,16]. Therefore, in our study, we adopted the S-learner framework, a metalearner for estimating individualized treatment effects using ML [17]. The ML based on metalearners can simulate the progression of hypertension and identify optimal PA patterns for managing these conditions.

We hypothesized that the associations of PA patterns with mortality would differ based on individual patient characteristics. In other words, the optimal PA pattern for patients may exhibit heterogeneity depending on individual characteristics. To test this hypothesis, we derived and externally validated a potential outcome prediction model, which was further integrated into a web-based application to identify the optimal PA pattern for an individual with hypertension. In our study, PA patterns were defined using accelerometer data from the UK Biobank (UKB) and the National Health and Nutrition Examination Survey (NHANES) cohorts.

Methods

Study Design and Participants

Our study included two surveys: the UKB and the NHANES. The UKB is a prospective cohort study comprising 502,629 participants enrolled between 2006 and 2010. The NHANES is a biannual survey designed to assess the health and nutritional status of the US population. This study adhered to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines [18].

The inclusion criteria for this study were individuals with device-measured PA data and high BP. Exclusion criteria were participants with (1) poor device calibration, (2) inadequate wear time, or (3) missing values for the outcome and covariates. According to the 2024 European Society of Cardiology Guidelines for the management of elevated BP and hypertension [3], participants were classified as having high BP if they met any of the following criteria: systolic BP (SBP) ≥120 mm Hg, diastolic BP (DBP) ≥70 mm Hg, hospitalization records, or the use of antihypertensive medications. In our study, we further categorized high BP into two groups: elevated BP and hypertension. Participants with SBP between 120 and 139 mm Hg or DBP between 70 and 89 mm Hg who were not using antihypertensive medication were classified as having elevated BP; others were classified as having hypertension.

A total of 103,582 participants from the UKB and 14,631 participants from the NHANES cohort were initially considered. After applying the inclusion and exclusion criteria, 71,637 (69.2%) participants from the UKB and 5104 (34.9%) participants from NHANES were included in the final analysis.

Exposure Ascertainment

Information on the collection of accelerometer-based PA data in the UKB and NHANES studies is provided as follows. From 2013 to 2015, UKB participants were randomly assigned to wear an Axivity AX3 accelerometer (Newcastle upon Tyne) for 7 days to measure PA and sedentary behavior. The wrist-worn accelerometers were initialized to capture data with a sampling frequency of 100 Hz and a dynamic range of ±8 g. Poor device calibration was defined as a lack of sufficient orientation changes or as having implausible acceleration values. Good wear time was defined as having at least 3 days (72 h) of data and also having data in each 1-hour period of the 24-hour cycle (scattered over multiple days). The accelerometers recorded data in milligravity units (mg). Light PA (LPA) and moderate to vigorous physical activity (MVPA) were categorized via a published ML-driven approach specifically designed for classifying a wide spectrum of activities [19].

For the NHANES, we included individuals with accelerometer-based PA data from the 2003 to 2006 cycles of NHANES. According to the design of the NHANES study, information on sedentary behavior and total PA was collected using an accelerometer (ActiGraph model 7164; ActiGraph, LLC), worn on the waist for 7 consecutive days during waking hours, except while swimming or showering. Poor device calibration was defined as more than 60 consecutive minutes with zero counts. Good wear time was defined as a recorded wear time of 10 hours or more for at least 1 day [20]. Behavior categories were defined by count per minute thresholds for adults: sedentary behavior (<100 counts per minute), LPA (100 - 2020 counts per minute), and MVPA (≥2020 counts per minute) [21].

We defined four PA patterns according to the following criteria: active weekend warrior (WW; ≥150 min per week MVPA with ≥50% of total achieved in 1 - 2 d) [22], active regular (≥150 min per week and not meeting MVPA WW status) [22], active LPA (<150 min per week MVPA and ≥1900 min per week LPA), and baseline PA (<150 min per week MVPA and <1900 min per week LPA). The threshold of 1900 minutes per week for an active LPA pattern was determined based on the previous study [23], and our analysis of the dose-response relationship

between LPA and all-cause mortality was determined using the Cox regression models with restricted cubic splines (Multimedia Appendix 1).

Mortality Ascertainment

The primary outcome of this study was all-cause mortality, obtained from the National Health Service Information Center (England and Wales) and the National Health Service Central Register Scotland (Scotland) for the UKB study. At the time of analysis, mortality data were available through May 31, 2024, for England and Wales, and December 31, 2023, for Scotland. For NHANES, the National Death Index was used to ascertain all-cause mortality of included samples until December 31, 2019. The follow-up period was defined as the duration between the initial PA measurement and either death or the end of follow-up, whichever occurred first. The causes of death were confirmed based on ICD-10 coding.

Covariates

The covariates were age, sex, ethnicity, BMI, waist circumference, education, smoking status, alcohol consumption, added salt intake, sedentary time, sleep time, SBP, DBP, antihypertension medication, cancer, diabetes, myocardial infarction (MI), stroke, family cardiovascular disease (CVD), BP class, glycated hemoglobin (HbA_{1c}), high-density lipoprotein cholesterol, triglyceride levels, and glucose. Ascertainment and descriptions of covariates considered for both UKB and NHANES are provided in Multimedia Appendix 2.

To minimize the time interval between covariate assessment and accelerometer-based PA measurement (typically 2013 - 2015) in the UKB, we prioritized data from instance 1 (the repeat assessment in 2012 - 2013) when both instance 0 (the baseline assessment in 2006 - 2010) and instance 1 were available [22]. We assessed the reliability of covariates in participants with repeated measurements by the intraclass correlation coefficient [24] for continuous variables and Cohen κ [25] for categorical variables. The analysis indicated moderate to high reliability of the covariates; detailed results are provided in Multimedia Appendix 3. In contrast, the PA and covariates in the external validation set, NHANES, were measured during the same period, thus avoiding the aforementioned issues present in UKB.

Model Development and Estimation of Heterogeneous Associations

We randomly divided the UKB data into an 80% training set and a 20% internal validation set, with the NHANES dataset used for external validation. Predictors were selected using Cox regression with the least absolute shrinkage and selection operator (LASSO) penalization [26], where the optimal shrinkage parameter lambda was determined via 10-fold cross-validation [27]. The original predictive model was constructed using a multivariable Cox model that incorporated all second-order interactions between PA pattern and the selected predictors. Then, we applied a stepwise backward elimination method to refine the model, removing variables and interaction terms that did not significantly contribute to the model [28]. Model performance was evaluated in the internal validation set and the NHANES validation set and visualized using the calibration curves (with Brier score) and receiver operating characteristic (ROC) analysis (with the area under the ROC curve [AUC]) [29,30].

Our S-learner algorithm for estimating heterogeneous associations between PA and overall survival follows a 2-step process. First, it uses the trained prediction model to estimate the conditional expectations of survival time for each of the 4 PA patterns separately. Second, it computes the differences between these estimates to capture the heterogeneous associations.

On the basis of the S-learner framework, the trained prediction model was capable of handling potential variations in covariates, enabling the prediction of each patient's potential survival probabilities under the 4 PA patterns. Then, the best potential PA pattern for a certain patient was identified as the one leading to the highest predicted survival probability. To operationalize these findings, we developed an R Shiny web application that enables clinicians to simulate personalized survival curves for all 4 PA patterns based on individual baseline characteristics.

Patient Characteristics Associated With Predicted Individualized PA Patterns

All individuals in the UKB and the NHANES cohorts were stratified by PA patterns that might individually optimize overall survival. This stratification was used to identify the profiles of individuals who could benefit most from 1 of the 4 PA patterns presented, according to the constructed prediction model.

To facilitate rapid decision-making and clearly illustrate patient characteristics associated with predicted individualized PA patterns, a model of conditional inference tree (CIT) was established [31]. Specifically, we used the potentially optimal PA patterns predicted as the outcome and all covariates as predictors to build the CIT model.

Statistical Analysis

We introduced an indicator variable, referred to as an "inconsistent PA pattern," to distinguish between individuals whose actual and predicted optimal PA patterns were inconsistent and those whose patterns were consistent. Multivariable Cox models were used to estimate hazard ratios (HRs) and 95% CIs for all-cause mortality corresponding to the inconsistency of the current PA pattern with the predicted optimal PA pattern. The analyses were adjusted for covariates selected by LASSO.

As further stratification of participants with inconsistent PA patterns provides more clinically meaningful information, we subdivided the inconsistent group into two categories based on the predicted optimal intensity: (1) inconsistent MVPA pattern—participants whose predicted optimal PA pattern required more MVPA but whose actual activity was lower than predicted and (2) inconsistent LPA pattern—participants whose predicted optimal PA pattern required LPA primarily but whose actual activity (including active regular, active WW, and baseline PA patterns) differed. The original binary variable "inconsistent PA pattern" was thus updated to a category variable with three levels: consistent, inconsistent MVPA pattern, and inconsistent LPA pattern. We then used "consistent"

as a reference class for the aforementioned multivariable Cox model analyses. In addition, we conducted subgroup analysis in the actually observed nonbaseline group.

Sensitivity Analyses

To test the generalizability of the aforementioned analyses, we performed 4 prespecified sensitivity analyses. First, we repeated the statistical analyses using the NHANES dataset. Second, we replaced the all-cause mortality outcome with CVD-specific mortality and cancer-specific mortality outcomes. Third, to minimize the potential confounding effects of the COVID-19 pandemic, we restricted follow-up to the period before December 31, 2019. This prepandemic dataset was used as an additional validation cohort to assess the robustness of the model's performance and to repeat the statistical analyses. Finally, the statistical analyses were repeated using the internal validation set.

All analyses were conducted using R version 4.4.1 (R Foundation), with statistical significance set at $P<.05$.

Ethical Considerations

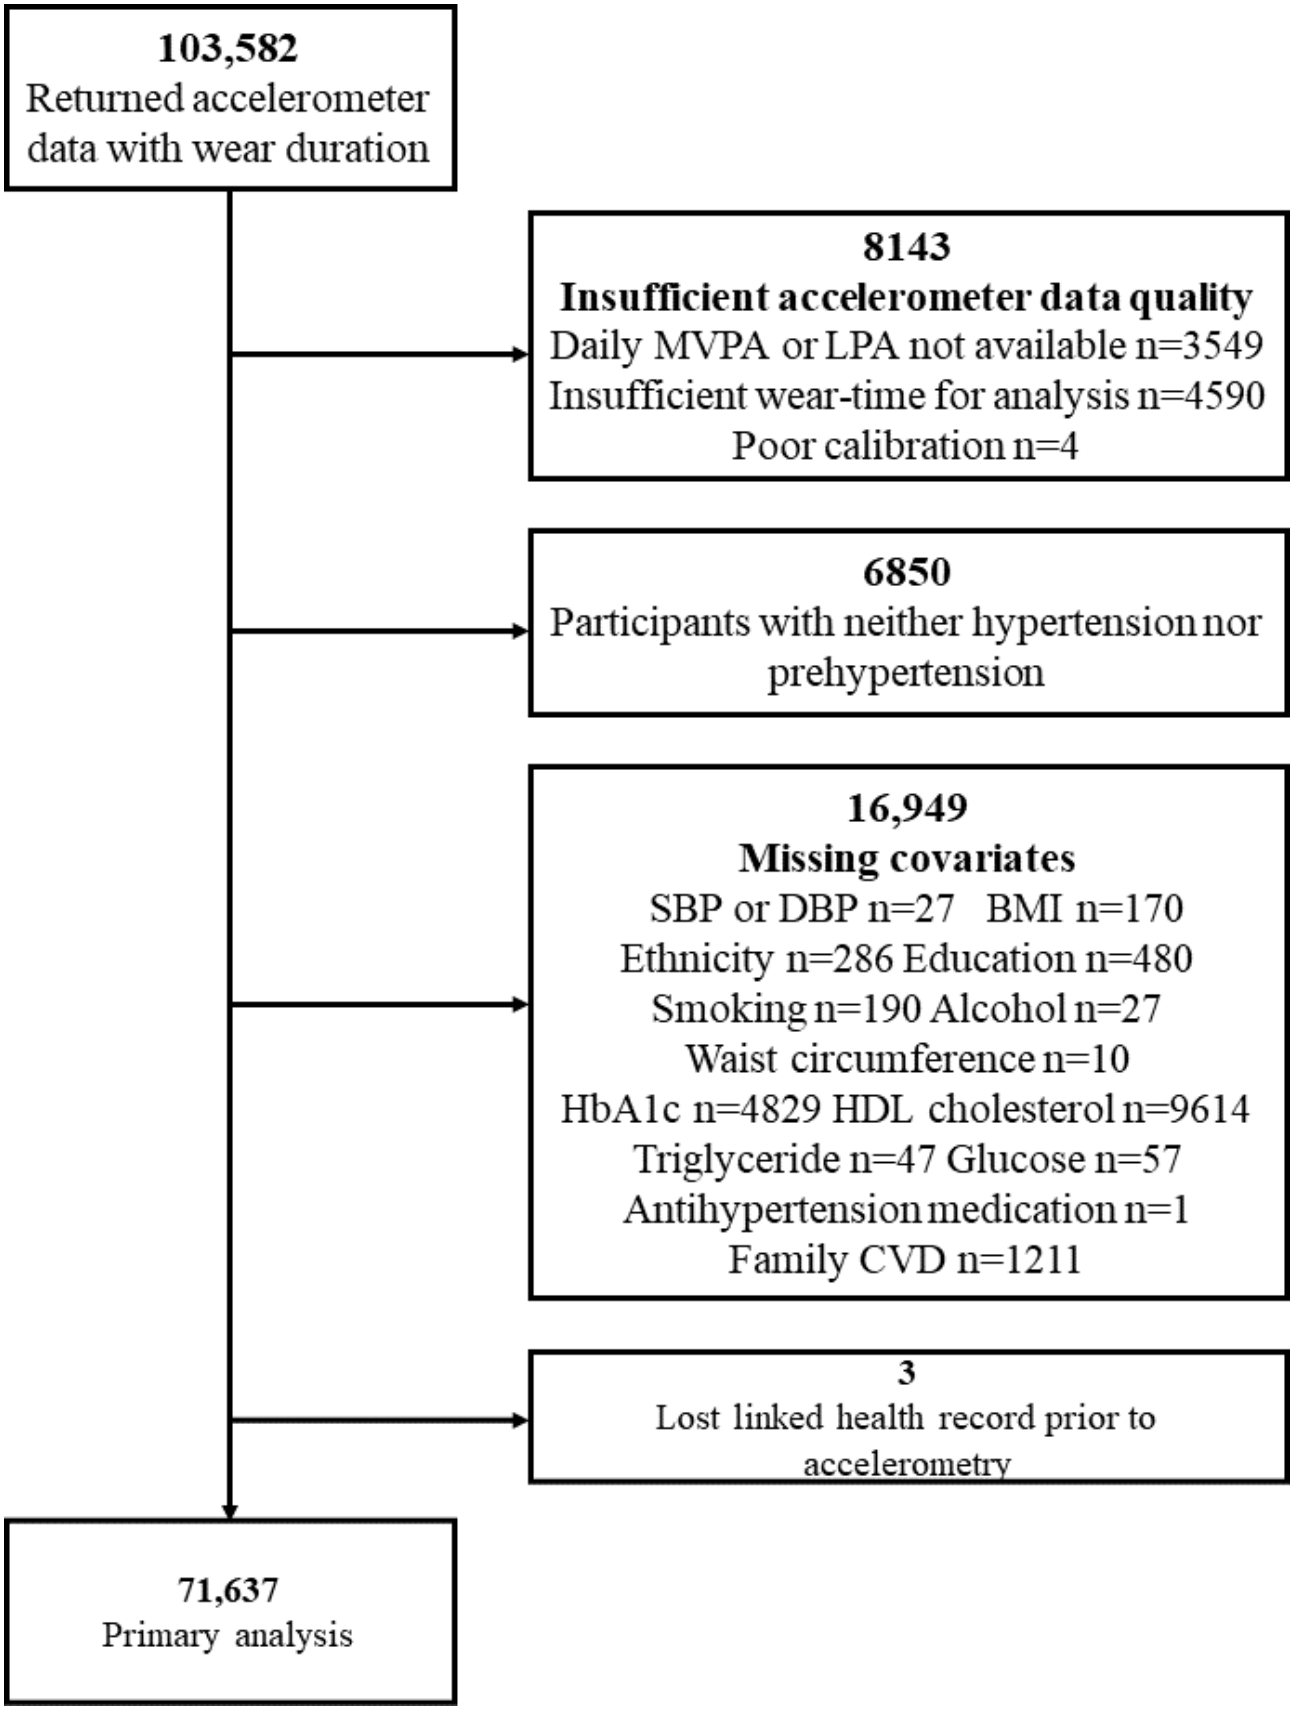
This study involved secondary analysis of data from the UKB and the NHANES, whose original data collection protocols were conducted in accordance with the Declaration of Helsinki. UKB was approved by the North West Multi-centre Research Ethics Committee (reference 21/NW/0157), and all participants provided written informed consent for health-related research, including secondary analyses. The NHANES study received ethical approval from the National Center for Health Statistics Ethics Review Board. The National Center for Health Statistics Ethics Review Board approved Protocol 98‐12 for the 2003‐2004 cycle and Protocol 2005‐06 for the 2005‐2006 cycle. All participants provided written informed consent. All data were anonymized or deidentified.

Results

Overview

For the UKB cohort, a total of 71,637 adults were enrolled and analyzed (Figure 1), with 4207 deaths confirmed during a median follow-up period of 9.5 years. For the NHANES cohort, we included 5104 individuals who underwent device-based activity measurements between the 2003 and 2006 cycles (Multimedia Appendix 4), with 1279 deaths confirmed during a median follow-up period of 14.3 years. The median follow-up time for survivors and nonsurvivors in both the UKB and the NHANES datasets is shown in Multimedia Appendix 5. The baseline characteristics of participants, stratified by 4 actually *observed* PA patterns, are summarized in Multimedia Appendix 6 for the UKB cohort and the NHANES cohort. At baseline in the UKB, 12,577 (17.6%) participants were classified as baseline PA, 12,782 (17.8%) participants were classified as active LPA, 15,141 (21.1%) participants were classified as active regular, and 31,137 (43.5%) participants were classified as active WW.

Figure 1. Study flow for UK Biobank. CVD: cardiovascular disease; DBP: diastolic blood pressure; HbA_{1c}: glycated hemoglobin; HDL: high-density lipoprotein; LPA: light physical activity; MVPA: moderate to vigorous physical activity; SBP: systolic blood pressure.

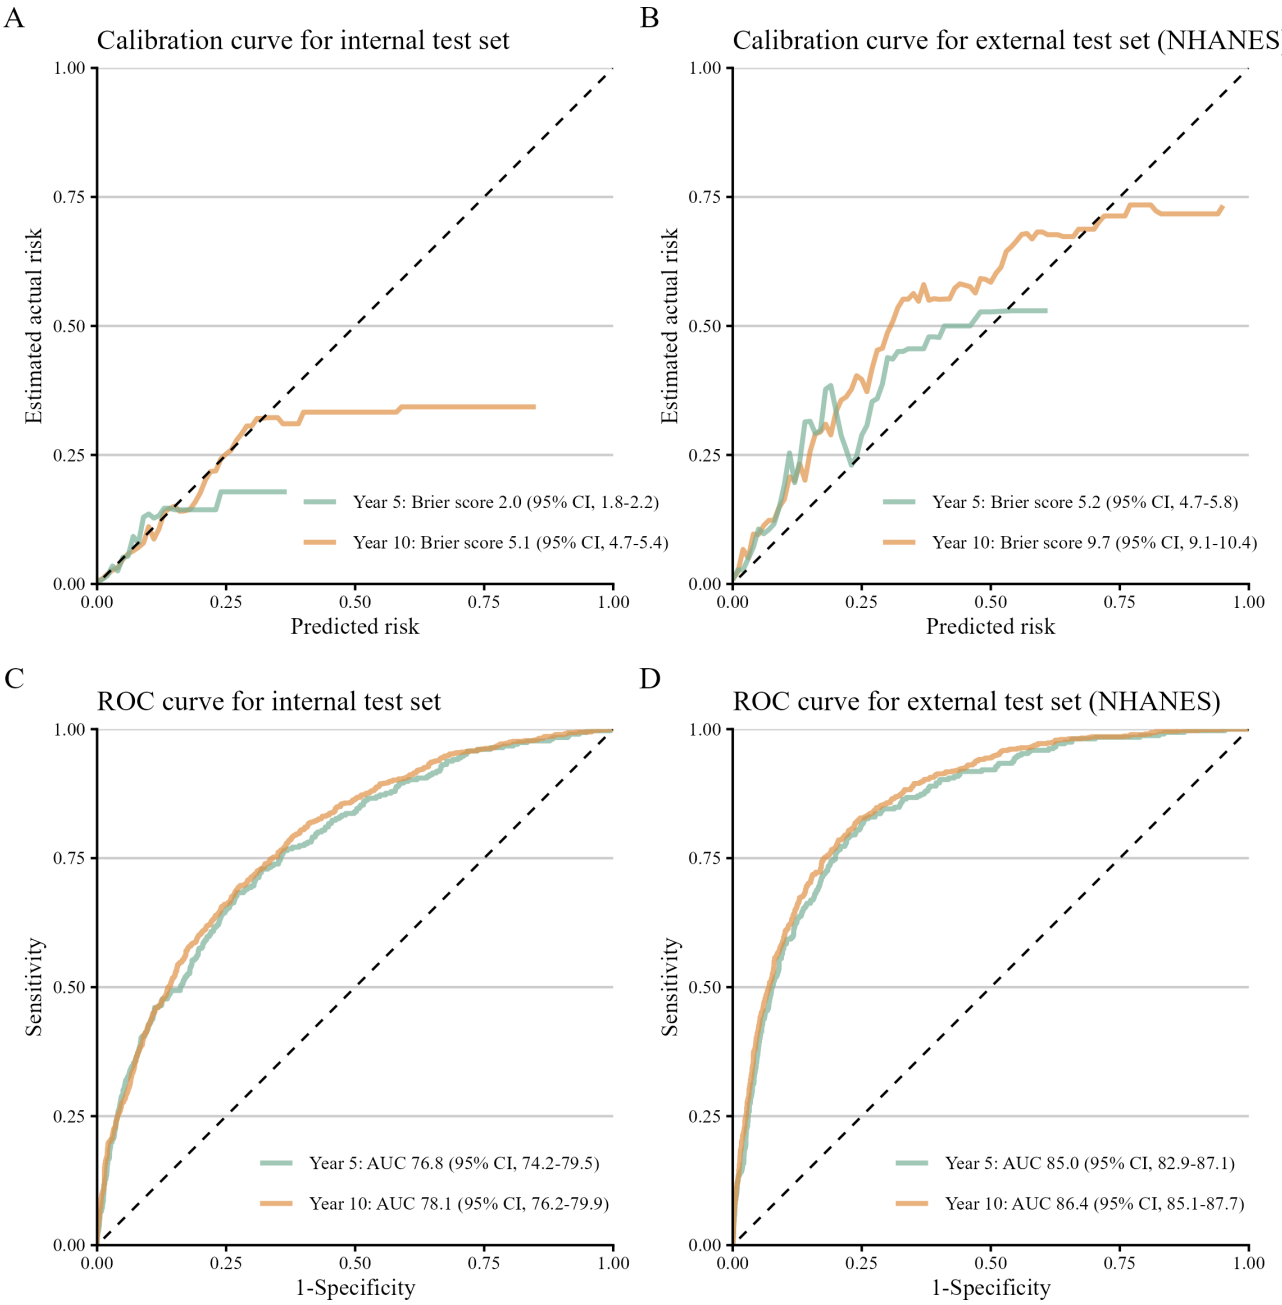


A Prediction Model to Identify the Best Potential PA Patterns

The detailed results from the LASSO-penalized Cox model for covariate selection are presented in Multimedia Appendix 7. In brief, the selected covariates included PA patterns, age, sex, sedentary time, smoking status, antihypertension medication, cancer, diabetes, MI, stroke, BP class, waist circumference, glucose, and HbA_{1c}. In the UKB cohort, the associations between covariates selected by LASSO and all-cause mortality were examined using univariate Cox models (Multimedia Appendix 8): PA patterns were found to be associated with overall survival, suggesting that adults with active LPA (HR 0.56, 95% CI 0.51 - 0.62), active regular (HR 0.45, 95% CI 0.41 - 0.50), or active WW (HR 0.47, 95% CI 0.43 - 0.51) were at a lower risk of death than those with the baseline PA pattern.

The original predictive model incorporated all second-order interactions of PA patterns with each selected covariate. Following stepwise backward elimination, the main effect of glucose and the interactions of PA patterns with waist circumference, smoking status, and glucose were removed from the model. The terms and coefficients of the final model are detailed in Multimedia Appendix 9. The model showed well-calibrated predictions in the internal test set, with Brier scores of 2.0% (95% CI 1.8% - 2.2%) for the 5-year and 5.1% (95% CI 4.7% - 5.4%) for the 10-year prediction (Figure 2A). Calibration remained acceptable in the external NHANES set, although it was slightly decreased, with Brier scores of 5.2% (95% CI 4.7% - 5.8%) for the 5-year and 9.7% (95% CI 9.1% - 10.4%) for the 10-year prediction (Figure 2B). The model also demonstrated good discriminative ability. In the internal set, the AUC was 76.8 % (95% CI 74.2% - 79.5%) for the 5-year and 78.1% (95% CI 76.2% - 79.9%) for the 10-year prediction (Figure 2C). This performance was further improved in the external validation set, with AUCs of 85.0% (95% CI 82.9% - 87.1%) and 86.4% (95% CI 85.1% - 87.7%) for the 5- and 10-year prediction, respectively (Figure 2D).

Figure 2. Performance of the model in predicting all-cause mortality. The calibration and ROC curves for internal (n=14,328) and external test data set (n=5104). AUC: area under the receiver operating characteristic curve; NHANES: National Health and Nutrition Examination Survey; ROC: receiver operating characteristic.



The prediction model identifying the best PA pattern has been integrated into an online application, accessible free of charge (Multimedia Appendix 10). To ensure broader accessibility of the application, we have provided both English and Chinese versions (Multimedia Appendix 10). Users need to enter the required clinical characteristics (including age, sex, sedentary time, smoking status, antihypertension medication, cancer, diabetes, MI, stroke, BP class, waist circumference, and HbA_{1c}) into the website. The tool then calculates the predicted 5-year and 10-year survival probabilities corresponding to the 4 PA patterns. After these probabilities are generated, the application identifies the pattern with the highest predicted survival probability. This information can support clinicians and patients in selecting the most appropriate personalized PA pattern.

Patient Characteristics Associated With Predicted Optimal PA Patterns

Our predictive model indicated that the optimal PA pattern varied among adults with high BP. Specifically, 26,643 (37.2%) participants were predicted to benefit most from the active regular pattern, 22,606 (31.6%) participants from the active LPA pattern, 21,749 (30.4%) participants from the active WW pattern, and 639 (0.9%) participants from the baseline PA pattern. Table 1 presents the characteristics of participants according to their *predicted* optimal PA patterns and compares these with the patterns they actually followed in the UKB cohort. In addition, we applied the same predictive approach to NHANES participants and compared *predicted* versus *observed* PA patterns, as shown in Multimedia Appendix 11.

Table . Baseline characteristics of participants stratified by the predicted optimal physical activity (PA) pattern.

Variables and levels	Baseline PA (n=639)	Active LPA[a] (n=22,606)	Active regular (n=26,643)	Active WW[b] (n=21,749)	*P* value

[c]WC: waist circumference.

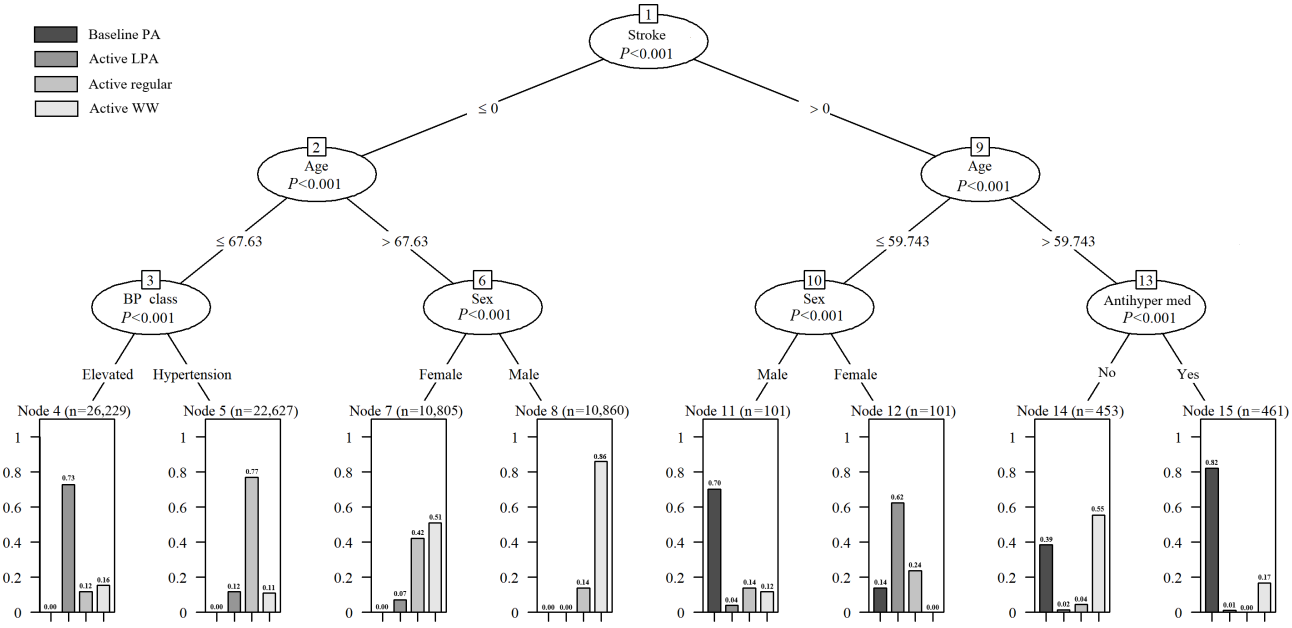
[d]MI: myocardial infarction.

[e]HbA_{1c}: glycated hemoglobin.

The results of the CIT model are shown in Figure 3. Briefly, the model is rooted by stroke, with subsequent branching by age, BP class, sex, and antihypertension medication (all *P*<.001). Adults with stroke are more likely to have baseline PA or active

LPA as optimal patterns. In contrast, for those without stroke, younger adults (≤68 y) tend to benefit more from active regular and active LPA, whereas older men (>68 y) are predicted to gain more from the active WW pattern. In summary, stroke, age, sex, BP class, and antihypertension medication are key factors driving heterogeneity in individuals' optimal PA patterns. Notably, the baseline PA pattern denotes a lower level of PA rather than complete physical inactivity or sedentary behavior.

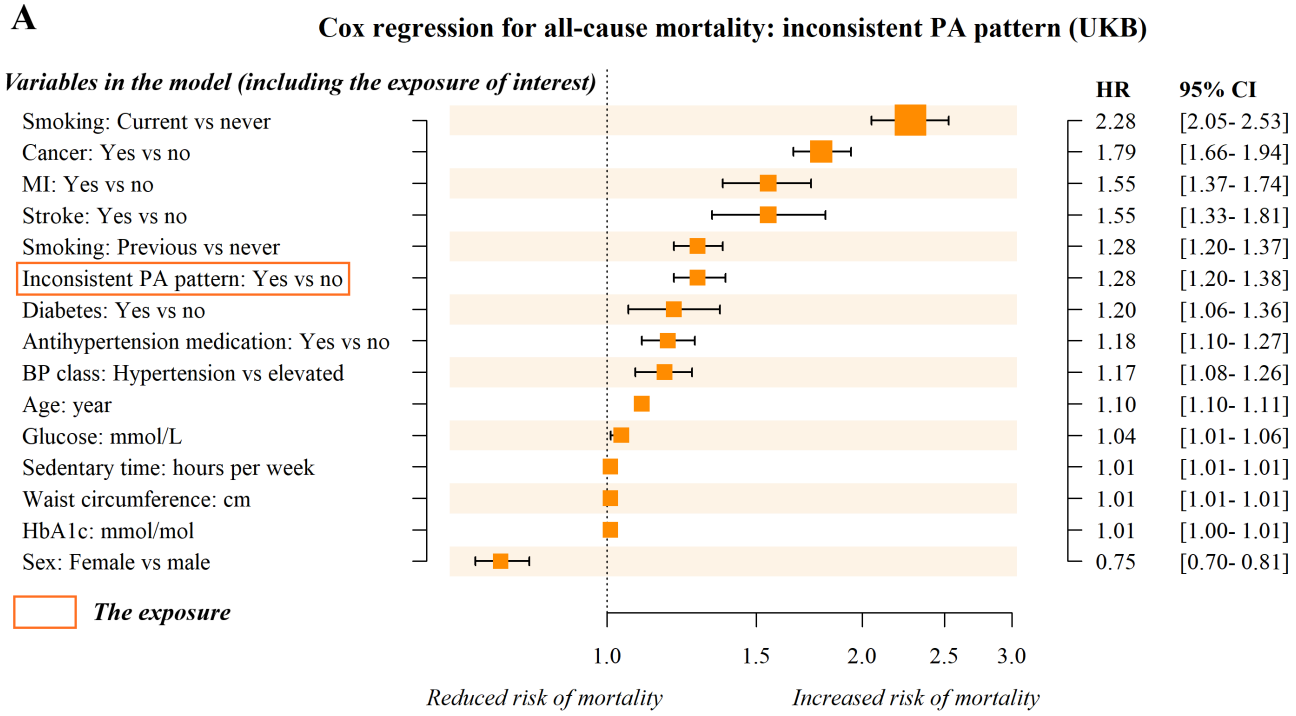
Figure 3. The derived conditional inference tree. The models were constructed by the optimal PA pattern predicted (outcome) and all covariates selected (predictors). Antihyper med: antihypertension medication; BP: blood pressure; LPA: light physical activity; WW: weekend warrior.



The Associations Between Inconsistent PA Patterns and Mortality

The PA patterns observed in 71.9% of participants in the UKB cohort and 78.9% of participants in the NHANES cohort were inconsistent with the optimal patterns predicted by our model. Compared to individuals whose actual and predicted optimal PA patterns were consistent, an inconsistent PA pattern was associated with a 28% increase in all-cause mortality risk on average (HR 1.28, 95% CI 1.20 - 1.38; Figure 4A) in the UKB cohort. Specifically, an inconsistent MVPA pattern was associated with a 31% increased risk (HR 1.31, 95% CI 1.22 - 1.41; Figure 4B), whereas an inconsistent LPA pattern was associated with a 14% increased risk (HR 1.14, 95% CI 1.01 - 1.30; Figure 4B). In subgroup analysis, we found no statistically significant association between the inconsistent LPA pattern and all-cause mortality (HR 1.06, 95% CI 0.91 - 1.23; Figure 5).

Figure 4. Forest plot of hazard ratios (HRs) from the multivariate Cox regression model. Outcome: all-cause mortality. Exposure: inconsistent PA patterns (distinguishing between individuals with consistent [actual vs predicted optimal PA patterns] and inconsistent PA patterns). In Figure 4A, the exposure is a binary variable (consistent vs inconsistent); in Figure 4B, it is a categorical variable with 3 levels (consistent [reference group], inconsistent MVPA pattern, and inconsistent LPA pattern). The Cox regressions were analyzed and sorted by HR. BP: blood pressure; HbA_{1c}: glycated hemoglobin; LPA: light physical activity; MVPA: moderate to vigorous physical activity; PA: physical activity; UKB: UK Biobank.



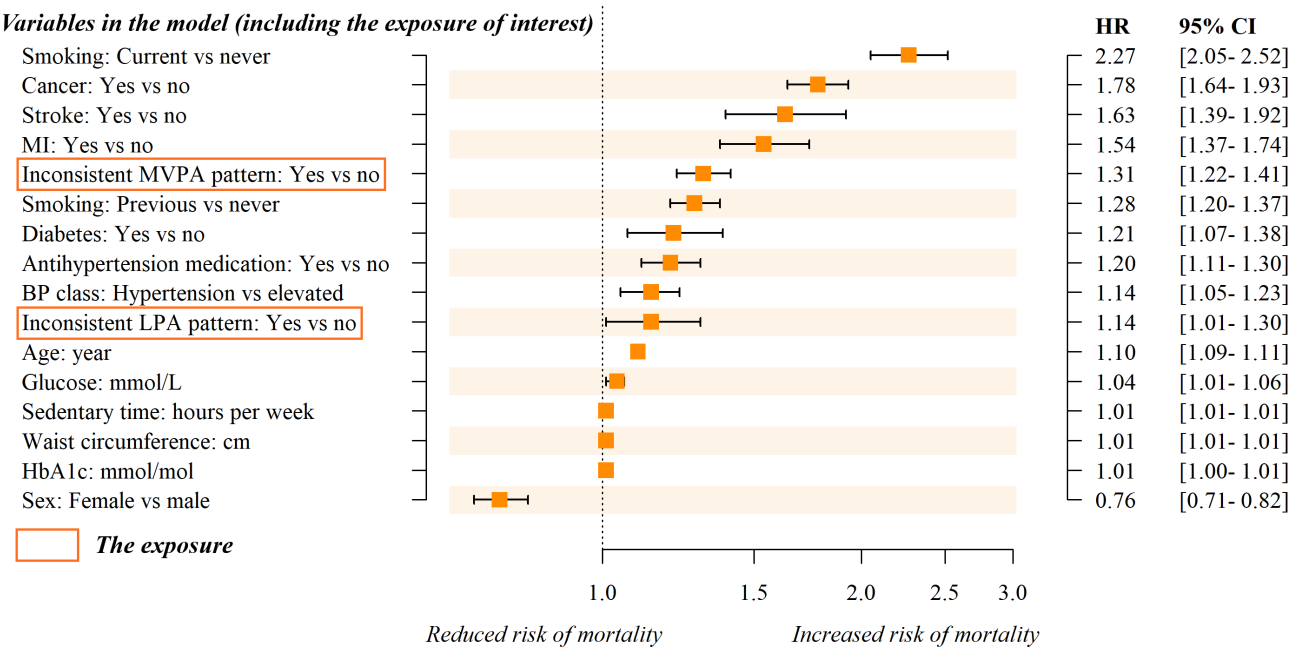


Figure 5. Forest plot of hazard ratios (HRs) from the multivariate Cox regression model in the nonbaseline subgroup. Outcome: all-cause mortality. Exposure: inconsistent PA patterns (distinguishing between individuals with consistent [actual vs predicted optimal PA patterns] and inconsistent PA patterns) with 3 levels (consistent [reference group], inconsistent MVPA pattern, and inconsistent LPA pattern). The nonbaseline group comprises participants whose actually observed PA pattern was not the "baseline PA" pattern. The Cox regressions were analyzed and sorted by HR. BP: blood pressure; HbA_{1c}: glycated hemoglobin; LPA: light physical activity; MVPA: moderate to vigorous physical activity; PA: physical activity; UKB: UK Biobank.

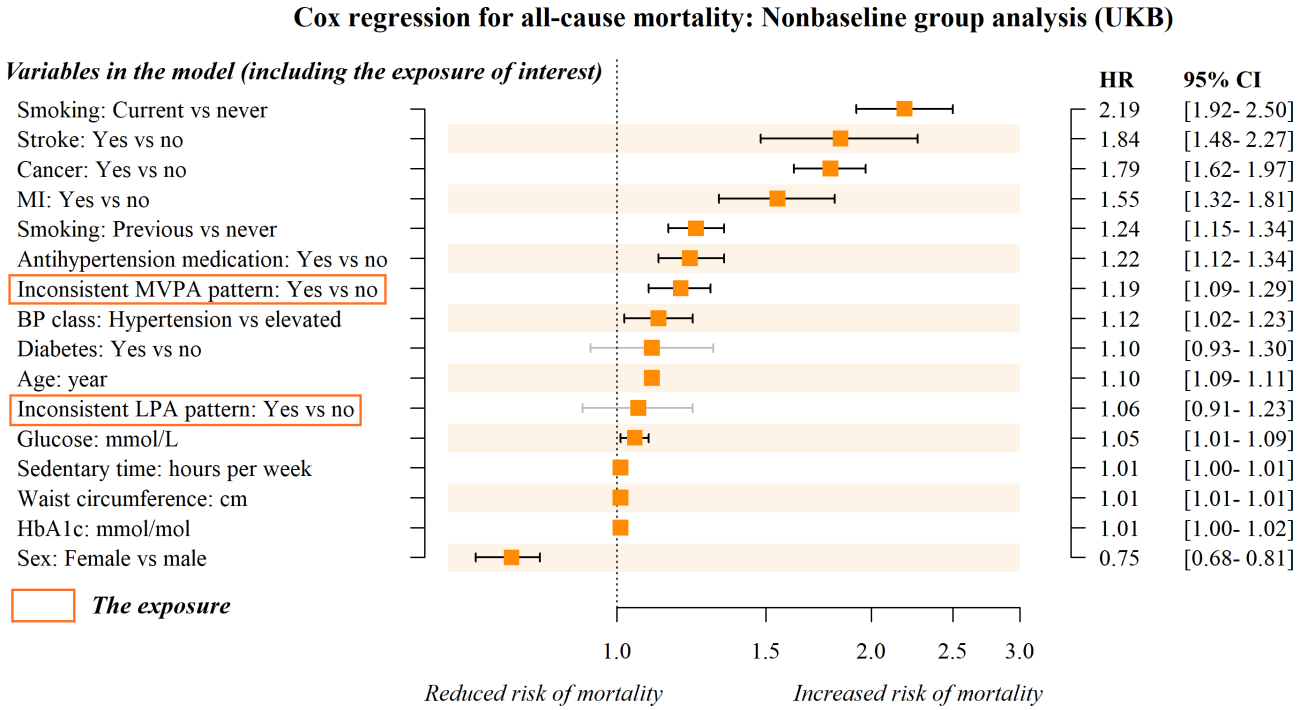

Sensitivity Analyses

The results of the sensitivity analyses are demonstrated in Multimedia Appendix 12. The results of the first sensitivity analysis using the NHANES data showed that an inconsistent PA pattern was associated with a 26% increase in all-cause mortality risk (HR 1.26, 95% CI 1.06 - 1.51), compared to individuals with consistent actual and predicted optimal PA patterns. The analyses of the associations between inconsistent MVPA or LPA patterns and mortality, as well as subgroup analyses, also yielded results similar to those in the UKB cohort. The results of the second sensitivity analysis using cause-specific mortality outcomes indicated that an inconsistent PA pattern was associated with an 18% increase in cancer mortality risk (HR 1.18, 95% CI 1.07 - 1.30) and a 33% increase in CVD mortality risk (HR 1.33, 95% CI 1.18 - 1.49). Subgroup analyses revealed that the inconsistent LPA pattern was not statistically significantly associated with either cancer or CVD mortality in the UKB cohort. In the third sensitivity analysis, we used the prepandemic dataset for external validation. The results showed that the Brier score of our model for predicting 5-year mortality was 2.0% (95% CI 1.8% - 2.3%), and the AUC was 78.1% (95% CI 75.3% - 80.8%). In addition, both the overall and subgroup analyses indicated no statistically significant associations between the inconsistent LPA pattern and all-cause mortality. The results of the fourth sensitivity analysis were consistent with those of the primary analysis.

Discussion

Principal Findings

On the basis of the analysis of 2 temporally and geographically distinct cohorts, we found that patients' individual characteristics modified the benefit of PA patterns on all-cause mortality. Our findings in recognition of the best potential PA pattern revealed that up to 67.6% of patients with high BP were advised to engage in over 150 minutes of MVPA per week (37.2% for active regular and 30.4% for active WW). However, we also found that only 31.8% of them were actually with the predicted optimal PA pattern. In other words, according to the prediction model, a significant portion of the participants may not follow the most suitable PA pattern based on their underlying personal characteristics. Moreover, we found that the risk of death was significantly lower when current PA patterns were consistent with the predicted optimal patterns. This suggests the urgent need to implement standardized, individualized, and evidence-based PA pattern recommendations for patients with hypertension to enhance their prognosis.

Our subgroup analysis of the nonbaseline participants revealed no statistically significant associations between the inconsistent LPA pattern and all-cause mortality. As the subgroup with an inconsistent LPA pattern among nonbaseline participants was predominantly engaged in MVPA, this null finding suggests that increasing PA intensity and volume beyond the predicted levels may not offer additional benefits. Therefore, identifying such subgroups may be important, as simple goals could increase patients' confidence [32] and adherence [33] to PA engagement. However, while our study strongly supports the importance of

meeting the minimum PA intensity threshold, evidence on the potential harm of excessive exercise beyond the predicted level remains weak. This warrants further studies with stronger causal evidence, such as randomized controlled trials [34,35].

Hypertension frequently coexists with cardiovascular disease, obesity, diabetes, or cognitive decline, particularly among older adults [36-39]. These comorbidities complicate PA management in hypertensive patients due to two key challenges: (1) older people with comorbidities tend to have limited physical ability to engage in MVPA [40] and (2) VPA may attenuate PA's cardiovascular benefits by inducing adverse cardiac remodeling in vulnerable individuals [41-43]. Consequently, PA regimens should be tailored to individual physical conditions, and our model provides insights to guide this personalization. For instance, the identified interaction terms reveal that the associations between specific PA patterns and mortality differ by comorbidity. Specifically, for patients with MI who are engaged in cardiac rehabilitation, regular MVPA may offer greater benefits [44]. Hypertensive individuals with diabetes may benefit more from light-intensity PA, as excessive exercise could lead to hypoglycemia [45]. Additionally, participants with a stroke comorbidity are more likely to benefit from a lower level of PA due to the physical limitations and health risks associated with stroke recovery. Light-intensity PA offers a safer, more sustainable option, promoting cardiovascular health and functional recovery without overwhelming the individual [46,47]. However, for high-comorbidity groups, the model-predicted optimal pattern may serve as a prognostic marker rather than a prescriptive target for exercise limitation due to potential unmeasured confounders.

Advances in artificial intelligence have the potential to make personalized health advice more accessible and affordable for a broader range of individuals [48,49]. The model derived and online application proposed in this study could simulate various prognostic scenarios under different PA patterns for adults with hypertension and help patients choose the individualized PA pattern. Importantly, our algorithm can be integrated into current practices that rely on in-person assessments and regular follow-ups, as a support but not as a replacement for the physicians' professionalism and experience [50].

Study Limitations

This study also has several limitations. First, PA patterns were assessed at baseline using a short-term (7 d) estimate, whereas the median follow-up was 9.5 years for UKB and 14.3 years for NHANES. This may not accurately reflect typical PA patterns over time. Additionally, our predictive model assumes a static PA pattern, which limits its clinical applicability. Second, although we prioritized covariate data from the repeat assessment (2012 - 2013) to align with the accelerometer measurement period (2013 - 2015), most of the covariate data were sourced from the baseline assessment (2006 - 2010). This introduces the risk of measurement error due to temporal changes in lifestyle or health status, thereby compromising the tool's real-world predictive accuracy. Third, the ML model we developed was based on the observation survey rather than a randomized controlled trial, so the capacity of our results to elucidate causal relationships is limited. Fourth, the observed association between the "inconsistent PA pattern" and higher mortality risk may be influenced by residual confounding from unmeasured health-seeking behaviors. While our sensitivity analysis results have enhanced the reliability of our conclusions, the unmeasured confounders cannot be overlooked. Fifth, the majority of participants were White, which limits the generalizability of the model and means its predictions may have limited applicability to non-White populations. Sixth, the prediction model was trained and validated using objective accelerometer data; however, the use of self-reported sedentary time as input in the web application may result in inaccurate survival predictions [51]. In addition, the reliance on objective sedentary time and the need for recent blood biochemical marker data may limit the tool's applicability to the general public and primary prevention. Finally, as the optimal PA pattern driven by small increases in survival probability may lack clinical significance, establishing an appropriate threshold should be an important focus for future research. In addition, the threshold selection of the "active LPA pattern" merits further inquiry to verify its biological and clinical significance.

Conclusions

Our study found that the optimal PA pattern was heterogeneous based on individuals' underlying characteristics, whereas only a few participants actually followed the most suitable PA pattern as we predicted. The algorithm presented herein could assist in assigning patients with high BP to the individualized PA pattern based on their specific characteristics, which can be easily accessed through an online application.

In "Combining Artificial Intelligence and Human Support in Mental Health: Digital Intervention With Comparable Effectiveness to Human-Delivered Care" [1], the authors noted one error.

Author CH-J was previously listed with no academic qualifications. His qualification has been revised to "MSc."

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Correction of: https://www.jmir.org/2025/1/e64303

(J Med Internet Res 2026;28:e88495) doi:10.2196/88495

In "Culturally Adapted Guided Internet-Based Cognitive Behavioral Therapy for Hong Kong People With Depressive Symptoms: Randomized Controlled Trial"[1], the authors noted some errors.

One sentence has been changed. In the "Measurements" section, the third sentence in the third paragraph originally appeared as follows:

> *Item scores were summed for the positive and negative subscales, with higher total scores indicating more positive and negative automatic thoughts, respectively.*

This sentence now reads:

> *Item scores were averaged for the positive and negative subscales, with higher total scores indicating more positive and negative automatic thoughts, respectively.*

The originally published Tables 2 and 4 have been revised due to typos. The new Table 2 and Table 4 that are replacing the original published versions are shown below (with changes marked in italics).

Table 2. Comparison of treatment effects between active and WLC[a] groups at post-treatment (intent-to-treat analysis).

Abstract

Artificial intelligence–generated informed consent forms for oral surgery demonstrated higher quality and better readability than conventional web-based forms, though both fell short of recommended comprehension levels.

(J Med Internet Res 2026;28:e59851) doi:10.2196/59851

KEYWORDS

oral surgical procedures; informed consent; quality control; artificial intelligence; oral surgery; consent form; AI; dental health; oral surgeon; patient care; paitent autonomy; dentistry

Introduction

Informed consent is a foundational element of ethical and legal medical care, ensuring patients understand the nature, risks, and alternatives of proposed treatments [1,2]. In oral surgery, where procedures can be complex and invasive, clear and high-quality informed consent forms (ICFs) are especially critical. However, many ICFs exceed the recommended 6th-grade reading level, limiting patient comprehension [3]. With the recent rise of artificial intelligence (AI), particularly large language models (LLMs), there is growing interest in their potential to improve patient communication [4,5]. This study aimed to assess the quality and readability of conventional, web-based oral surgery ICFs and compare them to those generated by AI-based LLMs.

Methods

Ten common oral surgery procedures were selected (ie, apicoectomy, biopsy, bone augmentation, cystectomy, dental implants, incision and drainage, local anesthesia, periodontal surgery, tooth extraction, and wisdom tooth removal). Using Google Chrome in incognito mode, 300 web-based ICFs (ie, 30 per procedure) were collected (see search strategy in Multimedia Appendix 1). In parallel, four LLMs (ChatGPT 3.5, Claude, Bard, and Bing Chat) were prompted to generate ICFs for the same procedures using standardized requests. Per every procedure and LLM, two basic and non-directive prompts were developed to minimize bias and ensure neutrality, resulting in 80 AI-generated ICFs (see Multimedia Appendix 1). Subsequently, two oral and maxillofacial surgeons screened the collected forms using predefined inclusion and exclusion criteria (see Multimedia Appendix 1).

Quality was assessed using a newly developed alteration of the well-established DISCERN instrument [6], namely the Graz Assessment Tool for Written Informed Consent Keypoints (GATWICK; see Multimedia Appendix 1). It was validated through expert review for content relevance and consistency. It includes 11 items scored on a 5-point Likert scale (total score range 11 - 55). Two oral and maxillofacial surgery residents independently rated all forms. Readability was evaluated using six established formulas (ie, Automated Readability Index, Coleman-Liau, Flesch-Kincaid, FORCAST, Gunning Fog, and Simple Measure of Gobbledygook), and an average reading grade level was calculated [7]. Statistical analyses included the Mann-Whitney *U* test, Kruskal-Wallis test, and Kendall tau-b, with significance set at $P \leq .05$.

Results

Of 380 screened documents, 213 ICFs met the inclusion criteria: 136 web-based and 77 AI-generated ones. The inter-rater reliability for GATWICK scores was excellent (intraclass correlation coefficient=0.948).

Regarding the quality, AI-generated ICFs had significantly higher total GATWICK scores compared to web-based ones (median 32.5, IQR 28-35.5 vs median 27.5, IQR 20.375-37; *P*=.007). Items related to treatment alternatives, rationale for recommended intervention, and discussion of options scored particularly higher in AI-generated forms. Web-based ICFs scored better in perioperative behavior instructions.

Considering the readability, web-based forms were significantly harder to read (median grade level 12.45, IQR 11.3-13.325) than AI-generated forms (median 10.7, IQR 10.1-12.4; *P*<.001), although neither met the recommended 6th-grade level. Readability was weakly correlated with overall quality (τ=0.132; *P*=.005).

The word count was higher for web-based forms (median 794 words, IQR 475.25-1068.75 words) than AI-generated ones (median 338 words, IQR 296-381 words; *P*<.001). Longer forms showed a weak correlation with higher quality (τ=0.270; *P*<.001).

Among LLMs, ChatGPT-powered services (ie, ChatGPT 3.5 and Claude) scored significantly higher in terms of quality. ICFs on tooth extraction scored significantly worse when compared with periodontal surgery forms. AI-generated informed consent forms performed significantly better than conventional versions, with notable differences across oral surgical procedures and among the types of LLMs used (Table 1).

Table . Quality of informed consent forms (ICFs) measured through the GATWICK (Graz Assessment Tool for Written Informed Consent Keypoints) score.

Quality	Median (IQR)	*P* value
Overall quality		.007[a]
Conventional (i.e., web-based) ICFs	27.50 (20.125-37)	
Artificial intelligence-generated ICFs	32.50 (28-36.25)	
All combined	31.00 (23-37)	
Differences by procedure		.004[b]
Apicoectomy	27.00 (21.75-34.875)	
Biopsy	30.50 (25.75-33)	
Oral bone augmentation	31.50 (25.75-37.5)	
Dental cystectomy	31.25 (23-33.875)	
Dental implants	33.25 (20.625-37.125)	
Oral incision and drainage	31.50 (23.5-39.5)	
Dental local anesthesia	28.50 (21-34.5)	
Periodontal surgery	36.50 (32.5-42)	
Tooth extraction	23.50 (20-32.75)	
Wisdom tooth removal	28.25 (20-36.875)	
Differences by large language model		<.001[b]
ChatGPT	34.25 (33-37)	
Claude	40.50 (35-43)	
Bing Chat	30.00 (27.25-31.75)	
Google Bard	26.50 (22.75-31.375)	

[a]Mann-Whitney *U* test.

[b]Kruskal-Wallis test.

Discussion

Principal Findings

This study found that conventional oral surgery ICFs available online are generally of modest quality and exceed recommended reading levels. AI-generated ICFs outperformed web-based ones in both quality and readability, although they too fell short of ideal readability standards.

These findings are consistent with prior research across medical disciplines, which show that most ICFs are written at a level too advanced for the average patient [8,9]. Notably, AI-generated forms more consistently addressed key informed consent components such as treatment alternatives and rationale, suggesting that LLMs may serve as valuable tools in drafting patient-centered documents. However, AI models may also produce inaccuracies or omit procedure-specific nuances, highlighting the need for expert review [10].

The limitations of this study include its focus on English-language materials and the variability inherent in AI outputs depending on prompt phrasing or model version. While

the GATWICK tool demonstrated strong reliability, further validation is needed.

Conclusion

AI-based LLMs offer a promising avenue for improving the quality and accessibility of oral surgery informed consent documents. Future efforts should focus on refining AI outputs and integrating clinician oversight to ensure accuracy, comprehensiveness, and patient comprehension.

Abstract

Inflation-adjusted funding for artificial intelligence and machine learning research increased by 233% between fiscal year 2019 and 2023, outpacing the overall National Institutes of Health's budget increase of 12%.

(J Med Internet Res 2026;28:e84861) doi:10.2196/84861

KEYWORDS

artificial intelligence; AI; machine learning; ML; National Institutes of Health; NIH; research funding

Introduction

Artificial intelligence (AI) and machine learning (ML) technologies have begun to revolutionize the practice of medicine. Recent studies have shown that 2 in 3 physicians currently use AI in their clinical practice and more than 3 in 4 scientists currently use AI in their research [1]. Recognizing the growing importance of AI tools, the National Institutes of Health (NIH) began tracking AI and ML as its own funding category in fiscal year (FY) 2019. While previous studies have broadly assessed NIH funding trends for AI and ML research, no studies report data more recently than 2020 [2,3]. Moreover, little is known about the principal investigators (PIs) driving this research. In this study, we aimed to examine trends in NIH-funded AI and ML research and characterize the population of funded PIs.

Methods

We conducted a cross-sectional study of NIH RePORTER (Research Portfolio Online Reporting Tools Expenditures and Results) data between October 1, 2018, and September 30, 2023. We extracted studies indexed under the "Machine Learning and Artificial Intelligence" funding category and collected data on funding institute, mechanism, and award amount (in US $). We also selected a random sample of approximately 25% of PIs who were awarded grants, and we conducted an internet search to collect data on educational background (eg, MD), research setting (eg, academic), and clinical specialty (as appropriate). We searched official websites (eg, university), LinkedIn, or publicly available curriculum vitae. To account for potential differences in educational background (eg, PhD) and clinical specialty (eg, internal medicine) among PIs funded by different institutes, we balanced our random sampling according to the original institute-level proportions of funded grants. Three authors (JM, JPL, and JSF) conducted the search. CIs for proportions were calculated using the Wald method. Tests of trend were conducted using Poisson and linear regression, as appropriate. Analyses were performed using Stata/SE (version 17.0; StataCorp LLC).

Results

Total active projects (including multiyear grants) increased from 1229 to 3449 and total funding increased nominally from US $0.6 billion to $2.3 billion between NIH FY 2019 and 2023 (Figure 1).

There were 5418 unique projects from 4365 unique researchers. Funding trends according to NIH institute and grant mechanism are available in Figures S1 and S2 in Multimedia Appendix 1. We randomly selected approximately 25% of PIs (1091/4395) to conduct further data extraction via internet searches. Among this random sample, the most common educational background was PhD only (70%, 758/1091), followed by MD or DO only (11%, 115/1091), and MD or PhD (9%, 93/1091) (Table S1 in Multimedia Appendix 1). Individuals with only a PhD accounted for 64% of funding dollars, compared to 18% of those with a medical doctoral degree (eg, MD or DO) but no PhD, and 11%

for those with a clinical or professional degree (RN, MD, or PharmD) and a PhD. There were 251/1091 (23%) PIs who held medical doctoral degrees (MD or DO), and of these, 229 (91%, 95% CI 87%-94%) listed residency training. The proportions of total projects and funding dollars by medical specialty are available in Figure 2.

Figure 1. Overall National Institutes of Health (NIH)–funded artificial intelligence and machine learning research projects and funding (in US $) between NIH fiscal year 2019 and 2023. Plotted funding (US $) represents nominal values unadjusted for inflation. Inflation-adjusted values are presented in Table S2A and S2B in Multimedia Appendix 1.

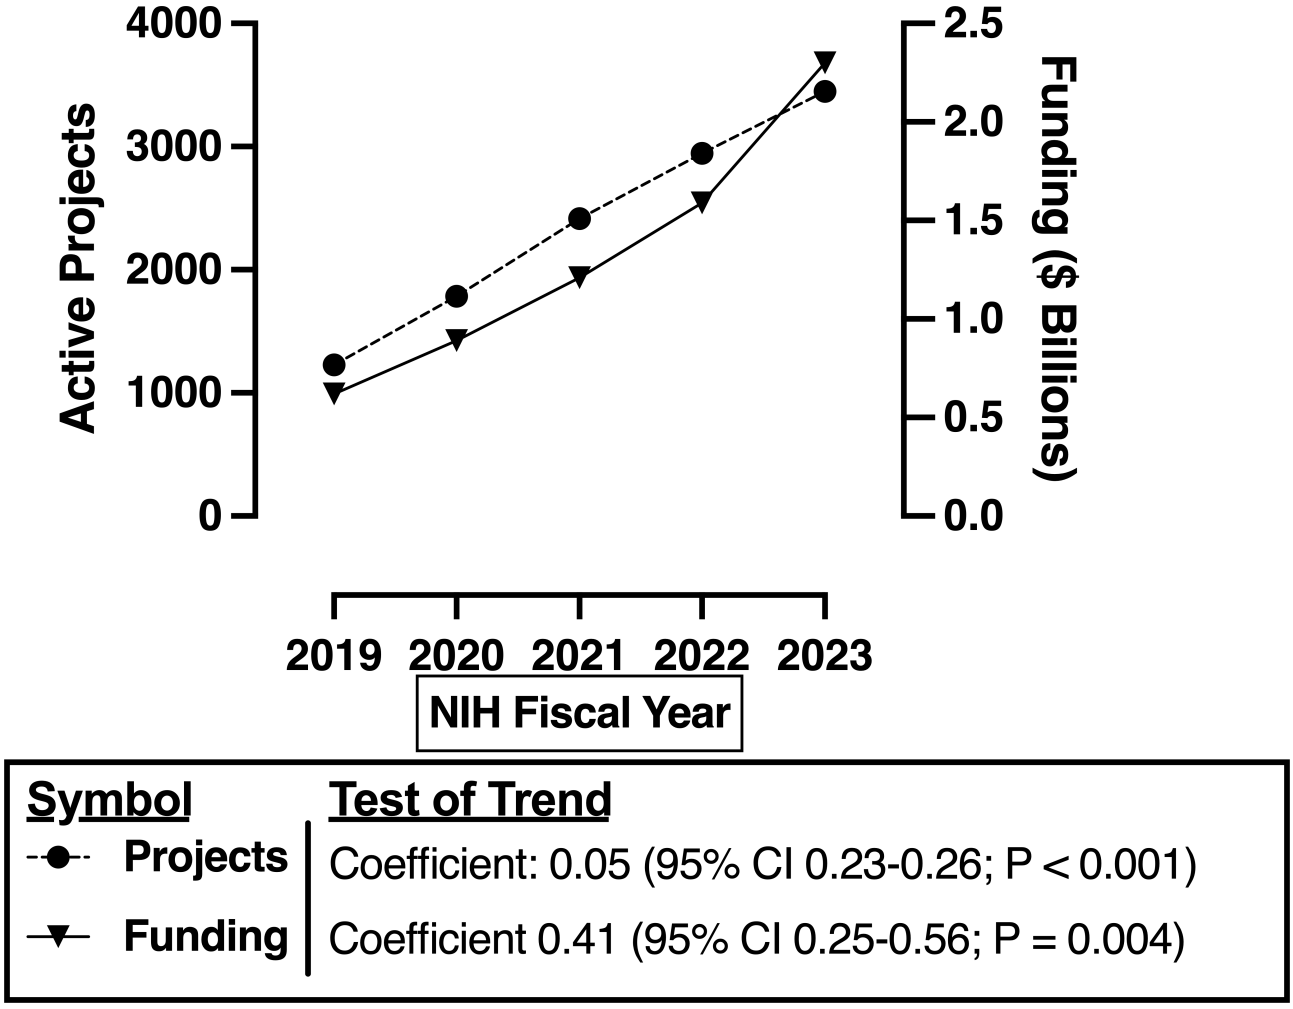

Figure 2. (A) Proportions of total funded principal investigators (PIs) and (B) total funding by specialty. Data from random sample of 1091 unique PIs with National Institutes of Health–funded projects in artificial intelligence or machine learning. CC: critical care; Gen: general; GI: gastroenterology; ID: infectious diseases; IM: internal medicine; Med: medical; Peds: pediatrics; SS, subspecialty; Surg: surgery. *Includes general surgery, urology, vascular surgery, transplant surgery, head and neck surgery, pediatric surgery, neurosurgery, obstetrics and gynecology. †Includes general pediatrics, cardiology, infectious diseases, hematology/oncology, pulmonology, endocrinology, neonatology. ‡Includes endocrinology, rheumatology, nephrology, hematology/oncology. §Includes emergency medicine, anesthesiology, pediatric emergency medicine, dermatology, and PIs with more than one specialty.

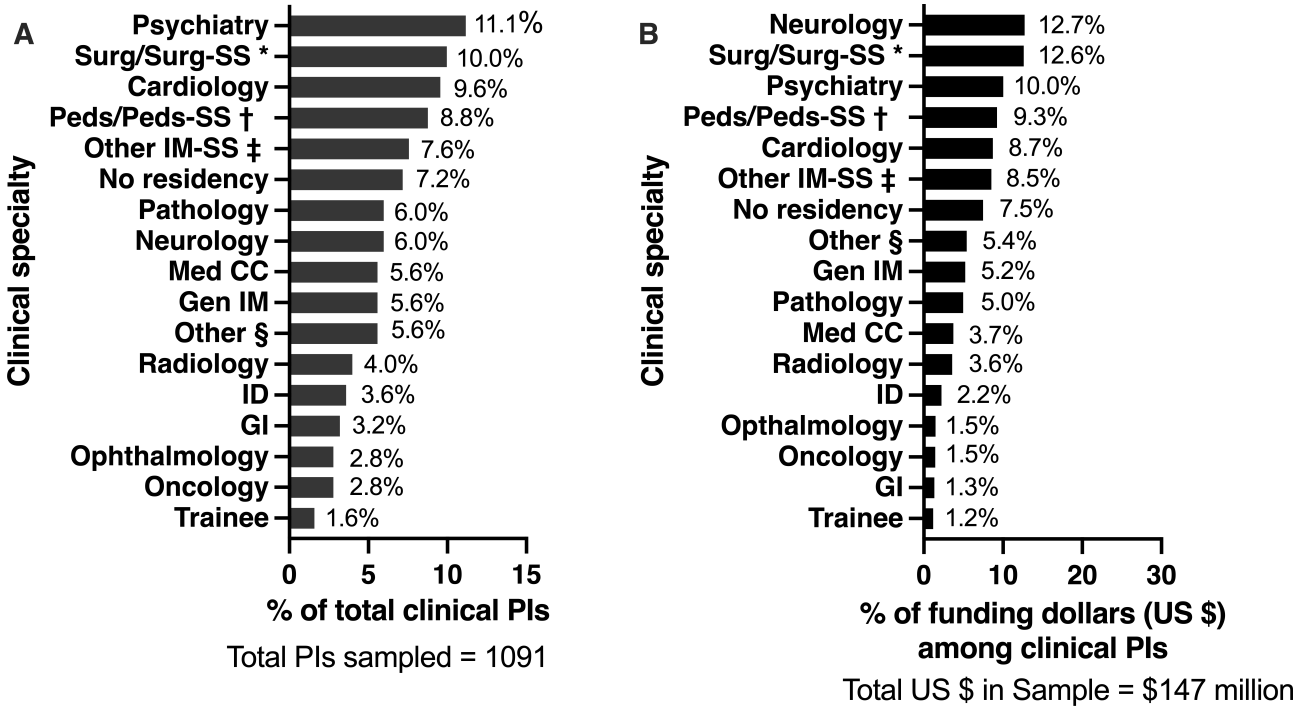

Discussion

In 2017, which was before the NIH began tracking AI and ML as its own spending category, one study found that the NIH supported 535 projects totaling US $264 million, representing approximately 0.7% of the total NIH budget (NIH budget FY 2017; $34.301 billion) [2,4]. Our analysis of 2023 NIH RePORTER funding revealed $2.3 billion in funding (including direct, indirect, and supplemental costs) in this spending category, representing approximately 4.7% of the total NIH budget (NIH budget FY 2023; $49.2 billion) [4]. While the NIH budget increased by 12% (adjusted for inflation) between 2019 and 2023, funding for AI and ML research increased by 233% (adjusted for inflation) over this same period (Table S2A and S2B in Multimedia Appendix 1) [4].

Most AI and ML researchers held only a PhD (70%), and this group accounted for almost two-thirds of all NIH research funding dollars in the AI and ML funding category. By contrast, researchers who held a medical doctoral degree (MD or DO) and who had completed a clinical residency program were relatively underrepresented, accounting for less than 20% of funded researchers and total research dollars. In our sample of researchers who held a medical doctoral degree (MD or DO), those with training in psychiatry had the most funded projects and accounted for the third-highest proportion of funding dollars. While the list of possible applications is extensive and growing, notably, funding among specialties such as emergency medicine, anesthesiology, dermatology, ophthalmology, and various individual medical or surgical subspecialties was considerably lower. These gaps are similar to those seen across other research disciplines and represent clear targets for future NIH strategic investment [5,6].

As US federal funding priorities have been modified by the current administration and the NIH faces anticipated contraction in federal discretionary spending for FY 2026, our findings come at a critical moment [4,7]. Indeed, a recent study demonstrated the potential “ripple effects” of NIH funding cuts, including delays in innovation, workforce attrition, loss of talent to universities and corporations overseas, and increased long-term health care costs [8]. These proposed changes are likely to substantially weaken the United States’ contributions to this critical emerging field.

Our analysis included PIs, but data on coinvestigators were not captured. Data related to PI education and training background were obtained from publicly available online sources, which may have been incomplete or outdated at the time of collection. PIs with multiple specialties may have been misclassified. Our spending estimates are higher than those published by the NIH because we aggregated all funding (eg, direct costs, indirect costs, subprojects, and supplemental costs); we believe this methodology provides a more complete view of total research funding [9]. While our random sample of PIs was balanced according to institute-specific proportions, we cannot exclude the possibility of sampling bias. Lastly, the study period overlaps with the COVID-19 pandemic, which may confound funding trends during this time.

In summary, we found that total NIH projects and funding dollars increased substantially between 2019 and 2023. As the US government has enacted substantial NIH budget cuts for FY

2026, future studies are needed to examine the impact of current fiscal policy on future NIH-funded AI and ML research.

Abstract

This study uses keyword filtering, a transformer-based algorithm, and inductive content coding to identify and characterize cannabis adverse experiences as discussed on the social media platform Reddit and reports a total of 1177 self-reported adverse experiences requiring medical attention.

(J Med Internet Res 2026;28:e82661) doi:10.2196/82661

KEYWORDS

cannabis; adverse events; reddit; machine learning, topic modeling

Introduction

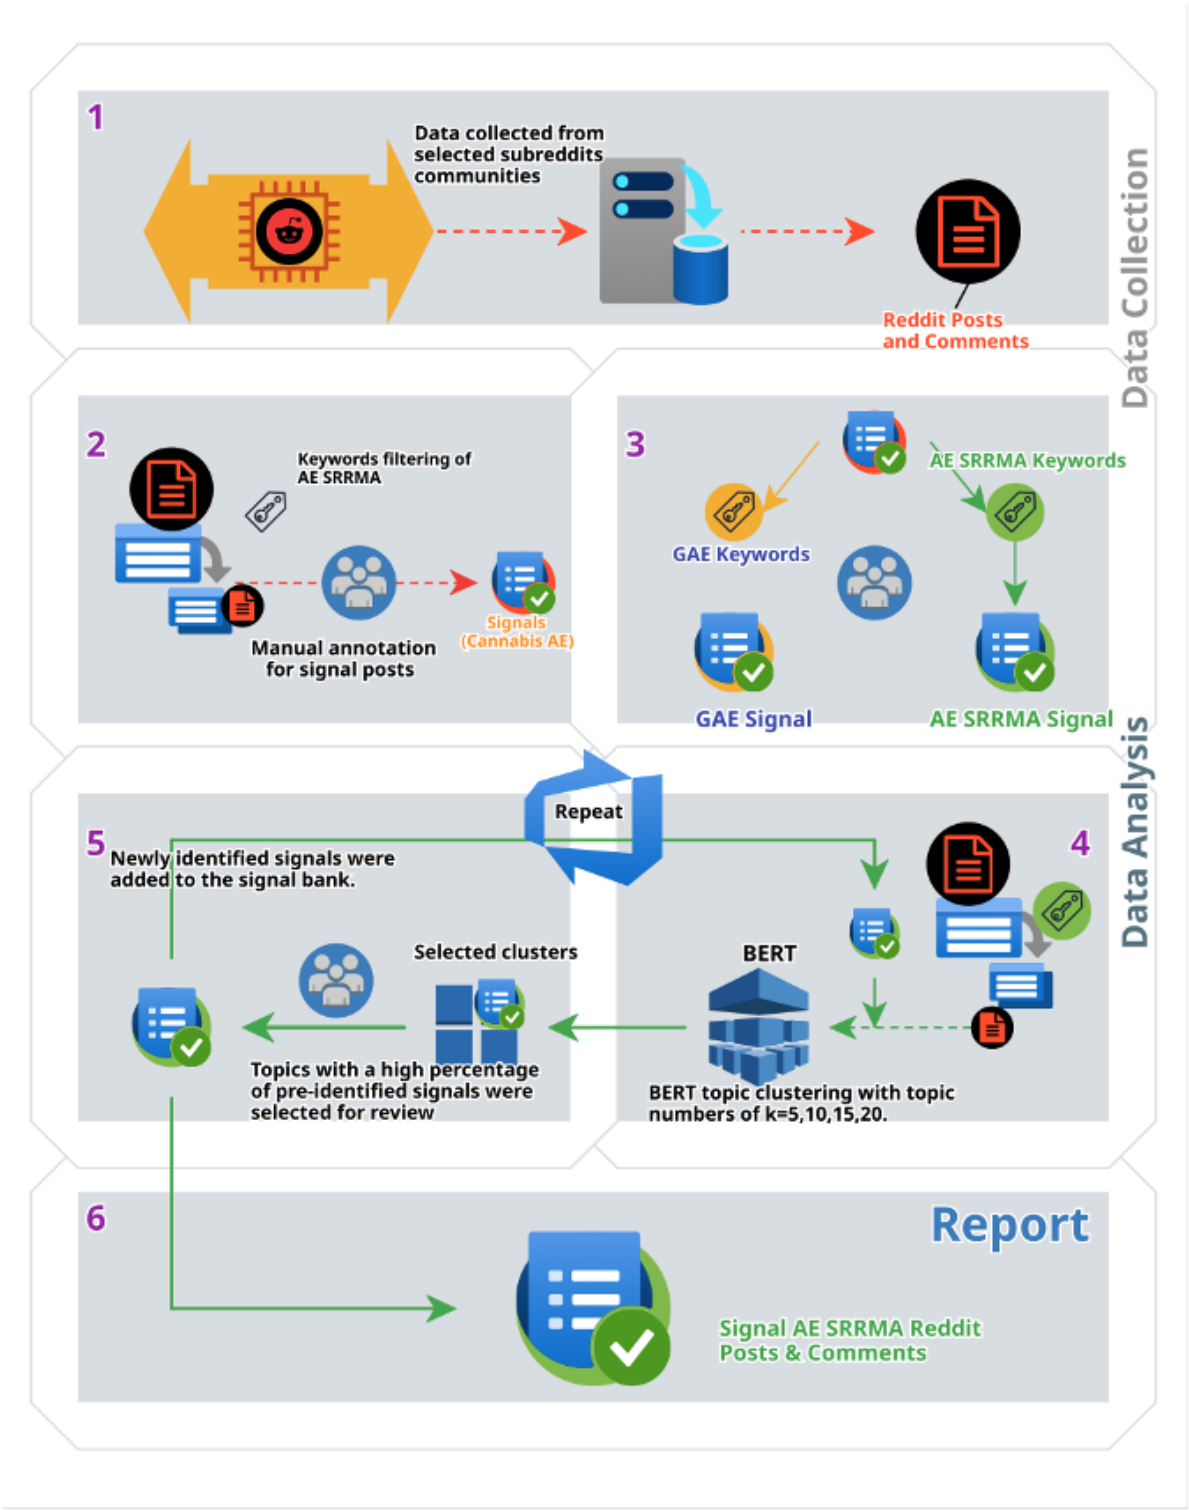
Cannabis is one of the most frequently used intoxicating substances in the United States [1]. Changing policies and attitudes have increased cannabis use, yet safety profiles for different cannabis-derived products (CDPs) (eg, products containing tetrahydrocannabinols, cannabidiol, or cannabinoids derived from cannabis) are not well understood. Studies have examined internet and social media data for health concerns among cannabis users, including for adverse health outcomes [2-8]. However, no study has specifically characterized the types of adverse experiences requiring medical attention, as self-reported online. We aimed to use a transformer-based algorithm to identify and characterize adverse experiences self-reported as requiring medical attention (SRRMA) on Reddit.

Methods

For this observational retrospective study, we collected user-generated posts and comments from 27 subreddits(/r/) related to cannabis use (Figure 1; Multimedia Appendix 1). A set of keywords for adverse experiences SRRMA was used for data mining and manual coding to generate a sample of “signal” Reddit data (ie, posts about cannabis product adverse experiences requiring medical attention: hospitalization, or visiting a health care professional, emergency room, or urgent

care). This initial sample of SRMMA prelabeled “signal” was joined with data from the full Reddit data corpus.

Figure 1. Summary of the study methodology, including data collection, data processing/filtering, BERT (bidirectional encoder representations from transformers) analysis, and results (signal data): (1) data collection for cannabis-related subreddits (both posts and comments); (2) keyword filtering for adverse experience self-reported as requiring medical attention (AE SRRMA)-related signals; (3) separation of sample of “signals” for general adverse experiences (GAE) self-reported as not requiring medical attention and AE SRRMA; (4) use of BERT topic model (k=5, 10, 15, 20) after data filtering with a sample of AE SRRMA keywords and labeled AE SRRMA data joined with the unlabeled dataset to analyze the full corpus of Reddit posts and comments; (5) selection of BERT topic clusters with the highest yield of prelabeled signals for AE SRRMA that were manually annotated to identify additional AE SRRMA signals (process repeated to achieve higher thematic saturation); newly identified signals were joined with the unlabeled dataset for the next round of BERT topic modeling; and (6) AE SRRMA signal identification from Reddit posts and comments summarized in this publication.



Natural language processing was applied to cluster Reddit posts and comments for further manual annotation. We used the bidirectional encoder representations from transformers (BERT) topic model with the Python (version 3.7) package BERTopic (version 0.6.0), which is a pretrained, self-supervised transformer-based algorithm that embeds texts, extracts topics, and then clusters texts.

BERT was used to cluster groups of nonlabeled data with SRRMA prelabeled signal data into k topic clusters, where the value of k is determined according to the dataset size ($5 \leq k \geq 20$). In each generated cluster, we calculated the percentages of SRRMA prelabeled signal data in that topic cluster to estimate how well that cluster was related to our SRRMA prelabeled data (% of potential SRRMA prelabeled signal data in a cluster that could be appended to the SRRMA prelabeled dataset = amount of SRRMA prelabeled training signal data in a cluster/amount of total data in a cluster). The higher the percentage, the more likely the uncoded data were related to our SRRMA prelabeled topic. Cluster selection was determined based on the highest percentages. The new signals were then added to our coded signal pool for the next iteration of BERT modeling: we filtered the uncoded dataset with the keywords repeatedly, combined the filtered uncoded data with all prelabeled signal data, and then performed the next iteration of BERT to find the best clusters to manually annotate for identifying additional signals. Posts and comments from these clusters were extracted, and an inductive coding approach was used to label and characterize cannabis-related adverse experiences and adverse experiences that met the SRRMA criteria. Human ethics and consent to participate were not applicable, as all information was from the public domain and did not involve user interaction, and any identifiable information was aggregated and removed from the results.

Results

We collected 1,795,478 Reddit posts/comments. After BERT and coding, 1177 posts/comments comprising 1542 user-generated mentions of SRRMA adverse experiences for cannabis products were detected between July 2017 and December 2022 (Table 1). Coders (TKM, MN, MZ) achieved a high intercoder reliability score (κ=0.90). From the 27 subreddits, the top 10 SRRMA adverse experiences were vomiting (284/1542, 18.42%), nausea (171/1542, 11.09%), panic attack (122/1542, 7.91%), abdominal/stomach pain (96/1542, 6.23%), concern over elevated heart rate (92/1542, 5.97%), anxiety (60/1542, 3.89%), chest pain (53/1542, 3.44%), general complaints of sickness (31/1542, 2.01%), symptoms attributed to Cannabinoid Hyperemesis Syndrome (30/1542, 1.95%), and paranoia (30/1542, 1.95%). Additionally, 108 (9.18%) SRRMAs mentioned a CDP but not a specific adverse experience. SRRMA adverse experiences included users self-reporting seeking medical attention with visits/admissions to hospitals (533/1177, 45.28%), emergency rooms (569/1177, 48.34%), health care professionals (70/1177, 5.95%), and urgent care (5/1177, 0.43%).

For cannabis product use characteristics with an SRRMA, most (988/1177, 83.94%) were inhalation (eg, inhaler, joint, vape) followed by ingestion (59/1177, 5.01%; eg, edibles) products. For users reporting intent of use (ie, post and comment), 94.65% (1114/1177) were adult use (ie, recreational), followed by 3.57% (42/1177) therapeutic (ie, for health benefit), 1.02% (12/1177) unknown, 0.42% (5/1177) medical (ie, from a medical dispensary), and 0.34% (4/1177) unintentional use. A subset of users reported co-use with other substances, specifically tobacco and nicotine products (n=7), prescription medications (eg, alprazolam, antidepressants, n=22), illicit drugs (eg, lysergic acid diethylamide, cocaine, n=5), and dual use with other cannabinoids (eg, general tetrahydrocannabinol use, cannabidiol, delta 8, n=12).

Table 1. Characteristics of adverse experiences self-reported as requiring medical attention, posted online on Reddit between July 2017 and December 2022.

Post and comment type/intent of use	Adverse Experiences Self-Reported as Requiring Medical Attention (AE SRRMA)[a]				
	Hospitalization (n=533), n	Health care professional visit (n=70), n	Emergency room visit (n=569), n	Urgent care (n=5), n	Proportion of platform AE SRRMA posts (N=1177), n (%)
Medical	1	0	4	0	5 (0.42)
Recreational	513	66	530	5	1114 (94.65)
Therapeutic	15	4	23	0	42 (3.57)
Unintended	0	0	4	0	4 (0.34)
Unknown	4	0	8	0	12 (1.02)

[a]AE SRRMA indicates that a cannabis user sought medical care because of a concern that their symptom or symptoms were serious or potentially life-threatening. Intent of use categories included medical (user mentions acquiring a product from a medical dispensary); recreational (user mentions using a cannabis product, price, or acquisition, in the context of a recreational or social event or circumstance); therapeutic (user mentions using a cannabis product for medical reasons); unknown (could not be determined based on data that was available); and unintended (user mentions using a cannabis-derived product accidentally or unintentionally).

Discussion

We identified 1177 Reddit user-generated posts that described CDP SRMMA adverse experiences. Results are similar to those of a study analyzing 28,630 cannabis exposures/cases reported to state poison control centers from 2017 to 2019 that found CDP concentrates, vaporized liquids, and edibles documented with “moderate or greater” medical outcomes (ie, effects usually requiring a form of medical treatment) [9]. Studies using transformer-based and large language models also found similar reports of adverse experiences by Reddit users but only coded for generalized adverse health outcomes [7] or only reviewed a single subreddit (r/delta8) [8,9]. Our study builds on the methodology of these prior studies by using a transformer-based algorithm “seeded” with prelabeled signal data to find additional unlabeled data—an approach similar to a few-shot learning approach but without formal model training.

Study limitations include terms not inclusive of all cannabis safety-related experiences and lack of cross-validation of users’ self-reports (eg, lack of validation with clinical data). Further, social media data are not representative of all cannabis use behavior, and what cannabis products may have led to adverse experiences (eg, contaminated/adulterated products or products not from licensed dispensaries) were unclear (eg, we observed more Reddit discussions on adult-use cannabis [ie, recreational] than on medical cannabis use, which may limit generalizability). Though exploratory, study results may be used in conjunction with other cannabis-related adverse experience surveillance data (eg, National Poison Data System and FDA MedWatch [6]) and can provide important context to adverse experiences that result in medical attention for purposes of helping consumers and clinicians better understand potential cannabis risks.

Acknowledgments

Generative artificial intelligence was not used for any portion of this manuscript in its writing, editing, or generation.

Funding

This research was supported by the Food and Drug Administration (FDA) of the US Department of Health and Human Services (HHS) as part of a contractual award (contract 75F40123C00030) totaling US $174,971.73, with 100% funded by FDA/HHS. The contents are those of the author(s) and do not necessarily represent the official views of, nor an endorsement, by FDA/HHS or the US government.

Abstract

Background: Frailty constitutes a growing challenge for health and social care systems around the world. In England, 35% of adults aged 65 years and older live with frailty, with international estimates indicating that almost half of all hospital inpatients within the same age group are frail. This population often experiences multimorbidity and frequent care transitions. Written documentation and verbal handovers may lack the precision and nuance required to understand an older adult's presentation and support needs. Video recordings of individual patients, capturing aspects of their functional abilities and condition, may help to enhance multidisciplinary team communication and care continuity, yet little is known about their use in the care of older inpatients with frailty.

Objective: We aimed to evaluate the acceptability, feasibility of implementation, and perceived effectiveness of video-based patient records (the Isla Health Digital Pathway Platform) for supporting the assessment and care of older inpatients with frailty within the acute hospital setting.

Methods: A nonrandomized mixed methods pilot study was conducted within 3 acute medicine wards for older adults. The video-based patient records intervention, permitting videos to be embedded securely within the electronic patient record, was implemented over a 3-month period alongside usual care. Patient enrollment and retention figures; qualitative interviews with patients, carers, and clinical staff; and video capture and view metrics were used to address the study objectives. The Theoretical Framework of Acceptability of Healthcare Interventions was applied to the framework analysis of interview data, capturing concepts such as intervention ethicality, burden, and coherence. Patient and public involvement and engagement informed each research stage.

Results: Twenty-nine patients were enrolled (56.9%); 1 patient withdrew before receiving the intervention. Modal reasons given by patients for nonparticipation included not wanting to take part in research (n=8) or feeling too unwell (n=2). Staff identified multiple opportunities for capturing patient videos, including documentation of mobility assessments or seizures. The intervention was considered acceptable on the grounds that safeguards were always in place, including secure data storage and upholding of patient dignity. Implementation barriers and facilitators were identified; factors such as difficulties in capturing videos within busy ward environments and scheduling issues were voiced by participants. Video view metrics and data from interviews collectively suggested low rates of engagement with videos by clinical staff once captured. Potential intervention impacts included perceived enhancements to clinical assessment and person-centered care.

Conclusions: Our findings suggest that the intervention is largely acceptable to patients, carers, and clinical staff. Conclusions as to intervention feasibility were mixed, with limited engagement with videos suggesting further work is required to promote sufficient uptake among staff. Finally, this research presents promising patient, carer, and clinical opinion as to the potential effectiveness of video-based patient records for improving aspects of patient care.

KEYWORDS

frailty; video recording; digital health; patient safety; quality of care

Introduction

Background

Frailty can be understood as impairment in a person's ability to recover following an injury or illness [1]. It is commonly characterized by exhaustion upon low energy expenditure, diminished muscle strength, and unplanned weight loss [2], and represents a pertinent challenge for health and social care systems globally in the context of population aging [3]. Over one-third (35%) of adults in England aged ≥65 years are thought to live with frailty [4], with a synthesis of international literature indicating a pooled prevalence rate of 47% for frailty among hospital inpatients in the same age group [5].

Older adults with frailty typically have complex care needs, experience multimorbidity, and require input from several care providers spanning multiple, fragmented health and social care organizations [6,7]. Evidence suggests that such patients are particularly vulnerable to experiencing shortfalls in safety and quality of care, owing to poor care continuity [8,9]. This can contribute to avoidable deconditioning in older adults [10], who may struggle to return to their usual activities and routines upon discharge from the hospital to community-based care.

The World Health Organization acknowledges the inherent risks to patient safety at transitions of care, where treatment delays, duplication of tests, and increased rates of adverse events are among identified challenges [11]. Frequent transitions between health and social care settings are commonplace in the care of frail older people [9]. Therefore, effective communication within and between services involved in the care of these patients is imperative [12]; providers require timely access to comprehensive, accurate, and up-to-date information about a person's presentation, in a format that readily supports meaningful interpretation [13].

Written documentation and verbal handovers vary in quality and may fail to convey the complexities of an older adult's condition, including functional capabilities and support needs. A growing body of literature suggests that the use of digital multimedia, such as photographs and videos, may help to enhance communication in patient care. A Cochrane review indicated that transmission of digital images between care providers may reduce time to commence treatment once a patient has presented to a service [14]. Moreover, a scoping review reported on the value of patient-generated photos and videos in helping professionals to obtain a more holistic understanding of patients, supporting diagnostic processes and monitoring of treatment outcomes, for example, documenting the healing of postoperative wounds [15]. Our recent systematic review synthesized empirical research evidence and professional and regulatory guidance on video recording patients for direct care purposes [16]. Review findings suggest that video recording patients to support care delivery is largely acceptable to patients, where privacy and data security risks are suitably mitigated [16].

Video recordings may support improvements in the safety and quality of care for older adults with frailty, in providing detailed visual information about a patient's functional presentation, support needs, and care preferences. Nevertheless, ethical considerations warrant detailed examination prior to the routine use of video recordings within patient care [16]. Previously, a lack of secure and efficient ways to acquire, store, and share photographs and videos may in part explain why multimedia data have not been fully exploited in health care. Further research is required to explore the acceptability, feasibility, and potential value of video recordings that are securely embedded within the electronic patient record (EPR) for use in the care of older people living with frailty.

Objectives

The primary objective of this study was (1) to determine the acceptability of using video recordings to capture the functional abilities, support needs, and preferences of older inpatients with frailty, to support clinical assessment and care delivery. Secondary objectives were (2) to explore the feasibility of implementing video-based patient records (the Isla Health Digital Pathway Platform) within the acute medical ward setting for older adults, and (3) to appraise the perceived effectiveness of patient videos for supporting care in this context. Study findings will be used to inform the decision-making about progression to a definitive trial, examining the effectiveness of patient video recordings for improving the quality and safety of care transitions.

Methods

Design

This study comprised a single-center, nonrandomized, mixed methods pilot study with an embedded process evaluation (ClinicalTrials.gov ID: NCT06504641) to inform decision-making about progression to a definitive trial to evaluate clinical impact. Where applicable, in line with guidance for nonrandomized pilot and feasibility research [17], the study reporting adheres to the CONSORT (Consolidated Standards of Reporting Trials) extension to pilot and feasibility trials [18], with intervention description informed by the Template for Intervention Description and Replication (TIDieR) guidelines [19].

Setting and Participants

Participants were recruited from 3 acute medical wards for older adults within a large acute National Health Service (NHS) Trust in London, United Kingdom. We aimed to recruit 30 patient-carer dyads and 35 clinical staff members from the

wards, according to the eligibility criteria defined in Table 1. Carers consisted of family members or friends who provided the patient with unpaid, informal care. Our sampling approach was designed to permit appraisal of acceptability and feasibility in principle, through a pragmatic yet purposively diverse sample of patients, carers, and ward staff.

Table . Overview of study eligibility criteria for the nonrandomized mixed methods pilot study involving older adult inpatients with frailty.[a]

Participants	Inclusion criteria	Exclusion criteria
Patients	• Inpatient within acute medical wards for older adults during the 3-month intervention pilot phase • Aged >65 years old • Assessed as frail or prefrail by the direct care team • Capacity to consent to participate OR lacked capacity to consent and a "personal consultee" was available to advise on patient's likely wishes about participating	• Lacked capacity to consent AND a "personal consultee" was not available to advise on the patients' likely wishes about participating
Carers	• Aged >18 years old • Provided unpaid assistance to the patient for daily activities	• Carers were excluded if the patient declined study participation
Ward staff	• Clinical staff working on 1 of 3 participating acute medical wards for older adults • Working regular shifts during the study initiation and 3-month pilot phases	• Ad hoc bank or agency staff members • Permanent staff members who are on long-term leave (eg, sickness and parental leave) during the 3-month pilot phase.

[a]Carers included family members and friends who provided the patient with unpaid, informal care.

Intervention

The Isla for Frailty intervention provided a video-based patient record function via the web-based Isla Health Digital Pathway Platform, which interfaces with EPR systems such as Cerner. Isla Health is a technology company delivering a digital pathway platform for health care staff to support patients throughout their care journey. One of its features is a visual patient record, which enables health care staff to securely capture and review videos as part of a patient's care. Video data are securely stored within encrypted cloud storage; health care staff can view these data within the EPR system, or directly via the Isla platform, using a secure weblink requiring the user's NHS email address and password. To capture visual data using the Isla platform, the user must be logged in on a mobile device (eg, smartphone and tablet) with an in-built camera and Wi-Fi connection. The Isla Health Digital Pathway Platform is approved by NHS Digital and satisfies NHS data security and protection requirements. Wards were supplied with a designated tablet device to use for video capture.

Video recordings were captured to document aspects of a participating patient's condition or functional ability considered by the direct care team as potentially useful in supporting clinical decision-making, care continuity, or multidisciplinary team (MDT) communication within the patient care journey. For example, videos might be used to capture a patient's mobility and transfers, behavior, or patient preferences. Personal care or toileting was not recorded. Patient videos were viewable by the direct care team during the patient's ward stay. Ward staff were encouraged to view and use videos in a way they felt was useful for supporting patient care, such as to support communication during shift handovers, to inform discharge planning, or in discussions with family members. The study protocol did not dictate when videos should be reviewed; therefore, the study examined the real-world use of patient videos within the acute older adult ward setting.

Participating staff had completed prior mandatory training in Data Security Awareness and were also trained in using the intervention prior to the 3-month pilot. Training emphasized the need to confirm participating patients' consent prior to video capture and to stop recording if a patient showed any signs of distress (verbal or nonverbal) or if another patient entered the shot. Staff were advised to protect patient dignity, ensuring patients were appropriately dressed and drawing curtains around the bed space where required. Contact details for the study clinical lead were shared with all participating staff who wished to discuss any questions or concerns.

Recruitment

Enrollment of Ward Staff

We engaged with staff working on the acute medical wards for older adults over a 2-month period (February 12-April 13, 2024) directly preceding the 3-month pilot phase for the video-based patient record intervention, inviting them to take part in the study. All clinical staff working on the 3 pilot wards received written and verbal information about the study aims, the intervention purpose, permitted uses of the video recordings, and information governance procedures. Staff were reassured that they could take part but opt not to be involved in video recording patients or appearing in patient videos themselves. They were also informed that they could choose not to participate in the evaluation of the video recording intervention, or to decline participation altogether without giving a reason. Staff who wished to take part were given opportunities to ask questions prior to providing their written informed consent.

Enrollment of Patients With Capacity to Consent

Patient screening and enrollment procedures are displayed in Multimedia Appendix 1. Over the 3-month intervention pilot phase (April 15-July 14, 2024), potential participants (inpatients on the 3 participating wards and their carers) were screened for eligibility by the direct care team, who explained the study purpose and provided patients and carers with participant information sheets. The direct care team flagged all potential participants to the researchers. Once the patient was clinically stable, a member of the research team visited the patient on the ward to confirm eligibility and complete enrollment procedures. Patients were offered opportunities to ask questions about the study and asked whether they might be interested in participating. Where required, easy-read participant information sheets were used to support patient understanding about what taking part would involve. Potential participants were offered additional time to decide whether they wished to take part. Where the direct care team reported concerns that a patient may lack capacity to consent to participation, the study team assessed and documented decision-specific capacity, considering whether the patient could understand what participation would involve, retain the study information, weigh this information to make a decision, and communicate their decision.

After consideration, patients who wished to participate and who had the capacity to consent were asked to sign a version of the consent form for patients with capacity. Patients were reassured that they could withdraw at any time. Within the consent process, patients were asked to consider whether they would like to remain in the study, should they lose capacity during the study period (eg, due to delirium onset). Patients were also asked whether they would still like their data to be used in the study. Participant information sheets contained a clear statement regarding retention and use of identifiable data following loss of capacity. Continued participation for such patients was subject to the same protocols for enrolling patients lacking capacity to consent, as detailed in the next section. During the study, the capacity of participants was monitored by the direct care team; the clinical lead communicated with the research team regularly about capacity concerns.

Enrollment of Patients Lacking Capacity to Consent

For patients assessed to lack the capacity to consent to participate, the research team still provided the potential participant with information about the study according to their level of understanding, using visual aids as needed (eg, the easy-read participant information sheets). In line with the requirements of Section 32(3) of the Mental Capacity Act 2005 and the Department of Health's Guidance on nominating a consultee for research involving adults who lack capacity to consent (2008), reasonable steps were taken to identify a personal consultee for these patients [20,21]. Personal consultees were identified by the patient's direct care team and included family members and carers (unpaid), who knew the patient well and who assisted them with their daily activities (eg, decisions about their welfare). Members of the ward staff team could not be nominated as personal consultees due to their own involvement in the study. Patients were excluded where no appropriate person could act as a personal consultee.

Potential personal consultees were approached first by the direct care team, who outlined the study purpose and the role of a consultee, emphasizing their right to decline acting as a consultee for the patient. For potential personal consultees who agreed to be contacted directly by the research team, a member of the research team then provided detailed written and verbal information about the study, including the consultee participant information sheet. The consultee was asked to consider the patient's likely wishes about taking part. The research team made it clear to the consultee that they were not being asked to provide their personal views on study participation, nor to consent to the study on the patient's behalf. Recruitment decisions were made by the research team in line with the consultee's advice and any previous relevant statements or wishes communicated by the patient, whether verbal or nonverbal. Consultee advice was documented on a printed consultee declaration form or via an electronic version of the form. Where a consultee advised that the patient would not have wanted to take part, the researcher abided by this. Patients were also excluded if the consultee declined to offer advice about the patient's likely wishes.

Enrollment of Carers

Carers of participating patients were also invited to take part in the evaluation during the 3-month pilot phase. Where carers were present while a member of the research team was on the ward, they were approached by the researcher accordingly. Otherwise, a ward team member contacted carers to ascertain whether they were happy to be contacted (via email or telephone) by a member of the research team. Carers who wished to participate after reviewing the carer participant information sheet were asked to sign a consent form for carers, via a printed version of the form, or an electronic form sent to the carer via email or text message. For all patients and carers, reasons for nonparticipation were documented within a screening and enrollment log.

Data Collection

Study data sources are summarized in Table 2 and described below.

Table . Overview of outcomes, measures, and data sources for each objective of the nonrandomized mixed methods pilot study involving older adult inpatients with frailty.

Study objective, outcomes, and measures	Data source
Acceptability	
Patient recruitment and retention	
Percentage of eligible participants who were enrolled into the study	Screening and enrollment log
Percentage of eligible participants declining enrollment and reasons for nonparticipation	Screening and enrollment log
Video recording requests by care team	
Number of videos requested, attempted, and submitted	Video tracker
Suitability of patient videos	Video evaluation questionnaire
Desire to see more patient videos in the future	Video evaluation questionnaire
Perceived acceptability	
Patient and carer-reported acceptability	Semistructured interview at or within 2 weeks of discharge
Ward staff team-reported acceptability	Semistructured interview after the 3-month pilot
Feasibility	
Diversity of patient sample	
Patient clinical and demographic characteristics	Screening and enrollment log
Privacy and security concerns	
Number of videos raising cause for concern reported to the clinical lead	Video tracker
Use of the Isla Health Digital Pathway Platform	
Percentage of participants with one or more video linked to EPR[a]	Isla Health Digital Pathway Platform metadata
Reasons for unsuccessful attempts to take a video	Video tracker
Video view metrics	Isla Health Digital Pathway Platform metadata
Intervention barriers and facilitators	
Patient and carer-reported intervention barriers and facilitators	Semistructured interview after the 3-month pilot
Ward staff team-reported intervention barriers and facilitators	Semistructured interview after the 3-month pilot
Perceived effectiveness	
Perceived impacts on: assessment and clinical decision-making; multidisciplinary team communication; care continuity during a hospital stay; person-centered care during a hospital stay	
Potential usefulness of intervention to ward staff team	Video evaluation questionnaire
Ward staff team-reported perspectives on intervention impacts	Semistructured interview after the 3-month pilot
Patient and carer-reported perspectives on intervention impacts	Semistructured interview at or within 2 weeks of discharge

[a]EPR: electronic patient record.

Screening and Enrollment Log

The screening and enrollment log was used to document patient recruitment status, demographic characteristics, and, where applicable, reasons for nonparticipation. A paper version of the log was initially populated. It was then digitized at regular intervals within the 3-month intervention pilot phase and stored in Imperial College Healthcare NHS Trust's iCARE secure data environment.

Video Tracker

A video tracker spreadsheet (Microsoft Excel) was developed to document patient video requests, attempts, submissions, and any issues associated with taking the recordings. The video tracker also captured information about the aspect of a participating patient's care or functional abilities to be video recorded. For example, video foci may include a person's mobility baseline or their support needs when eating and drinking.

Video Evaluation Questionnaires

Staff experience of viewing patient videos was appraised using a brief, anonymous, paper-based video evaluation questionnaire, consisting of closed-ended, multiple-choice questions with space for free-text comments (Multimedia Appendix 2). Participating

staff were asked to complete the questionnaire for each video they viewed. At the end of the 3-month pilot, questionnaire data were digitized (Microsoft Excel) and stored securely within the iCARE secure data environment.

Interviews With Patients and Carers

Patients with the capacity to consent to participation and carers were invited to take part in brief, semistructured interviews at or within 2 weeks of hospital discharge. Consent to take part in an optional interview was provided during the enrollment phase. All patients with the capacity to participate in an interview who had not declined the optional interview component at enrollment were invited to take part as they approached hospital discharge. Likewise, all participating carers were contacted to arrange the optional interview, unless they had previously declined at enrollment. Where the direct care team or research team felt it appropriate, patient capacity was assessed again prior to undertaking the interview, due to the potential for fluctuating capacity in this group. Patients and carers were asked to verbally confirm their consent prior to starting the interview. Interviews were conducted on the ward prior to discharge, or via telephone where patients had already been discharged.

Interviews were conducted by a member of the research team (PA or RO) using a topic guide for patients and carers (Multimedia Appendix 3), seeking to understand patients' experiences of being video recorded. Researchers adapted their language to the patient's level of understanding to enable patients with cognitive impairment to participate. Patient and carer interviews were completed by August 14, 2024, reflecting the date of discharge of the final patient who was eligible to take part in an interview. Interviews were audio-recorded and professionally transcribed. Names and identifiers were replaced with pseudonyms during the transcription process. Transcripts were transferred to and stored within the iCARE secure data environment.

Interviews With Ward Staff

Semistructured interviews with consenting staff members were undertaken within 2 months of the end of the 3-month intervention pilot phase. All participating staff members were approached to take part in an interview, unless they had declined this optional study component at the point of enrollment. Interviews used a version of the topic guide for staff and explored their experiences with the video-based patient records (the Isla Health Digital Pathway Platform) and perceived impacts on patient assessment and clinical decision-making; team communication; and care delivery (Multimedia Appendix 4). Audio-recorded interviews were conducted in a private space on or near the ward, or via telephone according to interviewee preference, with the final interview taking place on October 3, 2024. Written consent for the interviews was documented at recruitment. Names and identifiers were replaced with pseudonyms during the transcription process. Transcripts were transferred to and stored within the iCARE secure data environment.

Isla Health Digital Pathway Platform Metadata

At the end of the 3-month video-based patient record pilot (the Isla Health Digital Pathway Platform), video view metrics were exported from the Isla audit log. The anonymized video view metrics spreadsheet was transferred to and stored within the iCARE secure data environment.

Outcomes

In line with study objectives, the primary outcome we sought to assess was patient, carer, and ward staff team perspectives on the acceptability of the video-based patient records (the Isla Health Digital Pathway Platform). Use of the Isla platform and intervention barriers and facilitators were among secondary outcomes measured to assess the feasibility of implementing video-based patient records within the acute medical inpatient setting for older adults. Finally, 4 outcomes, including perceived impacts on care continuity in the hospital, were appraised to examine the perceived effectiveness of video-based patient records for supporting older adult inpatient care. Outcome measures and data sources for each objective are summarized in Table 2.

Data Analysis

Using Microsoft Excel, descriptive statistics were computed to summarize numerical data as to participant recruitment and retention rates; proportions of patients with videos linked to the EPR; video view metrics; and numbers of videos raising cause for concern. Frequencies and percentages were calculated for categorical variables, with means and SDs presented for continuous variables. Framework Analysis, following the 5-step approach described by Ritchie and Spencer, was applied to qualitative study data [22]. Accordingly, following a phase of familiarization with interview transcripts and free-text video evaluation questionnaire data, key concepts and ideas were noted by 1 author (PA) and discussed iteratively with 2 further authors (RO and AT), to interrogate immediate observations and assumptions about these data. At this stage, the researcher's analytical observations were used together with the Theoretical Framework of Acceptability of Healthcare Interventions by Sekhon to shape an initial thematic framework [23], combining a priori concepts with inductively generated codes. The Theoretical Framework of Acceptability of Healthcare Interventions comprises 7 constructs for appraising intervention acceptability: affective attitude, burden, ethicality, intervention coherence, opportunity costs, perceived effectiveness, and self-efficacy. Component constructs are defined in Multimedia Appendix 5. The derived thematic framework was then applied to all transcripts by 2 authors (PA and RO), with regular collaborative coding meetings convened by coders to appraise consistency and appropriateness in use of the framework. Data were then charted into a framework matrix for review and interpretation (PA, RO, and AT).

Information Power

Adequacy of the participant sample and subsequent data collection were appraised on an ongoing basis according to the 5 dimensions of "information power" [24]. Several qualities of the study suggested that a less extensive sample would be required to achieve sufficient information power. First, our a priori study objectives were narrowly focused on the acceptability, feasibility, and perceived effectiveness of a specific intervention. Second, the study eligibility criteria

ensured dense sample specificity, where participants all held characteristics which were highly specific to study objectives (eg, patients who were older adults with frailty admitted to 1 of 3 pilot study wards, carers who were unpaid carers to enrolled patients, and ward staff who were clinical staff employed on a permanent basis on one of the pilot study wards). Third, our primary objective to examine intervention acceptability was underpinned by established theory, in the form of the Theoretical Framework of Acceptability of Healthcare Interventions by Sekhon [23]. A fourth dimension, concerning the quality of dialogue, could only be assessed during the data collection phase, rather than at the study outset. We therefore reflect on this later in the paper. Finally, since Framework Analysis approaches entail both within- and between-case analysis using the derived framework matrix, we deemed that a larger volume of data would be necessary to evaluate study objectives, relative to a solely within-case analysis.

Patient and Public Involvement and Engagement

Patient and public involvement and engagement (PPIE) was central to this research. A member of the public with lived experience of caring for an older family member with frailty joined the team as a PPIE researcher, developing a storyboard characterizing patient experiences of frailty and discontinuity at care transitions. This was used to engage ward staff members as to the potential value of the research, helping to support successful staff enrollment. Contributions to data analysis, interpretation, and coauthoring this paper ensured that the perspectives of patients and carers informed each stage of the study.

Ethical Considerations

Ethics approval was granted by an English NHS research ethics committee (IRAS ID: 313814). Informed consent was obtained from all participating carers and ward staff members via completion of paper or electronic consent forms. For patients with the capacity to consent to participation, informed consent was documented by signing a paper consent form. Personal consultees, who knew the patient well and assisted them with their daily activities, were asked to consider the patient's likely wishes about taking part for those patients assessed to lack the capacity to consent to participation. Consultee advice was documented on a printed or electronic consultee declaration form. Enrollment and consent procedures are described in detail in the "Recruitment" section. Participant names and identifiers were replaced with pseudonyms and all study data were securely stored within Imperial College Healthcare NHS Trust's iCARE secure data environment. Further details are provided within the "Data Collection" section. Research participants did not receive payments or other compensation to take part.

Results

Overview

We recruited 107 study participants, consisting of 58 ward staff team members, 29 patients, and 20 carers. Twelve carers additionally acted as a personal consultee for recruited patients. Participating staff included registered nurses and nursing assistants (36/58, 62.1%); physiotherapists, occupational therapists, and therapy assistants (9/58, 15.5%); doctors (11/58, 19.0%); and administrative staff (2/58, 3.4%). Table 3 shows the baseline characteristics for patients who were invited to participate, by enrollment status. Video evaluation questionnaires were completed by just 4 staff members who had watched one or more patient videos (2 nurses and 2 therapy professionals), owing to issues with interpreting Isla Health Digital Pathway Platform metadata, detailed below alongside feasibility findings. Postintervention interviews were conducted with 70 participants, comprising 10 patients, 16 carers, and 44 staff members and lasted between 2 and 25 minutes (mean 11, SD 4.7 minutes).

Table . Baseline characteristics of older adult inpatients with frailty who were invited to participate by enrollment status.[a]

Characteristics	Enrolled patients (n=29)	Nonenrolled patients (n=22)
Sex, n (%)		
Male	18 (62.1)	12 (54.5)
Age (years), mean (range)	82.9 (72-96)	82.2 (66-92)
Ethnicity, n (%)[b]		
White	14 (48.3)	13 (59.1)
Black, Black British, Caribbean or African	3 (10.3)	2 (9.1)
Asian or Asian British	2 (6.9)	3 (13.6)
Mixed or Multiple Ethnic Groups	0 (0)	1 (4.5)
Other	8 (27.6)	2 (9.1)
Not stated	2 (6.9)	1 (4.5)
Dementia diagnosis, n (%)		
Diagnosis received	10 (34.5)	4 (18.2)
Main language spoken at home, n (%)		
English	27 (93.1)	18 (81.8)
Clinical Frailty Scale, n (%)		
1: Very fit	0 (0)	0 (0)
2: Well	0 (0)	0 (0)
3: Managing well	0 (0)	0 (0)
4: Vulnerable	0 (0)	2 (9.1)
5: Mildly frail	5 (17.2)	3 (13.6)
6: Moderately frail	8 (27.6)	4 (18.2)
7: Severely frail	16 (55.2)	13 (59.1)
8: Very severely frail	0 (0)	0 (0)
9: Terminally ill	0 (0)	0 (0)

[a]Other languages spoken at home included Urdu, Gujarati, Greek, and Kurdish.

[b]Ethnicity categories were defined according to UK Census classifications. White includes English, Welsh, Scottish, Northern Irish or British, Irish, Gypsy or Irish Traveller, Roma, and any other White background. Black, Black British, Caribbean or African includes Caribbean, African, and any other Black, Black British, or Caribbean background. Asian or Asian British includes Indian, Pakistani, Bangladeshi, Chinese, and any other Asian background. Mixed or Multiple Ethnic Groups includes White and Black Caribbean, White and Black African, White and Asian, and any other Mixed or multiple ethnic background. Other includes Arab, and any other ethnic group.

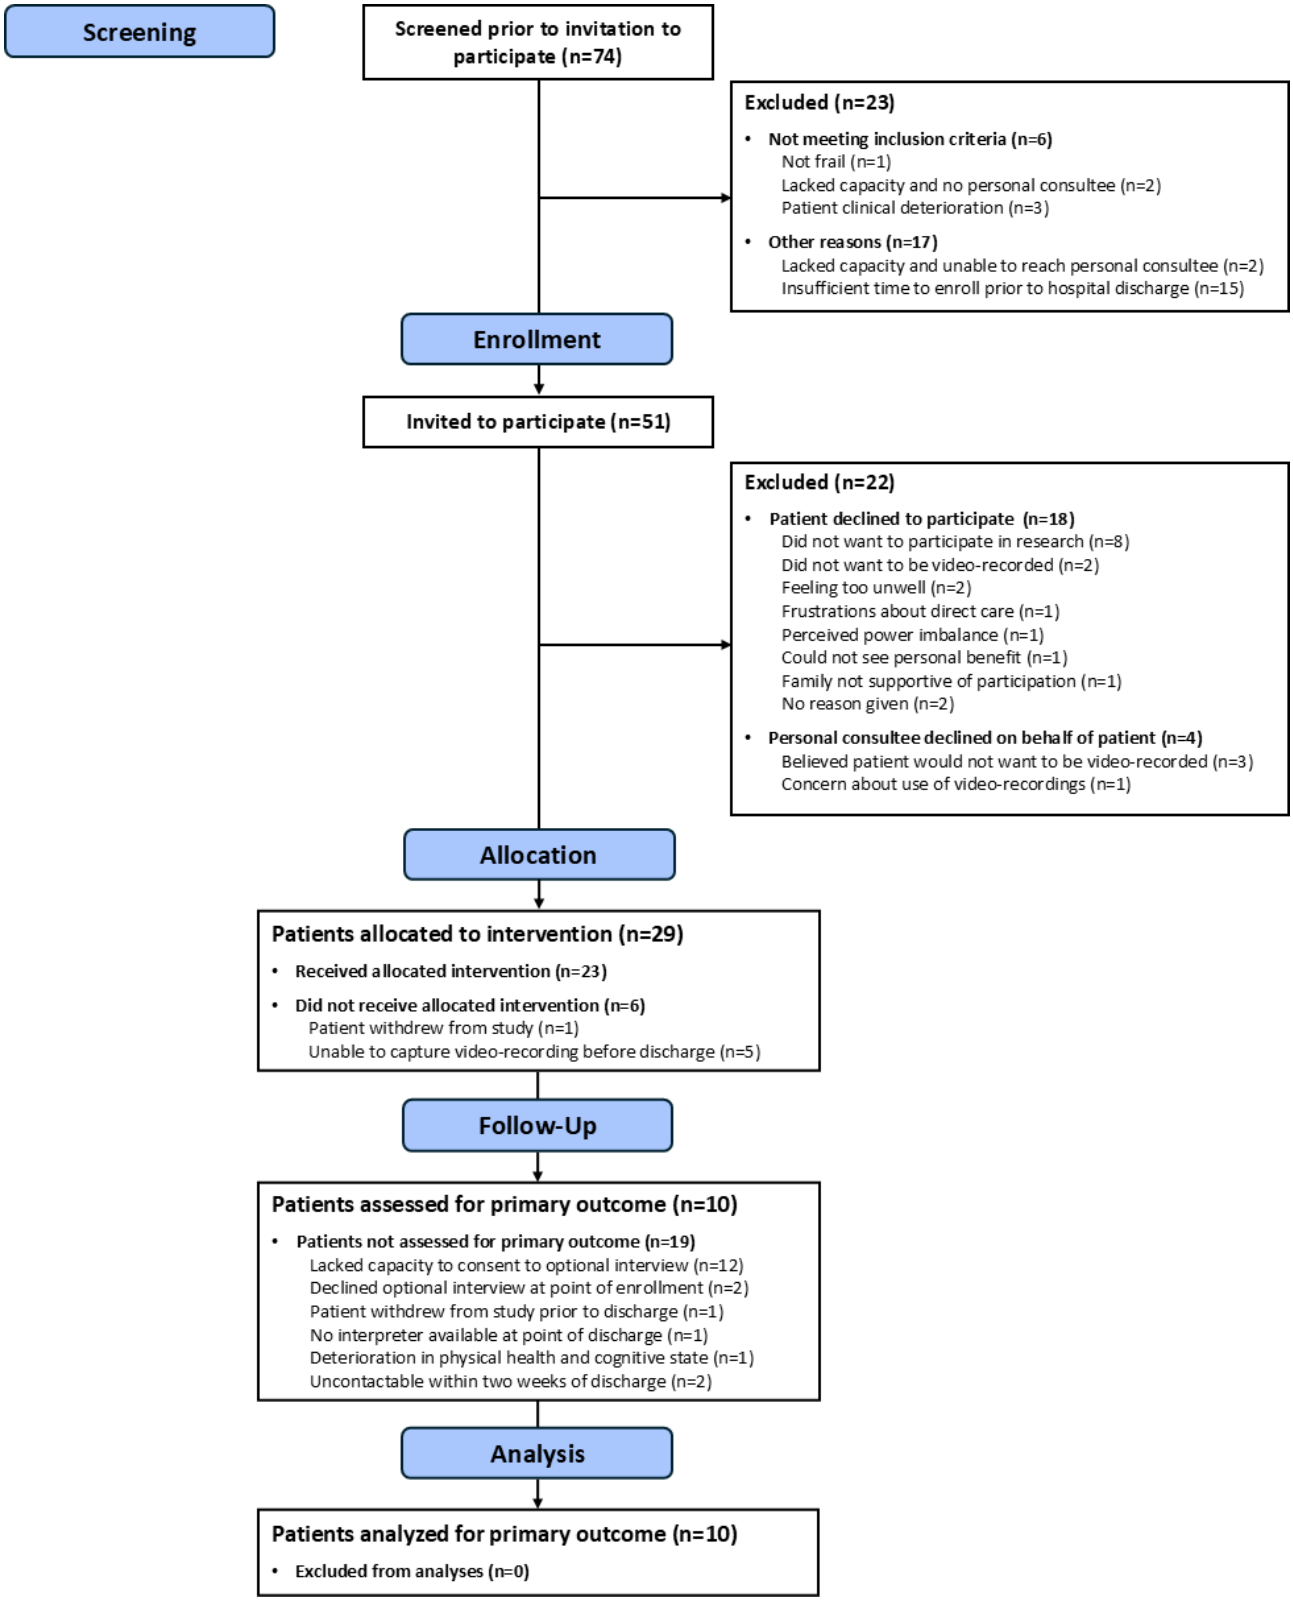
Acceptability

Patient Recruitment and Retention

Fifty-one patients were invited to participate, of whom 29 patients (56.9%) were recruited: 17 (58.6%) patients gave informed consent, while a personal consultee was involved in the decision for 12 (41.4%) further patients (Figure 1). One patient withdrew from the study prior to receiving the intervention. Among those who declined participation (22/51, 43.1%), key reasons given by patients included not wanting to take part in research (n=8), not wanting to be video-recorded (n=2), or feeling too unwell (n=2). Consultees who declined on behalf of a patient did so due to believing that the patient would not like to be video recorded (n=3), or concerns about how video recordings would be used (n=1).

Only patients with the capacity to provide their own consent to participate were invited to take part in an interview to assess outcomes. Participating patients were not excluded from interviewing based on whether they had personally received the allocated intervention during the pilot, defined as having at least one video linked to the EPR prior to hospital discharge. As such, follow-up status is displayed for all patients initially enrolled to the study.

Figure 1. Patient flow throughout the nonrandomized mixed methods pilot study (modified from CONSORT [25]). CONSORT: Consolidated Standards of Reporting Trials.



Video Recording Requests by Care Team

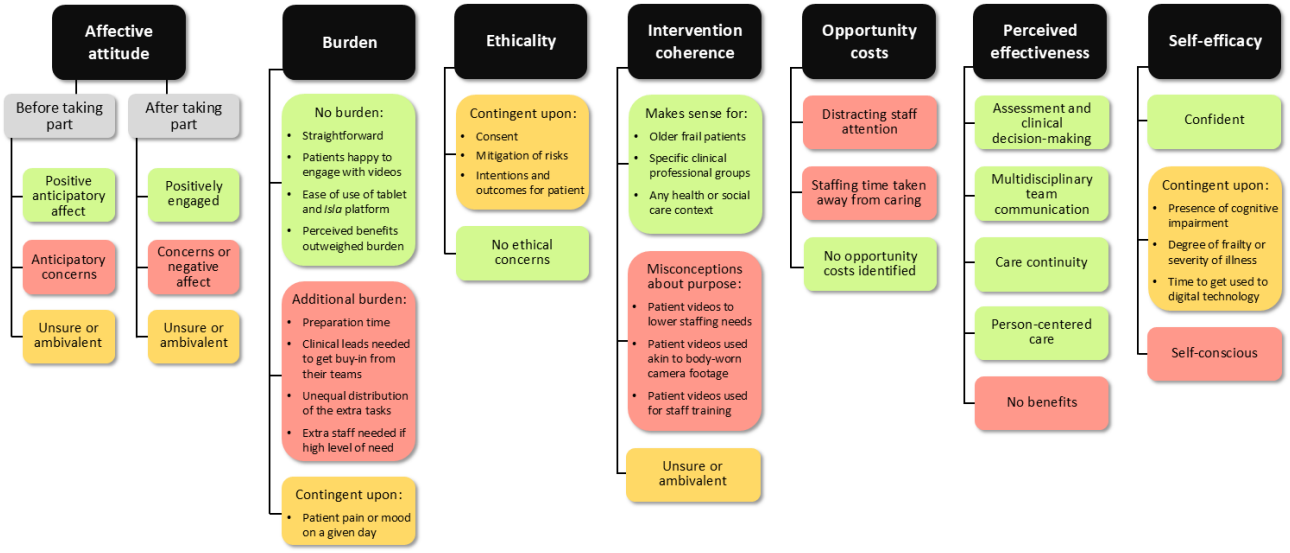
During the 3-month intervention pilot, 44 videos were requested by ward staff, with 37 video recordings attempted and 36 submitted within the EPR. Video recordings were focused on patient transfers (n=16), other aspects of mobility (n=13), eating and drinking support (n=3), and patient behavior (n=2). Further videos documented patient-staff interactions (n=1) and seizures (n=1). Video evaluation questionnaire data indicated the suitability of patient videos and the desire among those staff to see more videos in the future. Indeed, all 4 respondents endorsed that videos were of suitable length and quality for clinical interpretation, expressing a desire to see more patient videos in the future.

Perceived Acceptability

Overview

Interviewed patients, carers, and ward staff alike (66/70, 94.3%) typically rated video-based patient records as "completely acceptable" or "acceptable." Three participants stated that they had "no opinion" (4.3%), while a single patient felt that the intervention was "unacceptable" (1.4%); no explanation was provided for this rating. Detailed qualitative findings as to the acceptability of video-based patient records, informed by the Theoretical Framework of Acceptability of Healthcare Interventions by Sekhon, are presented as follows and summarized in Figure 2 [23].

Figure 2. Overview of nonrandomized mixed methods pilot study findings about the acceptability of using video recordings as part of older adult inpatient care.



Affective Attitude

Reflecting on how they felt about the intervention prior to participating, those with positive anticipatory affect gave several reasons for this perspective. Video-based patient records were expected to help in establishing an individual's baseline function upon admission, allowing patients and staff alike to appraise progress during the inpatient stay. Staff believed the intervention could foster improved MDT communication and clinical decision-making, valuing the opportunity to pilot the intervention prior to decisions about rollout into routine care:

> *We get new things turn up all the time, "Oh we are doing this now, we got this new policy", whereas because it's being studied in a research way there is going to be lots of oversight, consent, and feeding back.* [Doctor]

Anticipatory concerns were about information security and maintaining patient dignity, particularly where patients lacked the capacity to personally consent to taking part. Staff were also apprehensive about potential workload impacts and whether patients and families would be supportive of the intervention. In practice, capturing and viewing patient videos was less burdensome than expected and staff were surprised to find that many patients were enthusiastic about taking part:

> *I was a bit skeptical, but found that the more we saw the patients, the more eager they were about the recording.* [Therapies staff]

Burden

Patients and carers believed that burdens to patients in participating in the intervention were limited:

> *I felt it was something that needed to be done, it didn't take very long. I didn't have a lot to do so it was very positive.* [Patient]

The potential to exacerbate behavioral symptoms in patients with agitation or cognitive impairment was carefully considered by staff and carers. This was mitigated by avoiding filming or terminating patient videos immediately upon any indication of patient distress (verbal or nonverbal). Burdens for staff included time required for preparation or additional staffing needs where patients required assistance of 2 for mobilization, with a third staff member needed to capture the video.

Ethicality

Participants regarded the use of video recordings within the assessment and care of older inpatients with frailty as ethical, on the grounds that certain conditions were met. A central view was that ethicality was contingent upon patient consent to appear in videos. Where a person was assessed to lack the capacity to consent, differing views were presented as to whether a personal consultee or next-of-kin should be allowed to make this decision on a patient's behalf. Given that a person's next-of-kin would typically be best positioned to understand the patient's likely wishes, next-of-kin consent was largely considered suitable. However, others voiced that patient consent was the only basis on which the intervention could be judged as ethical:

> *I would feel something like that needs to come from them [patients]… and I don't think the next-of-kin should be making that decision for them.* [Carer]

Mitigation of risks associated with video capture was another prerequisite for ethicality. A central principle was that a patient's dignity must always be upheld during video recording,

particularly given the permanence of digital patient records. Patient confidentiality and information security were further risks agreed by participants to warrant safeguards. Participants described feeling reassured about the extensive safeguards in place throughout the intervention pilot. There was consensus that patient videos should be viewed only by staff members who need to see them and must be stored in a secure digital environment that is resilient to cyberattacks.

The intentions and outcomes of the use of video-based patient records comprised another determinant of their ethicality. Where an individual's personal, religious, and cultural beliefs were considered and there was a clear clinical rationale for capturing a patient video to optimize an aspect of care, conditions for ethicality were met. Indeed, staff indicated that patient videos may help to accelerate processes of identifying discharge placements for patients, thus reducing other risks associated with lengthy hospital stays, including deconditioning or exposure to hospital-acquired infections. There was a perception that withholding such an intervention from patients, due to concerns about frailty or cognitive impairment, meant that older inpatients risked missing out on potentially enhanced care. Patients justified ethicality based on enjoying tracking their own progress and experiencing no negative outcomes from taking part:

> *It hasn't hurt me, so why should I complain?* [Patient]

Beneficial patient outcomes associated with video-based patient records were thought most likely to be realized where there is potential for an individual to return to their mobility baseline, while benefits were deemed less clear for extremely frail or cognitively impaired patients.

Intervention Coherence

It was evident from some participants' accounts that they understood how video-based patient records could support patient care and why the intervention had been piloted within the 3 wards. Those who could confidently explain the intervention aims felt it made particular sense to use patient videos in the care of older patients, where rapid changes in presentation may occur:

> *I can see now how it might be important for people to see the transformation in me, the way I was a few days ago. Now, I've lost ten years.* [Patient]

Comparisons to usual care were made at several points. Staff described the limitations inherent in text-based patient information and reflected upon the potential added value of visual data for obtaining insights into a patient's needs:

> *It's quite good technology to have, like I say, written documentation doesn't always convey what's going on, the patient's abilities. So, to actually see something, especially in regards to moving and handling, things like that.* [Nursing staff]

Staff believed that patient videos had applications for all MDT members. However, the intervention was thought most relevant to the work of physiotherapists and occupational therapists, as well as doctors. Moreover, others regarded that video recordings may be coherently used in any health or social care context.

In contrast, some patients and carers were unsure about how the intervention could be useful as part of clinical care. Furthermore, several misconceptions were expressed about the purpose of patient videos. Some staff members believed that patient videos would be used to reduce staffing requirements. Likewise, others misunderstood how and why patients may be filmed, believing that video capture would be used in the same way as body-worn cameras, which are typically used for continuous or targeted filming to document violence and aggression in health care or policing contexts.

Opportunity Costs

Opportunity costs, where other potential benefits were forgone in implementing the video-based patient record intervention, were seldom identified. A concern was that in capturing patient videos, staff may be distracted from risks on the ward, such as wandering patients:

> *If a patient fell… you obviously want to focus your attention on what's going on. You don't want to be thinking about, "Is that angle right? Am I capturing everything?"* [Therapies staff]

Second, an additional member of staff was often asked to assist in holding the tablet during video capture, thus stepping away from the task they were completing at the time.

Self-Efficacy

Finally, many participants expressed confidence in either capturing (staff) or appearing in videos (patients, carers, or staff). Self-efficacy was reportedly lower where patients had cognitive impairment; patients were also less comfortable appearing in videos on days when they were especially unwell. Some ward staff indicated initial hesitancy in using a new form of digital technology, needing time to become accustomed to using the tablet. A minority of patients and staff felt self-conscious over their physical appearance or about the sound of their voice when appearing in videos.

Feasibility

Diversity of Patient Sample

Enrolled patients were largely male (18/29, 62.1%), had a mean age of 82.9 (range 72 - 96, SD 6.7) years, mostly spoke English at home (27/29, 93%), and were diverse in ethnicity (Table 3). Clinical Frailty Scale scores for participating patients ranged from 5 (Mildly frail) to 7 (Severely frail), with most patients evaluated to be "Severely frail" (n=16) [26]. Around one-third (10/29, 34.5%) had a dementia diagnosis. Baseline characteristics were similar between enrolled and nonenrolled patients, apart from dementia diagnosis and main language spoken at home, where higher proportions of participating patients had dementia and spoke English.

Privacy and Security Concerns

During the 3-month pilot, the study clinical lead was asked to review a single patient video owing to privacy concerns. In the video, another patient could be observed stepping into the video background. The video was removed from the Isla Health Digital Pathway Platform, owing to concerns that the other patient might be identifiable from the footage.

Use of the Isla Health Digital Pathway Platform

Videos were captured on a total of 19 days within the 3-month pilot. The video recording process typically involves 2 or 3 staff members, with one to carry out the recording and others to provide direct support to the patient. Information as to those involved in this process was limited to the person capturing the video recording only, based on login data for the platform. We ascertained that 11 different staff members used their logins to capture and upload videos but were unable to determine the total number of staff members involved in the recording process in a supporting role.

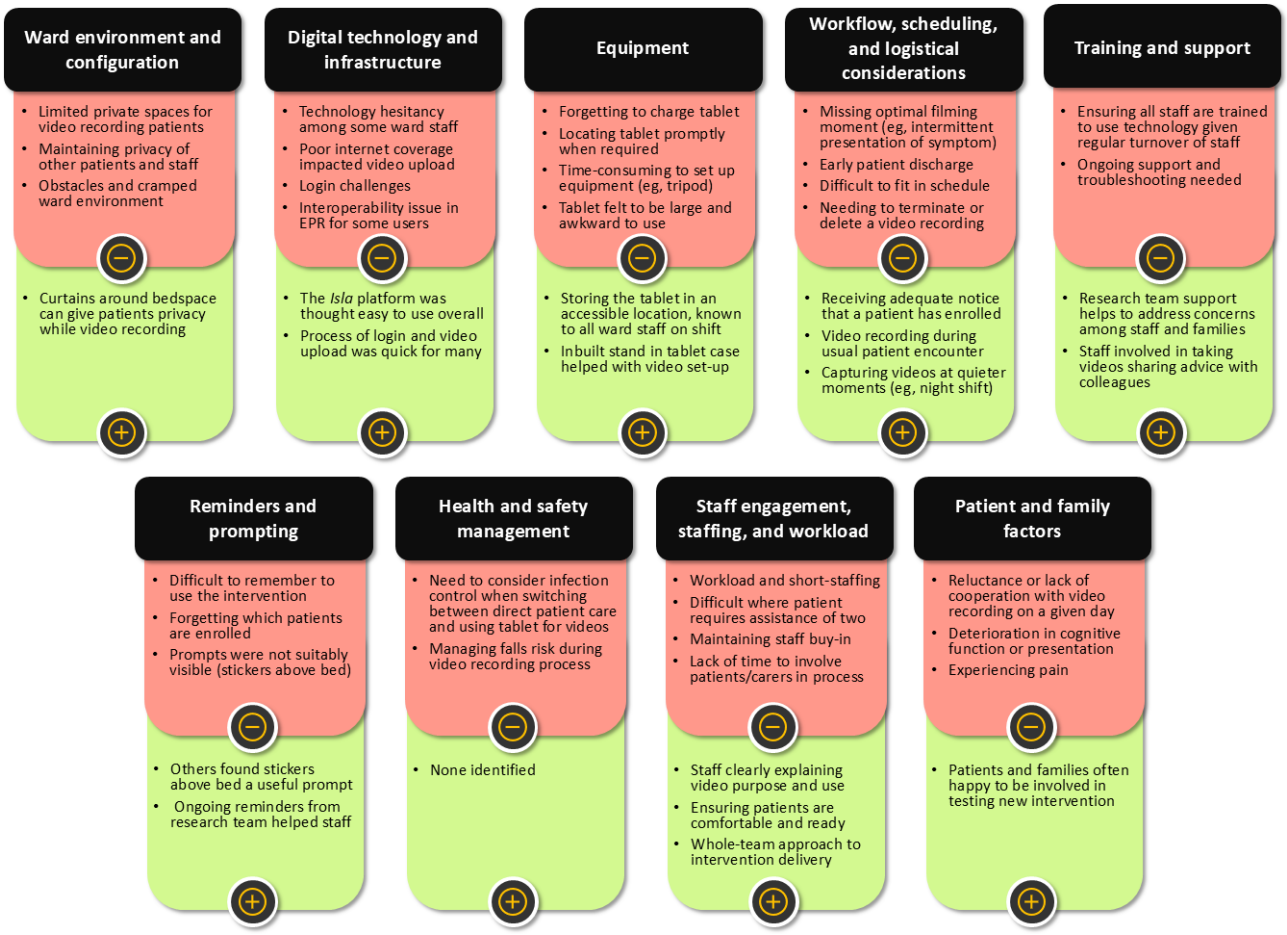
Use of the Isla Health Digital Platform Pathway was similar across the 3 pilot wards. Ward 1 captured 13 videos (among n=10 recruited patients), with 17 captured on Ward 2 (among n=13 recruited patients), and 6 on Ward 3 (among n=6 recruited patients). Overall, of 29 participating patients, 79.3% (n=23) had at least one video linked to their EPR at the point of discharge. The research team was notified of 12 unsuccessful attempts to take a video. Primary reasons documented included the patient declining (n=4), patient cognitive or medical deterioration (n=3), and insufficient staffing (n=2).

Video views by ward staff were quantified through Isla Health Digital Pathway Platform metadata, where staff clicked to view and expand a video tile, resulting in a documented "View submission" action. Four such views were counted. However, toward the end of the pilot phase, we ascertained through observing staff interact with the platform that watching a video without expanding on the video tile was instead recorded within the Isla platform metadata as "View folder." Accordingly, excluding cases where a "View folder" action occurred directly before or after the same staff member uploaded a video for a given patient (when the folder view likely served a different purpose), we estimate that there were 17 video views during the study. Seemingly low video view rates among staff were corroborated by anecdotal insights obtained through staff interviews. Although staff members could typically identify potential intervention benefits at the team level, when asked directly, interviewed staff commonly attested that they had not personally viewed or sought to access a patient video at any point during the 3-month pilot.

Intervention Barriers and Facilitators

Nine themes were inductively developed from interview data as to the barriers and facilitators to implementing the video-based patient records intervention in the care of older adult hospital inpatients with frailty (Figure 3).

Figure 3. Barriers and facilitators to implementing video-based patient records in acute medical wards for older adult inpatients with frailty. EPR: electronic patient record.



Ward Environment and Configuration

The crowded, busy ward environment and layout were such that staff struggled to capture patient videos while maintaining the privacy of participating patients. Likewise, difficulties were faced in ensuring that other patients and staff members were not captured in the background of patient videos. Curtains around the bed space were valued by staff for facilitating a degree of privacy during the video recording process.

Digital Technology and Infrastructure

Digital technology and infrastructure barriers stemmed from poor quality Wi-Fi coverage across the 3 pilot wards. Technology hesitancy and delays or challenges in logging into the video-based patient records system were also experienced by some staff members:

> *We are so tied down by logins, governance, two-factor authentication that if you want people to be able to have a low threshold to record, check, share something, you can't do it.* [Doctor]

Overall, the Isla Health Digital Pathway Platform was, however, considered straightforward to use.

Equipment

Staff reported several equipment-related challenges. Locating the designated tablet promptly when required or finding that the battery had not been charged by previous users were key frustrations. An inbuilt stand within the tablet case served as a facilitator to the video recording process, allowing staff to position the tablet on a surface within the ward (eg, bedside table) when another staff member could not assist with video capture.

Workflow, Scheduling, and Logistical Considerations

Further obstacles to using the intervention are related to ward workflow and logistical considerations. Videos often needed to be taken at an optimal moment when seeking to capture intermittent presentations (eg, seizures) or for fatigued patients. Patients were sometimes discharged earlier than expected, meaning that video recordings could not be captured in time or used to realize potential benefits. Staff described integrating video capture into their usual planned therapy sessions with participating patients, or capturing videos during quieter periods, to maximize efficiency and feasibility.

Training and Support

Regular staff turnover presented difficulties in ensuring all staff were trained in using the intervention. From the staff engagement and enrollment phase through to the end of the 3-month pilot, there were rotations in both junior doctors and specialty trainees on a national level. When asked about low apparent usage of videos, some staff members indicated that they could not recall how to access videos within the EPR:

> *I think it's quite straightforward when you record it, but I think there is still some sort of gap, like how you follow up with Isla outside of the iPad [tablet].* [Therapies staff]

Nevertheless, staff and patients alike appreciated access to ongoing training and support from the research team throughout the 3-month trial period.

Reminders and Prompting

Remembering to capture and use videos within patient care was a persistent challenge. This served as a barrier to uptake and achieving a meaningful intervention "dosage" for participants, where it was felt that more videos throughout an individual's inpatient stay would be necessary to visually demonstrate improvement or deterioration.

> *I was naively hoping it would be more visible. Having people nudging and reminding definitely helps, but that would be my concern for wider adoption.* [Doctor]

For other staff, there appeared to be low impetus to access and use patient videos once captured:

> *Not many people would go and check, or would say, "Okay, on Cerner [EPR], I want to go and see that video."* [Therapies staff]

Reminders used throughout the pilot study period (eg, stickers above beds of enrolled patients and reminders from the research team) were valued but thought insufficient for comprehensive implementation.

Health and Safety Management

Managing safety when capturing videos, including staff's ability to prevent patient falls during video-recorded mobility assessments, was an important consideration. Other challenges included infection control considerations when switching between delivering direct patient care and using the tablet to capture a patient video.

> *I got pointed out for infection control… they recommended me leaving the iPad [tablet] there, going to wash my hands, come back and go onto the tablet. But I can't leave the patient.* [Therapies staff]

Staff detailed practical issues in capturing videos, where handwashing was required between each activity.

Staff Engagement, Staffing, and Workload

Moreover, intervention feasibility was also contingent upon staff engagement, staffing, and workload factors. Barriers were presented when wards were short-staffed, resulting in high workload for clinical teams and limited spare capacity to assist with capturing videos. Reassuring staff that video recordings were not intended to be used for appraising staff practice and recognizing the efforts of staff to deliver the intervention were important for maintaining staff engagement. Implementation was reportedly best where an MDT approach to capturing patient videos was adopted, so that individual professional groups (ie, nursing or therapy staff) did not feel alone in shouldering additional task burdens. Likewise, carers emphasized the importance of staff taking time to explain to patients why they wished to capture a video of a given activity or symptom and how the video may be used as part of their care:

> *Is there rapport being built up? Is the person comfortable with those particular healthcare professionals?* [Carer]

By allowing time to develop positive staff-patient relationships, patients felt more comfortable with taking part.

Patient and Family Factors

Finally, patient and family factors were important to the implementation of video-based patient records. On some days, interviewees described that patients were reluctant to accept any care or interventions on the ward, including patient videos. Older, frail patients may decline to engage owing to experiencing pain or fatigue on a given day. Seemingly uncooperative behavior was displayed at times among participating patients due to confusion or fluctuation in cognitive function, presenting a barrier to delivering the video-based patient record intervention:

> *When they were trying to video something more positive with him, he decided not to be as positive! But that's hit and miss with any of the patients I would think.* [Carer]

Nevertheless, a key facilitator indicated by all participant groups was that patients and carers were often happy to be involved in trialing a new intervention which may improve their own care or that of others.

Perceived Effectiveness

Overview

Perceived effectiveness of the video-based patient records intervention was appraised according to ward staff views on its potential usefulness in the care of older adult inpatients with frailty, as well as patient, carer, and staff perspectives on intervention impacts. Participants conceived of multiple ways in which video-based patient records could be potentially effective for use in the present context. Some participants were unaware of any intervention impacts. Such patients and carers described a lack of follow-up from ward staff about their videos, meaning that they were unsure whether the video recordings had been beneficial. No adverse events were reported. Study data indicated several ways in which video recordings may improve aspects of patient care.

Assessment and Clinical Decision-Making

Data from the 4 completed video evaluation questionnaires showed that ward staff considered the video they had watched was "very useful" for supporting patient assessment and clinical decision-making. Interviewees elaborated on the potential for patient videos to improve assessment quality by mitigating subjectivity in clinical interpretation and speeding up the assessment process. For behaviors or symptoms occurring at unpredictable intervals, videos also permitted staff to obtain specialist advice from other teams:

> *It helped our neuro team see a patient who was having intermittent seizures… they [neurology team] would not have been able to see it otherwise.* [Nursing staff]

Further potential benefits were in offering clear information about an individual's care and support needs, providing evidence for referrals to other care providers. Staff reflected on challenges faced in securing onward care placements for patients who had exhibited fluctuating behavior and nursing care requirements in the hospital. Rehabilitation settings and nursing homes reportedly declined referrals or overestimated staffing costs necessary to provide patient care, based on patients having had an acute or episodic change in presentation (eg, delirium onset) during their admission:

> *If we had someone come in for assessments, we had this evidence to say "Okay, look, on a good day this patient did it this way, so you need to assess them based on that."* [Nursing staff]

In contrast, an alternative position was that videos merely provided a snapshot of a person's presentation:

> *You're putting someone into a slightly odd position saying, "Now, walk for us." And I think you'll get the Charlie Chaplin effect, people starting to do things that maybe they wouldn't normally do… I think a camera is not always going to bring out the truth in people.* [Carer]

Therefore, the potential for video-based patient records to improve assessment and decision-making precision was questioned.

Multidisciplinary Team Communication

All 4 staff members who completed video evaluation questionnaires reported that the video they had watched was "very useful" for communicating patient information to colleagues. The added communicative value of visual data over written documentation or verbal handovers was apparent from interview data. Carers were similarly supportive of patient videos, where their use might improve communication quality and concision:

> *I don't know whether that would completely eradicate the need for discussion… but it could perhaps enhance that, if there's something that someone needs to show someone else.* [Carer]

Participants also envisaged potential value for strengthening communication with other clinical settings. Carers felt that videos could optimize care timeliness and continuity by enabling remote communication with other care providers. This view was supported by staff, who also believed that patient videos may improve collaboration between clinical services, potentially reducing duplication of clinical assessments:

> *We have a deficit of trust across boundaries… but if you see a video they know we are not making it up.* [Doctor]

Moreover, videos were reportedly used to enhance communication with patients' families:

> *Sometimes the family says, "Oh, he could not do it at home." When they see the patient sitting out and walking, it's amazing them.* [Nursing staff]

As such, this helped to provide a tangible demonstration of care and interventions received in the hospital and apparent impacts.

Care Continuity

Study findings suggest that video-based patient records could improve care quality by optimizing continuity, both within and beyond an individual's hospital stay. Patient videos may support joined-up care by helping to establish a shared understanding of the goals of a patient's admission, informed by videos showing their functional baseline. Similarly, participants reported that videos allowed staff to objectively monitor patients over time, facilitating greater awareness of signs of improvement or deterioration:

> *For the patient it's better because we know their progress… I'm video-recording to compare. We see the difference from bedbound to mobilizing.* [Nursing staff]

Video-based patient records were also deemed valuable for aiding safe care transitions. Staff thought patient videos could assist community therapy teams to provide joined-up care following discharge. Since frail older adults often experience multiple hospital admissions, participants also envisaged using patient videos to gain insights into a person's presentation during prior inpatient stays.

Person-Centered Care

The potential for video-based patient records to improve person-centered care was a prominent theme. By providing a visual record of a patient's achievements throughout their hospital admission, patient videos promoted a focus on an individual's goals and needs, contributing to more personalized care experiences:

> *I was proud to see me in the video and pleased that I have made so much progress… it gave me great spirits.* [Patient]

Moreover, the use of patient videos was thought to improve the quality of staff-patient engagement. Staff described how the process of delivering the intervention offered opportunities for patients to receive additional encouragement from ward staff, which in turn improved staff satisfaction:

> *The patient was eager, because he was walking and the staff… they were following and cheering him on. It was so beautiful – he was able to mobilize himself. They were all so happy, the staff and the patient themself [sic] because he wanted to go home!* [Nursing staff]

Finally, there was a sense that patients appreciated the choice over whether to take part in the intervention:

> *It gives the patient a little say in what's going on in their life as a patient.* [Patient]

Where patients may feel they have limited involvement in care decision-making when in hospital, the opportunity to make choices about their care appeared to instill a sense of agency and empowerment.

Discussion

Principal Findings

Findings from this nonrandomized mixed methods pilot study suggest that the use of video recordings within patient assessment and care delivery is largely acceptable to older patients with frailty, their family members or carers, and clinical staff. This was demonstrated by promising participant recruitment and retention rates; enrollment targets for patients were almost met, while ward staff recruitment vastly exceeded intended numbers. The range of videos captured, from documentation of seizures through to establishing a person's mobility baseline, shows that staff discerned multiple use cases for patient videos. On the grounds that ethical preconditions are met, including mitigation of concerns about information security and patient dignity, video-based patient records were largely deemed to be acceptable.

A secondary objective to explore the feasibility of implementing video-based patient records within acute wards for older adults revealed mixed findings. Diversity of the patient sample in terms of clinical and demographic characteristics was encouraging, indicating that risks of widening health inequalities through inequitable uptake are low, should the intervention be implemented into routine care. Implementation barriers were multiple, yet participants described a range of facilitators that supported successful delivery. However, video view metric estimates and anecdotal evidence from interviews with ward staff suggested limited engagement with videos once captured, thus casting doubt on the feasibility of attaining sufficient uptake among staff. We estimate that over half of all videos captured were never viewed. Nevertheless, patient, carer, and clinical opinion as to perceived intervention effectiveness yielded evidence of promise. Videos were considered useful in supporting clinical assessment, enhancing MDT communication, strengthening care continuity, and promoting person-centered care.

Comparison With Wider Literature

Our findings are largely in accordance with the conclusions of a recent systematic review, which examined empirical research and regulatory guidance on the generation and use of video recordings as part of patient care [16]. Indeed, similarly to existing studies [16,27,28], we observed that video-based patient records were acceptable to patients, carers, and clinical staff alike, so long as ethical conditions were satisfied around upholding patient dignity and maintaining the security of these digital data [29]. Likewise, based on clinical opinion, we found that patient videos may aid the monitoring of care delivery and outcomes over time, aligning with the conclusions of comparable research [15].

Perhaps most striking was our finding that video-based patient records appear to be valuable for promoting person-centered care within the acute hospital setting. The intervention seemed to instill a sense of agency and empowerment in older adults with frailty who took part in video recordings. Staff experienced secondhand satisfaction upon observing a patient demonstrating a functional improvement, such as walking unaided, when they had previously felt too frail to do so. This finding resonates with

prior research from physiotherapy and rehabilitation contexts, where video recordings documenting improvements in patient gait throughout their inpatient stay were found to improve patient motivation and satisfaction [30]. Likewise, although we piloted the use of patient videos captured by ward staff, rather than exploring patient-generated visual media as reported within a further review [15], we similarly concluded that patient videos helped staff to gain a more individualized understanding of patients. A deeper understanding of patients as individuals likely, in part, underpinned the closer staff-patient engagement anecdotally reported by participating staff and patients.

Older adults with frailty often face multiple transitions between health and social care settings, owing to complex care needs stemming from multimorbidity [6,7]. An important application of the present intervention, as conceived by ward staff, lay in the potential to capture video footage which could be shown to other departments or providers to inform decision-making and support joined-up care. For example, staff spoke about the potential value in sharing footage with neurology specialists or with staff carrying out assessments for care home placements. For the purposes of this pilot study, staff could only show video recordings to health care professionals outside the direct care team who visited the pilot wards in person. Should wider implementation of video-based patient records be considered, the lack of interoperability of different EPR systems, a well-documented obstacle to delivering digital interventions at scale, warrants timely address [31,32].

The integration of new digital technologies into health care services resembles a complex challenge, with tailored strategies required to promote successful adoption and sustainability of a given intervention [33]. Our findings point to a series of barriers and facilitators to the implementation of video-based patient records, including those pertaining to staff engagement, workflow, and the adequacy of reminders and prompting used to encourage staff to capture and view patient videos. So that potential enhancements to patient care can be realized, theoretically informed strategies drawing upon behavioral science or implementation science frameworks are likely required to encourage uptake [34].

Finally, it is well documented that severely frail patients and people who are unable to consent to participation are seldom included within research studies [35,36]. Our findings reinforce existing literature which points to the need for careful ethical review of procedures for patient inclusion [37], to increase opportunities for such patient populations to contribute to applied clinical and health services research. This is so that they are not excluded from the development of innovations which may result in enhanced care.

Strengths and Limitations

Strengths of this study lie in its representation of patient populations who are underrepresented and underserved in clinical research. This includes older adults with severe frailty and people who lack the capacity to consent to research owing to cognitive impairment [35]. Exclusion of such patients from clinical trials is widespread, thus obstructing the potential to develop improved health care services and interventions that meet the needs of these populations [36]. High quality and comprehensiveness in qualitative data collection components were indicated according to multiple dimensions of information power [24]. For instance, data were sufficiently comprehensive given our narrow study aims, high sample specificity while capturing variation in patient demographic and clinical characteristics, and owing to the application of established theory. We ensured rigor in our analysis of interview data through the Framework Analysis approach [22], applying an existing theoretically informed framework to guide data charting [23], while inductively introducing new codes into the coding scheme to characterize each construct. Further strengths were in our approach to PPIE, ensuring that lived experience perspectives guided the study throughout the research cycle.

Issues in interpreting Isla Health Digital Pathway Platform metadata, such that video view figures were estimates that cannot be determined with exactness, represent an important limitation. Other limitations pertain to the study design. The single-site, nonrandomized nature of this research and the lack of a comparator group should be taken into account when considering our findings. While we appraised the quality of interview dialogue to be high overall, we hold that dialogue flow was at times impacted within the busy ward environment in which data were gathered. Interviews with patients were often inadvertently interrupted by staff or visitors, while staff were regularly distracted by other tasks (eg, incoming telephone calls) while being interviewed. We also note that among participating patients with the capacity to consent to an optional interview during enrollment, a number of these individuals were not interviewed due to reasons such as being uncontactable within 2 weeks of leaving the hospital, deterioration in cognitive state, and lack of interpreter availability at the point of discharge. Had it been possible to interview these individuals, it is plausible that a wider range of perspectives on the intervention may have surfaced, with greater information power to permit between-case analysis. Nonetheless, we offer a robust evaluation of intervention feasibility, applying our findings stringently to decision-making about progression to a definitive trial.

Implications

Study findings provide evidence that the use of video-based patient records within direct care delivery for older adults with frailty was largely deemed to be acceptable. We also offer compelling preliminary insights based on participating patient, carer, and clinical staff opinions as to the potential effectiveness of this intervention in the acute medical inpatient ward context. When implemented successfully, our findings suggest that the intervention could contribute to improved care quality and safety. However, the feasibility of intervention implementation must be questioned, given estimated video view metrics and anecdotal evidence from staff interviews, which indicated that uptake among staff in terms of capturing and viewing patient videos did not reach a threshold to permit full realization of benefits. Evidence for ethicality and a lack of adverse outcomes suggests that the intervention could be considered appropriate for use within other clinical services when indicated, for example, as part of efforts to empower patients and to promote person-centered care. Further professional and regulatory guidance to support clinical staff in the implementation of such an intervention is, however, warranted [16].

Conclusions

Addressing the primary objective of this pilot study, the video-based patient record intervention was found to be largely acceptable to older inpatients with frailty, carers, and staff. Participants also held promising opinions about possible intervention impacts. Optimizing assessments, enhancing care continuity, and empowering patients were considered important potential benefits of using patient videos within direct care. No adverse events were reported. Findings about patient diversity, alongside barriers and facilitators to intervention implementation, support encouraging indications overall as to the feasibility of implementing such an intervention within this care context. However, apparent limited engagement with patient videos after their capture during the pilot phase would likely obstruct our ability to measure intervention efficacy in future research. As such, we cannot endorse progression to a definitive trial to examine the effectiveness of patient videos for improving safety and quality of care transitions. Nevertheless, our findings provide an initial indication that the intervention could be ethically implemented into routine practice, with suitable ethical safeguards in place.

Acknowledgments

The authors would like to thank the patients, carers, and ward staff who took part for their valuable contributions to this research. We also express our sincere thanks to Dr Colin Mitchell and Dr David James for supporting the successful implementation and evaluation of the Isla for Frailty intervention within their wards.

Funding

This study was funded by the National Institute for Health and Care Research (NIHR) North West London Patient Safety Research Collaboration (NIHR204292) with Infrastructure support provided by the NIHR Imperial Biomedical Research Centre (NIHR203323). Abstract

Background: High-quality clinical chains-of-thought (CoTs) are essential for explainable medical artificial intelligence (AI); yet, their development is limited by data scarcity. Large language models can generate medical CoTs, but their clinical reliability is unclear.

Objective: We evaluated the clinical reliability of large language model–generated CoTs in reproductive medicine and examined prompting strategies to improve their quality.

Methods: In a blinded comparative study at a clinical center, senior clinicians in assisted reproductive technology evaluated CoTs generated via 3 distinct strategies: zero-shot, random few-shot (using random shallow examples), and selective few-shot (using diverse, high-quality examples). Expert ratings were then compared with evaluations from a state-of-the-art AI model (GPT-4o).

Results: The selective few-shot strategy significantly outperformed other strategies across logical clarity, use of key information, and clinical accuracy (P<.001). Critically, the random few-shot strategy offered no significant improvement over the zero-shot baseline, demonstrating that low-quality examples are as ineffective as no examples. The success of the selective strategy is attributed to 2 preliminary frameworks: “gold-standard depth” and “representative diversity.” Notably, the AI evaluator failed to discern these critical performance differences. Thus, clinical reliability depends on strategic prompt design rather than simply adding examples.

Conclusions: We propose a “dual principles” preliminary framework for generating trustworthy CoTs at scale in assisted reproductive technology. This work is a preliminary step toward addressing the data bottleneck in reproductive medicine. It also underscores the essential role of human expertise in evaluating generated clinical data.

chain-of-thought; large language model; assisted reproductive technology; explainable artificial intelligence; clinical data reliability

Introduction

Background

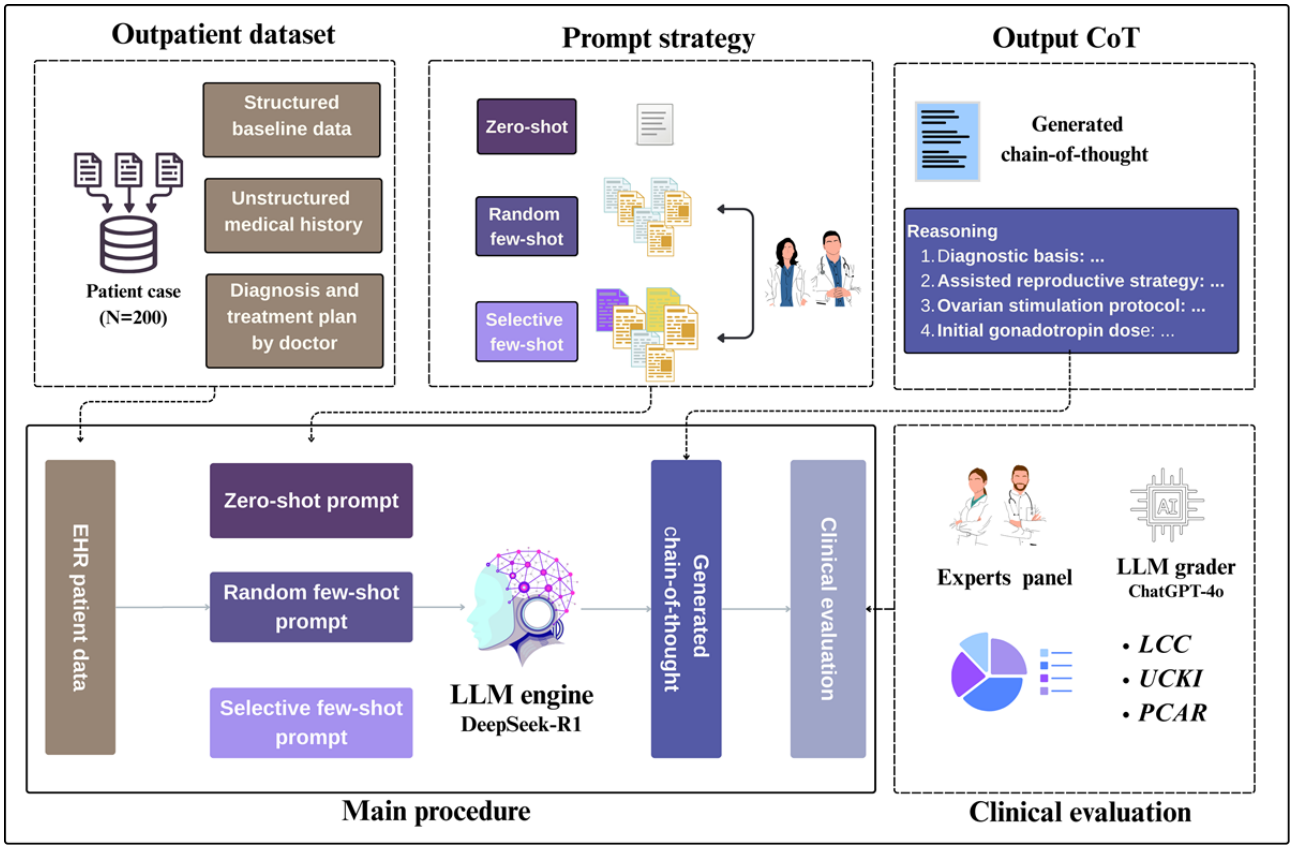
Assisted reproductive technology (ART) represents a cornerstone of modern medicine, offering solutions for millions facing infertility [1]. The clinical decision-making process in ART is exceptionally complex, requiring the synthesis of high-dimensional patient data, including baseline characteristics and medical history. This process is time-consuming and fraught with risk for both clinicians and patients, as minute variations in treatment protocols can lead to significant adverse outcomes. Furthermore, clinicians must navigate patients' personal values and ethical considerations, demanding a highly personalized and explainable approach to care [2].

Recent advancements in artificial intelligence (AI), particularly large language models (LLMs), have demonstrated considerable promise for answering medical questions, addressing clinical case challenges, and augmenting clinical diagnosis [3-7]. Within clinical decision support systems, these technologies can help synthesize large amounts of data, facilitating more comprehensive and standardized therapeutic strategies. However, while general-purpose LLMs like ChatGPT-4 and Gemini are powerful, their training on broad, nonspecialized data limits their utility in niche medical domains. Consequently, high-performing clinical AI applications are typically fine-tuned from general models using curated, domain-specific datasets [8-10]. The actual bottleneck, however, is not a lack of raw clinical data, but a profound lack of explainable data—data that record not just what decision was made, but why. This meticulous, expert-level reasoning, often captured as a chain-of-thought (CoT), is the very fuel required to train AI models that are not just accurate, but also trustworthy and scalable to clinicians. To move beyond "black-box" predictions, models require structured reasoning pathways, or CoT data, which simulate clinical logic and enhance explainability [11,12]. The challenge, therefore, narrows down to a scarcity of expert-authored CoT data within the specific area. The manual creation of such a dataset on a large scale is prohibitively expensive and time-consuming, presenting a significant barrier to progress in explainable medical AI.

To address this challenge, a promising direction is to leverage the generative capabilities of LLMs to synthesize clinical CoT data at scale. While this offers a scalable solution to the data bottleneck, it hinges on a critical, unverified assumption: the clinical reliability of the generated content. In a high-stakes domain like ART, this assumption cannot be taken for granted.

Therefore, this study is designed to examine this uncertainty under the ART setting through a rigorous, head-to-head empirical comparison. Figure 1 presents the conceptual framework of our comparative evaluation study. We hypothesize that a selective few-shot strategy, meticulously crafted with diverse and deeply reasoned examples, will improve the factual accuracy, logical clarity, and clinical information use of LLM-generated reasoning in infertility decision-making scenarios, compared with generic zero-shot and random few-shot prompting. To test this, we developed a novel prompting framework and validated it through a blinded evaluation protocol where senior clinicians from the reproductive department assessed the quality of CoTs from all 3 strategies. In a secondary analysis, we further contrast these expert assessments against the state-of-the-art (SOTA) AI evaluator (GPT-4o) at that time to critically examine the current capabilities and limitations of automated evaluation paradigms, which are widely used in supervised data generation. Ultimately, this work aims to establish an exploratory, practical, evidence-based methodology for the trustworthy generation of clinical reasoning of ART at scale.

Figure 1. Conceptual framework of the comparative evaluation study. EHR: electronic health record; LCC: logical coherence and clarity; LLM: large language model; PCAR: plausibility and clinical accuracy of reasoning; UCKI: use and coverage of key information.



The study workflow begins with a standardized patient case (N=200) as the input. Three distinct prompting strategies are evaluated in parallel pipelines: (1) zero-shot, which uses instructions only; (2) random few-shot, which uses 5 randomly selected examples; and (3) selective few-shot, which uses a curated set of 6 diverse examples representing all major ART categories in the cases. Each strategy, powered by the same LLM engine, generates a unique CoT. All 3 generated CoTs are then subjected to a rigorous, blinded "Doctor-in-the-Loop" evaluation by 2 parallel assessors: human clinical experts (the gold standard) and the SOTA AI evaluator (GPT-4o). This dual evaluation process yields the final reliability scores and rankings for each strategy.

LLMs in Health Care

Since the launch of ChatGPT-4, LLMs have rapidly spread into many industries, such as education, finance, and health care. For instance, Google's Med-PaLM 2, a leading specialized health care model, achieved 86.5% accuracy on the MedQA benchmark, a popular multiple-choice open domain question answering (OpenQA) medical problems dataset. Furthermore, its responses were preferred over those of generalist physicians in 65% of expert evaluations [13]. The LLMs are now used in many healthcare–related workflows, ranging from medical documentation assistance to clinical differential diagnosis [5,14-16]. However, to effectively address highly specialized tasks, these models are typically fine-tuned from pretrained LLMs using carefully curated datasets. Despite their impressive capabilities, current LLMs usually function as black boxes, producing outputs without offering interpretable reasoning. In clinical practice, however, physicians often require not just answers but also transparent explanations. This requires models beyond black-box behavior and provides interpretable, step-by-step reasoning processes. The increasing reliance on LLMs has also intensified the demand for high-quality data [17]. Alarmingly, some predict that the global supply of novel text data may be exhausted by 2050 and image data by 2060 [18]. In the health care domain, the situation is even more critical: clinical data are not only scarce but also highly sensitive and expensive to obtain. As a result, a central challenge emerges—how can we build datasets that are both sufficiently large and clinically trustworthy to support transparent, reliable medical AI systems?

Synthetic Data in Health Care

To overcome the data shortage in health care, researchers are increasingly turning to LLMs to create synthetic data. This approach is promising for several reasons. It allows for data generation at scale, addressing issues of data scarcity and privacy [19,20]. Furthermore, synthetic data can be tailored to balance underrepresented patient groups, potentially improving model robustness and fairness [21]. Generative models have demonstrated remarkable success in these areas, with some studies showing that LLM-generated narratives can be indistinguishable from those written by physicians [22]. This potential, however, is inextricably linked to a profound challenge: reliability. While LLMs can mimic the style of clinical text, ensuring the factual accuracy and clinical plausibility of the content is a far more difficult task. For instance, models have been used to generate both structured

electronic health records (EHRs) and unstructured clinical notes [23], but in both cases, the risk of hallucination—where the model generates incorrect or nonsensical information—poses a significant threat in high-stakes medical applications. Therefore, the core challenge moves beyond mere data generation to a more fundamental question of trust. While studies have shown that synthetic data can be effective for certain human labeling and fine-tuning tasks [24-28], these applications often involve relatively straightforward data points. The problem is magnified when the task requires complex, multistep medical reasoning. In such scenarios, "synthetic" must not equate to "inaccurate." This underscores the urgent need for rigorous evaluation methods, not just for the data points themselves, but for the underlying reasoning processes that produce clinical decisions. Our work focuses on this critical next step: assessing the reliability of synthetically generated reasoning paths.

Chain-of-Thought

CoT is a prompt engineering technique that enhances the output of LLMs, particularly for complex tasks involving multistep reasoning. It facilitates problem-solving by guiding the model through a step-by-step reasoning process by using a coherent series of logical steps [29]. This approach has been shown to significantly elevate performance on a wide range of complex reasoning tasks in general domains, especially for arithmetic problems and logical reasoning tasks [30,31]. To enhance the reasoning ability in domain-specific tasks, researchers have started fine-tuning the models with CoTs [12]. Within the medical domain, the potential of CoT is particularly compelling. Its step-by-step nature aligns naturally with the differential diagnosis and clinical reasoning processes used by physicians. Consequently, researchers have begun to apply CoT prompting to improve accuracy on medical question-answering benchmarks and in practice diagnosis [11,32]. More importantly, CoT offers a crucial pathway toward explainable AI in medicine. By externalizing the model's reasoning processes, CoT allows clinicians to scrutinize, understand, and ultimately trust the AI's recommendations, which is a prerequisite for its safe integration into clinical workflows.

The application of CoT is rapidly evolving. Beyond simple prompting, a new frontier in clinical AI is the (1) fine-tuning of models on datasets enriched with CoT data to build inherently more explainable systems, which, however, immediately confronts the fundamental bottleneck of medical AI; and the (2) prohibitive cost and time required for expert clinicians to manually author thousands of high-quality reasoning paths for a training set. An intuitive and scalable solution is to leverage foundational LLMs to synthetically generate these CoTs, creating a cost-effective pathway to train the next generation of trustworthy medical models. However, this entire paradigm hinges on a critical, yet largely unexamined, question: (3) Is the reliability of synthetically generated CoTs adequate to support their application in complex clinical scenarios? Literature to date offers little guidance. Most research focuses on the extrinsic value of CoT (ie, improving final answer accuracy), with scant attention paid to the intrinsic reliability of the reasoning itself. A model fine-tuned on flawed, albeit synthetically generated, logic could learn to produce seemingly correct answers for the wrong reasons—a risk that is unacceptable in clinical practice. Furthermore, standardized, expert-driven protocols for assessing the clinical validity, coherence, and faithfulness of machine-generated reasoning are conspicuously absent. Our study is designed to directly fill this foundational gap. Before the field can confidently use synthetic CoT for model training at scale, we must first have a rigorous method to measure its reliability. Therefore, we propose and implement a blinded, expert-led evaluation framework to answer the fundamental question: how reliable is synthetically generated sophisticated clinical reasoning, and what is the best prompting strategy to elicit it from LLMs?

Methods

Data Source

From the manually reviewed dataset, we randomly selected 200 cases as our evaluation set, covering a variety of ART. These ARTs are broadly categorized into 3 generations: in vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI), and preimplantation genetic testing (PGT). Each generation includes several clinical subtypes, such as short-protocol IVF and IVF with donor sperm. Among the 200 evaluated cases, IVF accounts for the largest proportion (140/200, 70%), including standard IVF (116/200, 58%), IVF with donor sperm (9/200, 4.5%), and short-protocol IVF (short-time insemination, 15/200, 7.5%). The second most common is ICSI (38/200, 19%), comprising standard ICSI (26/200, 13%), IVF+ICSI (5/200, 2.5%), and TESA (testicular sperm aspiration)+ICSI (7/200, 3.5%). PGT represents 11% (22/200) of the dataset, including preimplantation genetic testing for aneuploidies (PGT-A; 6/200, 3%), preimplantation genetic testing for monogenic disorder (PGT-M; 3/200, 1.5%), and PGT for structural rearrangements (13/200, 6.5%).

As shown in Table 1, the dataset consisted of three main components: (1) a structured set of baseline and demographic variables, (2) the preliminary diagnosis and treatment plan, and (3) an unstructured narrative description of the present illness history. The structured baseline data served as the quantitative and categorical foundation for clinical assessment, encompassing key indicators of ovarian reserve such as anti-Müllerian hormone and baseline follicle-stimulating hormone levels. The unstructured narrative provided essential clinical context, offering a detailed account of the patient's medical journey, which is critical for nuanced and context-aware medical reasoning. The output data, labeled as preliminary diagnosis and treatment plan, reflects the clinical conclusions and therapeutic strategies formulated by human experts in prior encounters. This component serves as the ground truth outcome. The LLM's task is to generate a reasoning path that logically connects the patient's input data to this expert-defined outcome. A detailed breakdown of all case data variables, including structured baseline indicators and narrative clinical history, is provided in Multimedia Appendix 1. Together, these inputs formed the foundation for CoT generation and model evaluation.

Table 1. Structure and description of input and output variables for each case[a].

Category	Variable
Baseline and demographics	• Female age • Menstrual cycle • Body weight • BMI • Anti-Müllerian hormone level • Duration of infertility • Gynecological ultrasound findings • Baseline follicle-stimulating hormone level
Present illness history	• Present illness history
Preliminary diagnosis and treatment plan	• Type of infertility • Controlled ovarian stimulation protocol • Initial gonadotropin dosage • Preliminary differential diagnosis • Initial assisted reproductive technology strategy

[a]This table outlines the variables provided to the large language model for each case, categorized into input (baseline and demographic and present illness history) and output (preliminary diagnosis and treatment plan). These variables form the basis for the chain-of-thought generation task.

Ethical Considerations

A set of EHRs recorded between 2020 and 2022 in the Infertility Outpatient Department at West China Second University Hospital was considered in this study. The study was approved by the institutional review board of West China Second University Hospital, Sichuan University (ID: 2022288). The EHRs have been manually reviewed and corrected to ensure data accuracy. All EHR data used in this study were fully deidentified before being accessed by the research team. The deidentification procedure followed HIPAA (Health Insurance Portability and Accountability Act) Safe Harbor standards, including the removal of all direct identifiers (eg, name, date of birth, medical record number, contact information, and provider information) and all quasi-identifiers (eg, dates, locations, and institutional identifiers). Only aggregated clinical descriptors necessary for the reasoning task (eg, high-level patient history and laboratory summaries) were retained. Access to the deidentified dataset was restricted to authorized study personnel through institution-managed credentials and encrypted storage. Reviewers performing the blinded evaluation accessed only the deidentified clinical vignettes and model-generated reasoning content through a secure, read-only interface; no downloads or reidentification attempts were permitted. All access was logged and monitored by an internal auditor to ensure compliance with institutional clinical data governance policies. Because the study used retrospective, fully deidentified EHRs, the requirement for updated informed consent for the following analysis was waived by the institutional review board in accordance with national regulations. No participants were contacted for this study, and no compensation was provided to participants.

Experiment Design

Overview

To systematically evaluate the reliability of LLM-generated CoT and to determine the impact of different prompting strategies, we designed a comparative study. The experiment was structured into 3 distinct arms, each representing a different level of contextual information provided to the model. Our design philosophy was to create a controlled, stepwise comparison to isolate the effects of in-context examples and the strategy used for their selection.

All 3 groups used the evaluation dataset (N=200) described in the data source, making sure of a fair comparison. A capable "Teacher Model" is key to generating better-quality data [33]. Considering the models' performance so far, we used the open-source model DeepSeek-R1-671b, which was known for its outstanding reasoning capability, as our consistent model shared by 3 arms [34]. Across all 3 arms, the LLM was assigned the same core task: generating a detailed, step-by-step ART CoT by integrating all provided patient information and the corresponding expert-provided reference output. All the inference was conducted via the application programming interface call. The model was executed with temperature=0.5 and max tokens=5000. We used temperature=0.5 to reflect typical clinical-LLM use, where deterministic decoding (temperature=0) may produce rigid or incomplete clinical reasoning. All prompting strategies were evaluated under identical generation settings to ensure fair comparison.

Group 1: Zero-Shot Baseline

In this group, we aimed to establish a fundamental baseline to evaluate the out-of-the-box clinical reasoning capabilities of general-purpose LLMs when applied to this specialized task. To this end, the model was prompted using a standardized directive instruction, with each clinical case embedded directly into the prompt (see Multimedia Appendix 2 for details). The outputs generated by the model, along with corresponding physician evaluations, served as a performance floor, quantifying the baseline reliability and limitations of an unadapted LLM in handling novel clinical scenarios.

Group 2: Random Few-Shot Prompting

This experimental arm was designed to establish a baseline for a standard, nonoptimized few-shot approach. Its purpose was

to measure the impact of providing generic, in-domain examples without a specific selection strategy. For each of the 200 test cases, the prompt was initially prepared with a fixed set of 5 examples to provide context for the model. These 5 examples were randomly sampled from our expert-authored data pool, excluding the existing evaluation dataset. The sample set used in the prompt for every test case consisted of 4 standard IVF cases and 1 short-protocol IVF case, accompanied by a concise reasoning chain authored by domain experts. The prompt structure and instructions were otherwise identical to those in the other arms. A representative example of a few-shot sample, detailing the input data and expert-written CoT, is provided in Multimedia Appendix 2. This approach represents a "naive" few-shot implementation. It is designed to test the hypothesis that the mere presence of in-domain examples, even without being specifically tailored to the test case, is sufficient to improve reasoning quality compared to the zero-shot baseline.

Group 3: Selective Few-Shot Prompting

This arm represents our proposed method and was designed to test the hypothesis that a deliberately curated set of diverse examples would improve reasoning reliability and generalization. Instead of random sampling, this approach used a clinically informed, representative selection strategy. Physicians curated a set of 6 exemplary cases from a pool of records not included in the 200 evaluation set (to prevent data leakage). These 6 examples were specifically chosen to represent the full spectrum of major ART categories present in our dataset, including IVF (standard IVF, short-protocol IVF, and IVF with donor sperm), ICSI, TESA+ICSI, and PGT (PGT-A). Their reasoning part was carefully crafted and covered all critical steps. The complete prompt is provided in Multimedia Appendix 2. For every test case, this same curated set of 6 diverse examples was prepended to the prompt. The purpose of this strategy was to provide the model with comprehensive and representative clinical guidance within the prompt itself.

In summary, this 3-arm design allows for a multifaceted analysis of CoT reliability. The comparison between group 1 and group 2 will isolate the general benefit of using in-context examples. The critical comparison between group 2 and group 3 will determine whether our proposed selective prompting strategy provides a statistically significant improvement over a random baseline. Together, these comparisons will build a clear evidence-based argument for the importance of a well-designed prompting strategy in generating reliable and accurate clinical reasoning.

Evaluation Metrics

Physician Evaluation

The evaluation was conducted by a panel of 2 board-certified reproductive physicians. Both subject matter experts are faculty members at the same academic medical center but work independently in separate clinical teams. They were invited through an internal clinical research collaboration mechanism, and participation was voluntary. Their sole role was to perform a blinded evaluation of the CoTs. Each evaluator possesses over 10 years of clinical experience in the field of ART. Prior to the formal evaluation, a calibration session was held where all evaluators scored 10 cases together. Any discrepancies were discussed to ensure a consistent understanding of the criteria. During the blinded evaluation, each physician reviewer received only the clinical vignette and the model-generated reasoning content. All identifying information, model names, and prompting strategies were removed to ensure full masking. The order of cases and strategies was independently randomized for each reviewer to prevent any presentation bias. Each physician independently scored the complete dataset without discussing their ratings with other reviewers. No reviewer saw any ground-truth labels or model metadata during the evaluation process.

In this study, we created an evaluation metric involving 3 dimensions: logical coherence and clarity (LCC), use and coverage of key information (UCKI), and plausibility and clinical accuracy of reasoning (PCAR). All generated CoTs were scored by the 5-point Likert scale (1=poor and 5=excellent) across 3 key dimensions of reliability, as shown in Table 2 and detailed in Multimedia Appendix 3. All paired comparison results are tested using the Wilcoxon test and adjusted for false discovery rate (FDR).

Table 2. Rubric for the evaluation of chain-of-thought (CoT) reliability[a].

Metric	Definition
Logical coherence and clarity	Assesses whether the reasoning process is internally consistent, logically structured, and expressed clearly and understandably.
Use and coverage of key information	Evaluates the extent to which the reasoning incorporates and addresses relevant clinical data points presented in the input.
Plausibility and clinical accuracy of reasoning	Measures whether the reasoning is clinically sound, aligns with standard medical knowledge, and leads to a reasonable interpretation or decision. Deduct points as appropriate across the 4 parts in the analysis.

[a]The table defines the 3 dimensions: logical coherence and clarity, use and coverage of key information, and plausibility and clinical accuracy of reasoning, used by both human experts and the artificial intelligence evaluator to assess the quality of generated CoTs on a 5-point Likert scale.

AI Grader Evaluation

In addition to manual evaluation conducted by human experts, we implemented a supplementary evaluation component leveraging a widely used LLM verifier [35], GPT-4o, to explore its feasibility as an automated evaluator of clinical reasoning. This design enables a direct comparison between AI-generated assessments and the human gold standard, thereby evaluating the feasibility of using LLMs for quality control in large-scale synthetic dataset generation. To ensure comparability, the evaluation criteria provided to the AI model were identical to those outlined in Table 2, including definitions of logical

coherence, clinical appropriateness, and key information use. The detailed prompt can be found in Multimedia Appendix 2. Each instruction consists of 2 blocks: the evaluation rubric and case vignette.

Statistical Analysis

All statistical analyses were conducted in Python (pandas, SciPy, and statsmodels; Python Software Foundation). Each case (N=200) was independently evaluated under 3 prompting strategies (zero-shot, random few-shot, and selective few-shot) across 3 dimensions: LCC, UCKI, and PCAR. Results are reported as mean (SD), with exact n values indicated in tables. To assess the reliability of the physician ratings, we evaluated agreement using three complementary measures: (1) linear weighted κ, (2) adjacent agreement rate (percentage of paired scores within ±1 point), and (3) raw interrater disagreement rates. Because the rating distributions exhibited strong ceiling effects (scores concentrated around 4-5), linear weighted κ is known to underestimate agreement under low variance conditions, a well-described statistical paradox. Therefore, in addition to reporting κ values for completeness, we emphasized adjacent agreement and disagreement rates, which more accurately capture clinical consensus when rating scales are narrow. Across all 600 evaluations (200 cases×3 strategies), disagreement rates were uniformly low, confirming strong consistency between the 2 raters. The selective few-shot strategy showed the lowest disagreement (LCC: 0.00, PCAR: 0.03, UCKI: 0.02), followed by the zero-shot (LCC: 0.04, PCAR: 0.04, UCKI: 0.07) and random few-shot strategies (LCC: 0.12, PCAR: 0.09, UCKI: 0.07). The highest disagreement observed across all metrics was only 12%. Adjacent agreement was correspondingly high, ranging from 88% to 100% depending on the metric and strategy, indicating excellent practical concordance despite the compressed scoring range. Given these properties, interrater reliability was interpreted primarily through adjacent agreement and disagreement rates, while κ statistics were retained as a formal but secondary indicator.

Normality of paired differences was assessed using the Shapiro-Wilk test and Q-Q plots. Because the evaluation scores are 5-point Likert ratings, the paired differences take on only a small number of discrete values (–2, –1, 0, +1, +2). As expected with large samples and discrete Likert data, the Shapiro-Wilk was extremely sensitive and returned significant results; however, Q-Q plots showed no meaningful deviations from approximate linearity beyond the expected discreteness. Parametric tests are generally robust to moderate deviations from normality in Likert-type data, especially with larger sample sizes. We retained the nonparametric Wilcoxon paired tests as primary analyses. All the statistical test details can be checked in Multimedia Appendix 4.

To account for multiple pairwise comparisons across the prompting conditions and evaluation metrics in the subgroups, adjusted *P* values were calculated using the Benjamini-Hochberg FDR correction across all 9 contrasts (3 comparisons per metric). For each metric, paired comparisons were conducted using Wilcoxon paired tests, and both the raw and FDR-adjusted *P* values were reported. A post-hoc power analysis was performed. For each evaluation metric, Cohen *d* effect sizes were computed using the pooled SD of paired observations. This analysis was conducted to assess the stability of estimates under small-sample conditions.

Results

Overview

All the results were obtained through the evaluation dataset (N=200), including several kinds of ART. As mentioned earlier, 3 metrics were used for evaluation: LCC, UCKI, and PCAR. The evaluation was done by a panel of experienced practitioners.

General Performance

Table 3 presents the average scores of each prompting strategy on LCC, UCKI, and PCAR. The selective few-shot strategy outperformed both zero-shot and random few-shot approaches across all 3 metrics. Specifically, it achieved mean scores of 4.56 (SD 0.50), 4.66 (SD 0.53), and 4.18 (SD 0.56), which were significantly higher than those of the zero-shot strategy (mean 4.18, SD 0.56; mean 4.30, SD 0.63; mean 3.85, SD 0.53, respectively; all *P* and adjusted *P*<.001; Cohen *d*=0.72, 0.61, 0.61) and the random few-shot strategy (mean 4.31, SD 0.64; mean 4.42, SD 0.58; mean 3.91, SD 0.63, respectively; all *P* and adjusted *P*<.001; Cohen *d*=0.45, 0.42, 0.46).

Table 3. The performance of the "zero-shot," "random few-shot," and "selective few-shot" strategies (N=200 cases per group)[a].

Strategy	LCC[b], mean (SD)	UCKI[c], mean (SD)	PCAR[d], mean (SD)
Zero-shot	4.18 (0.56)	4.30 (0.63)	3.85 (0.53)
Random few-shot	4.31 (0.64)	4.42 (0.58)	3.91 (0.63)
Selective few-shot	4.56 (0.50)	4.66 (0.53)	4.18 (0.56)

[a]Wilcoxon test used for paired comparisons; *P* values adjusted using the Benjamini-Hochberg false discovery rate procedure.

[b]LCC: logical coherence and clarity.

[c]UCKI: use and coverage of key information.

[d]PCAR: plausibility and clinical accuracy of reasoning.

Notably, there was no statistically significant difference between the zero-shot and random few-shot groups on PCAR, though samples did improve the model's capability on LCC and UCKI statistically significantly.

Subgroup Analysis

To further dig into the reasons for selective few-shot's winning, we did an analysis grouped by ART. Table 4 presents the scores of 3 ART generations.

Table 4. Subgroup analysis by assisted reproductive technology (ART) category[a].

ART and strategy	LCC[b]	UCKI[c]	PCAR[d]
IVF[e]			
Zero	4.20 (0.57)	4.34 (0.61)	3.88 (0.53)
Random	4.29 (0.67)	4.44 (0.53)	3.90 (0.65)
Selective	4.59 (0.49)	4.69 (0.51)	4.20 (0.55)
ICSI[f]			
Zero	4.16 (0.59)	4.29 (0.65)	3.87 (0.53)
Random	4.37 (0.54)	4.45 (0.69)	3.97 (0.59)
Selective	4.45 (0.50)	4.53 (0.60)	4.11 (0.56)
PGT[g]			
Zero	4.09 (0.43)	4.05 (0.72)	3.64 (0.49)
Random	4.32 (0.57)	4.27 (0.70)	3.86 (0.56)
Selective	4.59 (0.50)	4.68 (0.48)	4.18 (0.59)

[a]Subgroup analyses were based on the respective case counts (IVF: n=140; ICSI: n=38; PGT: n=22). This table aims to further investigate the performance differences of various prompting strategies across specific clinical scenarios. To achieve this, we categorized the 200 evaluation cases based on their primary type of ART, including IVF, ICSI, and PGT, and conducted a comparative analysis of evaluation outcomes within each group. Wilcoxon test used for paired comparisons; *P* values adjusted using the Benjamini-Hochberg false discovery rate procedure.

[b]LCC: logical coherence and clarity.

[c]UCKI: use and coverage of key information.

[d]PCAR: plausibility and clinical accuracy of reasoning.

[e]IVF: in vitro fertilization.

[f]ICSI: intracytoplasmic sperm injection.

[g]PGT: preimplantation genetic testing.

In the largest subgroup, IVF (n=140), a key distinction emerged. While the selective few-shot strategy significantly outperformed both other groups across all metrics ($P<.001$ and adjusted $P<.001$ for all comparisons, selective vs zero: Cohen $d=0.72$, 0.61, 0.59; selective vs random: Cohen $d=0.51$, 0.49, 0.50), there was no statistically significant difference observed between the random few-shot and zero-shot strategies ($P=.19$, .69, .10; adjusted $P=.22$, .69, .13).

The analysis of the PGT subgroup (n=22) revealed the clearest advantage for prompt diversity. The selective few-shot strategy, which was the only prompt containing a PGT example, outperformed the random few-shot strategy across all 3 metrics: logical coherence (LCC: $P=.03$; adjusted $P=.05$; Cohen $d=0.51$), information use (UCKI: $P<.001$; adjusted $P=.01$; Cohen $d=0.55$), and clinical accuracy (PCAR: $P=.03$; adjusted $P=.05$; Cohen $d=0.68$). Consistent with other findings, the random few-shot strategy showed no significant improvement over the zero-shot baseline in this category (LCC: $P=.17$; adjusted $P=.19$; Cohen $d=0.45$; UCKI: $P=.27$; adjusted $P=.27$; Cohen $d=0.32$; PCAR: $P=.13$; adjusted $P=.17$; Cohen $d=0.43$, respectively). However, we must admit that the limited sample size makes the subgroup analysis partially underpowered, and these comparisons should be interpreted with caution.

A similar pattern emerged in the ICSI subgroup (n=38). The selective few-shot strategy again demonstrated a measurable advantage. It achieved statistically significant improvements over the zero-shot baseline in 2 of the 3 key metrics: LCC ($P=.02$; adjusted $P=.15$; Cohen $d=0.53$) and PCAR ($P=.04$; adjusted $P=.17$; Cohen $d=0.44$). Although these comparisons did not remain significant after FDR adjustment, the effect sizes were moderate, and the directionality was consistent with the overall findings. For UCKI, the selective strategy again achieved the highest mean score, but this comparison did not reach significance ($P=.06$; adjusted $P=.17$), suggesting a positive but statistically inconclusive trend. The detailed subgroup statistical results can be checked in Multimedia Appendix 4.

Case Study

As shown in Figure 2, to qualitatively illustrate the stark differences in reasoning quality revealed by our quantitative analysis, we selected a representative and complex case involving PGT-M. This case is particularly illustrative, as it requires a multilayered understanding of genetics, ART procedures, and individualized patient factors. The main mistakes are listed in Table 5.

Figure 2. Representative PGT-M case illustrating qualitative differences in CoT reasoning across prompting strategies. This figure presents a representative and complex case involving PGT-M, selected to qualitatively illustrate the differences in reasoning quality observed in our quantitative analyses. The left panel shows the patient's clinical information, the correct physician's answer, and the color-coded annotation scheme (red: incorrect reasoning, yellow: irrelevant reasoning, and green: correct reasoning). The right panel displays the CoT outputs generated under zero-shot, random few-shot, and selective few-shot prompting strategies. Compared with the zero-shot and random few-shot generations, which omitted critical reasoning steps (eg, the presence of infertility diagnosis, the indication for intracytoplasmic sperm injection, and comprehensive gonadotropin dose considerations), the selective few-shot prompting was more closely aligned with clinical logic and included relevant patient-specific factors. CoT: chain-of-thought; PGT-M: preimplantation genetic testing for monogenic disorder.

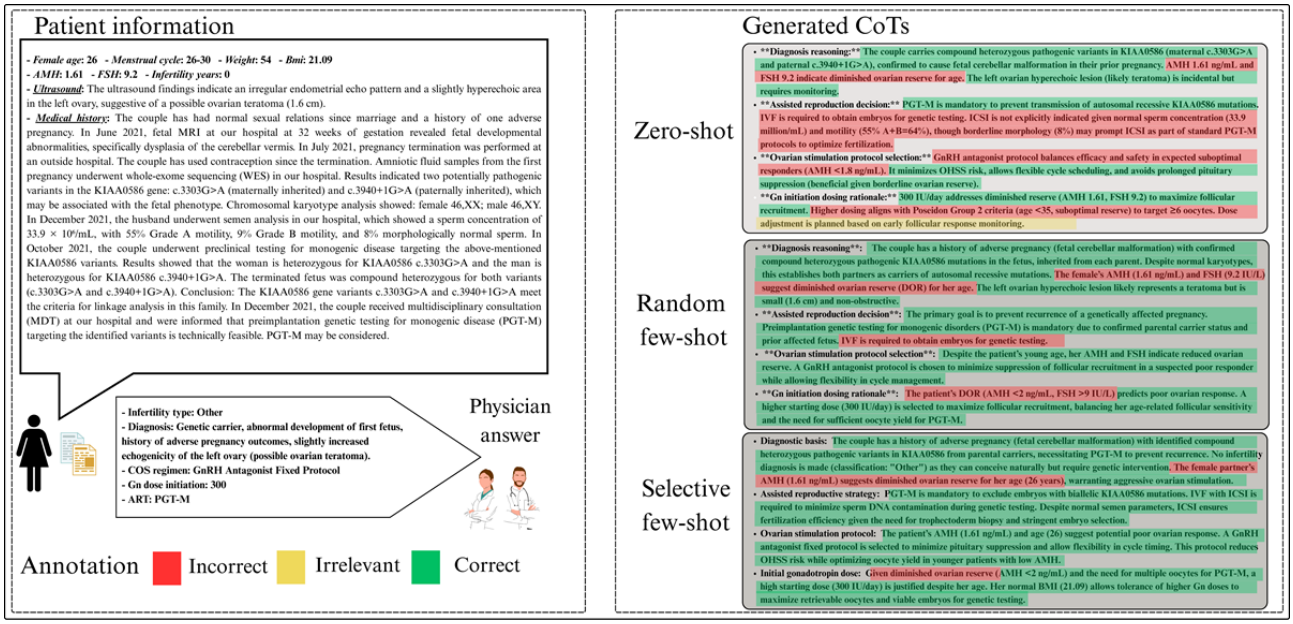


Table 5. Common reasoning errors in zero-shot and random few-shot chain-of-thought (CoT) outputs for a preimplantation genetic testing for monogenic disorder case.

Reasoning dimension	Flaws in zero-shot and random few-shot
Diagnosis reasoning	The model does not mention whether the patient has infertility issues.
Assisted reproduction decision	CoT incorrectly assumes that if the male's semen is normal, traditional IVF[a] can be used.
Ovarian stimulation protocol selection	The reason for choosing the antagonist protocol in CoT was "greater safety and avoidance of OHSS[b]," without considering the patient's specific circumstances (low AMH, first ovulation induction).
Initial gonadotropin dose	Only AMH[c] levels were considered, without taking into account weight, BMI, or PGT[d] goals (requiring more embryos).

[a]IVF: in vitro fertilization.

[b]OHSS: ovarian hyperstimulation syndrome.

[c]AMH: anti-Müllerian hormone.

[d]PGT: preimplantation genetic testing.

In this PGT-M case, both partners are carriers of a pathogenic variant in the KIAA0586 gene. During a previous pregnancy, the fetus was found to have a homozygous mutation in KIAA0586, resulting in abnormal brain development and subsequent pregnancy termination. Since then, the couple has been using contraception and therefore does not meet the criteria for an infertility diagnosis. This implies that they are still capable of conceiving naturally. Given the autosomal recessive inheritance pattern, there remains a possibility of achieving a normal or carrier embryo through natural conception. However, neither the zero-shot nor the random few-shot–prompted CoT generations mentioned the presence or absence of an infertility diagnosis, which appeared in the selective few-shot–prompted CoT.

To avoid the recurrence of a fetus with a homozygous mutation in KIAA0586, PGT-M is recommended. Due to the technical requirements of PGT, embryos must be obtained via ICSI to avoid DNA contamination during genetic analysis. While the zero-shot and random few-shot–prompted CoTs correctly reasoned the indication for PGT-M, they incorrectly concluded that ICSI was unnecessary because the male partner had normal semen parameters and suggested using conventional IVF instead—an error in clinical reasoning.

In selecting the ovarian stimulation protocol, clinical reasoning typically begins with evaluating the patient's ovarian responsiveness and any prior stimulation history. Although the patient is 26 years of age, her AMH level is only 1.61 ng/mL, suggesting a potential for diminished ovarian response. As this is her first controlled ovarian hyperstimulation cycle, a

gonadotropin-releasing hormone antagonist protocol was chosen for its controllability and to avoid excessive pituitary suppression. Among the 2 few-shot–prompted CoTs, the reasoning was more aligned with clinical thinking, while the zero-shot CoT emphasized the safety profile of the antagonist protocol (eg, avoiding ovarian hyperstimulation syndrome) without clearly reflecting clinical logic.

Regarding the initial gonadotropin dose, factors beyond ovarian responsiveness must be considered. Since this case involves PGT, it is important to optimize the number of oocytes retrieved. Additional considerations include the patient's weight and BMI, as these affect drug sensitivity. However, the zero-shot CoT mentioned only ovarian responsiveness, lacking a comprehensive rationale.

Feasibility Analysis of an AI Evaluator

As detailed in Table 6, the mean scores for all 3 prompting strategies were tightly clustered in a narrow and high-scoring range, between 3.96 and 4.00, suggesting that the model perceived all generated outputs as being of similarly high quality.

Table 6. Artificial intelligence (AI)–driven evaluation of chain-of-thought reliability across different prompting strategies[a].

Group	LCC[b], mean (SD)	PCAR[c], mean (SD)	UCKI[d], mean (SD)
Random few-shot	4.00 (0.00)	3.98 (0.14)	4.00 (0.00)
Selective few-shot	4.00 (0.00)	3.98 (0.16)	4.00 (0.07)
Zero-shot	4.00 (0.07)	3.96 (0.20)	3.98 (0.14)

[a]The high scores and minimal variation across all groups indicate a significant ceiling effect in the AI's evaluation. Paired comparisons between strategies were conducted using the Wilcoxon signed rank test; *P* values were adjusted using the Benjamini-Hochberg false discovery rate procedure.

[b]LCC: logical coherence and clarity.

[c]UCKI: use and coverage of key information.

[d]PCAR: plausibility and clinical accuracy of reasoning.

Inferential statistical analysis corroborated this observation. A series of Friedman tests found no statistically significant differences among the 3 groups for LCC (*P*=.37), PCAR (*P*=.37), or UCKI (*P*=.07). While a post-hoc pairwise Wilcoxon paired test identified a marginal statistical difference between the random few-shot and zero-shot groups on the information use dimension (*P*=.045), this isolated finding merits cautious interpretation, particularly, as the overall test for this dimension did not reach statistical significance.

Discussion

Principal Findings

This study critically evaluates the reliability of LLM-generated CoT reasoning in ART and shows that noncurated prompting methods are insufficient for clinical use. Both zero-shot and random few-shot strategies frequently produced reasoning errors, and random shallow examples offered no meaningful improvement over providing no examples at all. In contrast, the selective few-shot strategy, which is built on the principles of representative diversity and gold-standard depth, substantially improved coherence, information use, and clinical accuracy. These reliability gaps, as well as the strengths of the selective approach, were identifiable only through expert review; automated AI evaluators failed to detect these differences. Together, these findings outline a practical framework for evaluating ART reasoning quality and a feasible pathway for generating trustworthy synthetic clinical data.

The principle of representative diversity was clearly demonstrated in the PGT and ICSI subgroups. The findings provide empirical support for our initial hypothesis. The PGT category shows significantly higher scores, prompted by the selective few-shot approach, which includes an example of PGT-A treatment. The case study also shows errors in understanding and judgment in doctors' viewing, where zero-shot or random few-shot are more likely to make intrinsic mistakes. Notably, in the ICSI category, although the intergroup differences did not reach statistical significance when compared to the random few-shot group, we observed the same trend as in the PGT category—selective prompting consistently achieved the highest average scores and was significantly higher than zero-shot prompting, which had no difference with the random one. The analyses of both subgroups collectively suggest that a demonstration set covering key procedural subtypes within the domain is essential for enabling the model to evolve from a "specialist" to a "generalist."

Simultaneously, the principle of gold-standard depth was illustrated in the IVF subgroup. In our main results, we show that the quality of examples may influence the quality of generation. In subgroup analysis, we found that there is no significant difference between the zero-shot prompting and the random few-shot prompting on any subgroup, especially in the IVF subgroup, even if the random arm's sample cases indeed included 4 standard IVF and 1 short-protocol IVF. It performed ineffective learning under this situation. In this case, the reason may be attributed to the reasoning quality in the prompt. In the experiment design section, we mentioned that the random cases have a relatively concise CoT. This indicates that the LLM exhibits a strong tendency toward pattern imitation when engaging in in-context learning. A low-quality example tends to elicit correspondingly poor reasoning outputs, even if the model has huge potential in text generation. Therefore, this principle emphasizes that each few-shot example must serve as an expert-level exemplar: logically rigorous, richly detailed, and representative of ART strategy reasoning at the highest standard.

Comparison to Prior Work

Our findings align closely with a well-established principle in the broader AI research community: data quality often outweighs data quantity [36]. Our work provides domain-specific empirical support for the application of this principle in the reproductive medicine context of clinical CoT generation. More importantly, we go beyond simply affirming the importance of data reliability; we offer a concrete characterization of what high-quality examples mean in this setting, through our proposed dual principles of gold-standard depth and representative diversity. Together, these insights contribute a practical methodology for realizing data-centric AI specializing in reproductive medicine.

Another key finding highlights a critical limitation of current LLM-based evaluators in detecting subtle yet clinically meaningful variations in information use, logical rigor, and contextual accuracy. While our human expert assessments revealed substantial differences in reasoning quality across the 3 prompting strategies, the scores assigned by the AI evaluator (GPT-4o) showed no statistically significant differences between them across 3 metrics. This "ceiling effect" serves as a critical warning: in high-stakes medical applications, like ART strategy choosing, where patient safety is on the line, relying solely on automated evaluation for quality assurance is inherently risky. It reaffirms that domain expert oversight is not merely a "gold standard" for evaluation; it is an essential safeguard that cannot be replaced. Our results show that AI-based evaluation cannot be treated as a source of ground truth; all judgments involving factual accuracy, clinical appropriateness, or safety must rely on human experts. From a broader methodological perspective, the results underscore a growing challenge for the field. As the development of medical LLMs increasingly depends on large-scale synthetic data, evaluation may become the primary bottleneck. While models continue to improve in producing fluent clinical narratives, reliably detecting subtle but clinically meaningful reasoning errors remains far more difficult. Without dependable evaluators, synthetic or augmented clinical data cannot safely be incorporated into model training pipelines. Addressing this gap will require medically grounded evaluation frameworks, including domain-specific supervision signals, error-aware reward models, and structured representations of clinical logic. These capabilities are not yet captured by current general-purpose LLM judges, emphasizing the need for future research focused on building evaluators that meet the safety, sensitivity, and domain expertise required for clinical AI applications.

This study provides evidence within a single-center ART dataset, and further multicenter generalization is needed. Although we attempted to determine the reliability of AI-generated CoT in complex clinical cases, our cases are currently limited to reproductive medicine or ART treatment. To enhance generalizability and robustness, future research should include a more diverse set of complex clinical reasoning cases across different medical departments. This study has several limitations. First, all generations were produced using a single model (DeepSeek-R1), which restricts the external validity of the findings. Future studies will evaluate whether the advantages of the selective few-shot strategy generalize across different LLM families. Second, the use of temperature=0.5 introduces controlled stochasticity into the inference process; other decoding settings may produce output variations. To address this, future work will include sensitivity analyses across multiple temperature levels (eg, 0, 0.2, and 0.5) to assess the stability of reasoning patterns. In addition, all human evaluators were recruited from the same medical center, which may introduce institutional bias due to shared training backgrounds and practice standards. The AI-grader feasibility test also has limitations: the grader's sensitivity is partly dependent on its prompt design and model chosen, which may reduce its ability to detect subtle but clinically important differences within the reasoning block. Finally, the evaluation was conducted at the case level, and although the Likert-based rubric captures overall reasoning quality, subjective variability cannot be fully eliminated. Future work may incorporate sentence-level or error-type–specific analysis to support more objective and fine-grained identification of reasoning deficiencies. Given these constraints, this study should be interpreted as a vertical, domain-specific proof-of-concept, rather than a horizontal benchmark applicable across clinical specialties or model families. The selective few-shot strategy was examined within ART because it provides a well-defined and clinically coherent setting for studying structured reasoning, not because its performance should be assumed to generalize elsewhere. Whether the observed improvements reflect a domain-specific phenomenon or a more general pattern cannot be determined from this study. Future work will therefore focus on rigorously evaluating the approach across diverse clinical domains, datasets, and model families to assess its true generalizability. Beyond the constraints and limitations, an important consideration of this study is that the selective few-shot condition differed from the random condition not only in the conceptual selection principles but also in exemplar characteristics, including number, clinical depth, and ART subtype diversity, which creates a mixed signal. Although the numerical difference between 5-shot and 6-shot prompting is small, it may nonetheless introduce bias. More importantly, exemplar depth and subtype diversity were intentionally incorporated to construct a clinically coherent selective prompt, but these factors inherently covary in our current design. As a result, this study cannot attribute the observed improvements to any single component of the selective strategy nor determine whether the effect arises from exemplar depth, diversity, their interaction, or other uncontrolled influences. The findings should therefore be interpreted as exploratory and hypothesis-generating, rather than evidence of a validated mechanism. To address this joint pattern, future work will implement controlled ablation studies that (1) equalize exemplar number across conditions and (2) independently manipulate exemplar depth ("deep vs shallow") and subtype diversity ("diverse vs homogeneous"). Such studies will allow rigorous assessment of the independent and combined contributions of these factors to few-shot reasoning performance in clinical LLMs.

Our dataset contains 200 diverse cases, but for some subtypes, the number of cases may be too small for statistical analysis, particularly the PGT subgroup, which only included 22 samples. Although the post-hoc power calculation and *P* value correction were conducted, it still showed moderate effect sizes on part of

the comparisons. Accordingly, the subgroup findings should be interpreted as exploratory. A potential methodological improvement for future studies is the use of hierarchical partial-pooling or Bayesian shrinkage models, which may borrow strength across subgroups and produce more stable estimates under low-sample conditions. These models were not adopted in this study because our primary objective was descriptive comparison rather than multilevel estimation, but they represent a promising direction for future research. For future directions, given the limited context window of current LLMs, users may face an inherent trade-off when selecting few-shot exemplars, particularly in domains such as reproductive medicine where clinical presentations exhibit substantial subtype diversity. Balancing breadth and depth in exemplar selection becomes a critical challenge under these constraints. Recent work on dynamic prompting methods has sought to improve the performance-efficiency trade-off in resource-limited or accuracy-constrained settings [37], and incorporating such techniques may further enhance the practicality of selective prompting in clinical applications. In addition, future work will explore retrieval-augmented generation frameworks. Integrating authoritative domain sources (eg, American Society for Reproductive Medicine and European Society of Human Reproduction and Embryology guidelines) has the potential to improve factual grounding, reduce hallucination, and enhance explainability in ART-related clinical reasoning. Comparing closed-book reasoning with retrieval augmented generation augmented reasoning may clarify how access to external evidence shapes LLM decision-making and may improve the reliability of LLM-assisted clinical decision support tools.

Conclusions

The primary contribution of this study is 2-fold: an exploratory potential evaluation framework for how to evaluate and provide a methodology for a feasible approach and for how to generate trustworthy clinical ART reasoning steps in a single clinic center. First, we investigate a rigorous, domain-grounded framework for evaluating synthetic clinical reasoning within the ART strategy. Amid the rapid growth of AI in health care, we demonstrate that ensuring clinical validity requires moving beyond automated metrics. Our findings expose the critical limitations of SOTA AI evaluators (eg, GPT-4o) in detecting subtle but clinically vital reasoning flaws. This “ceiling effect” serves as a critical warning and highlights the indispensable role of structured, blind expert review as an essential safeguard in reproductive medicine AI development. Second, building on this evaluation framework, we offer a practical solution to the “explainability data bottleneck” in reproductive medicine. Through systematic comparisons, we show that a selective few-shot prompting strategy, which is based on the “dual principles” of gold-standard depth and representative diversity, substantially improves the quality and reliability of generated ART CoTs. This offers a feasible, cost-effective blueprint for generating trustworthy ART synthetic data at scale, without requiring immense annotated datasets. Finally, this study evaluates the clinical reliability of LLM-generated reasoning in the ART context as a step toward addressing data scarcity in explainable, domain-specialized AI development. However, our findings should not be interpreted as evidence that current LLMs are clinically safe or ready for autonomous use. Our evaluation focuses on reasoning quality, not deployment readiness. Establishing clinical go or no-go thresholds will require task-specific, prospective validation studies assessing safety, consistency, patient outcomes, and workflow integration—factors beyond the scope of this work.

Acknowledgments

The authors used the generative artificial intelligence (AI) tool to examine the potential use of LLMs in assisted reproductive technology. The authors declare the use of generative AI in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to generative AI tools under full human supervision: feasibility assessment and risk evaluation. The generative AI tools used were DeepSeek-R1-671B and ChatGPT4o. Responsibility for the final manuscript lies entirely with the authors. Generative AI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

The integration of medical open databases with artificial intelligence (AI) technologies marks a transformative era in biomedical research and health care innovation. Over the past 25 years, initiatives like PhysioNet have revolutionized data access, fostering unprecedented levels of collaboration and accelerating medical discoveries. This rise of medical open databases presents challenges, particularly in harmonizing research enablement with patient confidentiality. In response, privacy laws such as the Health Insurance Portability and Accountability Act have been established, and privacy-enhancing technologies have been adopted to maintain this delicate balance. Privacy-enhancing technologies, including differential privacy, secure multiparty computation, and notably,

federated learning (FL), have become instrumental in safeguarding personal health information. FL, in particular, represents a significant advancement by enabling the development and training of AI models on decentralized data. In Taiwan, significant strides have been made in aligning with these global data-sharing and privacy standards. We have actively promoted the sharing of medical data through the development of dynamic consent systems. These systems enable individuals to control and adjust their data-sharing preferences, ensuring transparency and continuity of consent in the ever-evolving landscape of digital health. Despite the challenges associated with privacy protections, the benefits, including improved diagnostics and treatment, are substantial. The availability of open databases has notably accelerated AI research, leading to significant advancements in medical diagnostics and treatments. As the landscape of health care research continues to evolve with open science and FL, the role of medical open databases remains crucial in shaping the future of medicine, promising enhanced patient outcomes and fostering a global research community committed to ethical integrity and privacy.

KEYWORDS

medical open databases; artificial intelligence; privacy-enhancing technologies; federated learning; dynamic consent systems

Introduction

The emergence of medical open databases, coupled with advances in artificial intelligence (AI), heralds a significant change in biomedical research and health care innovation, facilitating an era of enhanced accessibility and data sharing [1-3]. This movement toward open data science, augmented by AI technologies, enables researchers worldwide to access a wealth of data, including physiological signals [4,5], genomic [6], and health care information [7], and, most prominently, large-scale medical imaging archives. While this review covers the broad spectrum of medical data, the impact of open imaging databases has been particularly transformative for the application of AI. This movement toward open data science fosters collaboration and speeds up the pace of medical discoveries.

AI's role in analyzing vast datasets has been instrumental in uncovering patterns and insights that would be impossible for humans to detect unaided, leading to breakthroughs in understanding diseases and patient care. Initiatives like annual challenges and shared toolboxes have spurred the development of novel algorithms and techniques, leveraging AI to address complex biomedical challenges and advance medical diagnostics and treatments. This synergy between open medical databases and AI is transforming the landscape of health care, promising a future of more accurate, efficient, and personalized medicine.

Simultaneously, this rise in open data repositories brings to the forefront crucial privacy concerns [6,8]. The necessity to balance the imperative of research enablement with the protection of patient confidentiality has never been more pronounced. In this context, laws such as the Health Insurance Portability and Accountability Act (HIPAA) play a pivotal role in shaping the landscape of data deidentification and anonymization processes, ensuring that shared data comply with strict privacy standards [9]. Moreover, the introduction of privacy-enhancing technologies (PETs), such as differential privacy [10], synthetic data [11], homomorphic encryption [12], secure multiparty computation [13], and federated learning [14], represents a proactive approach to safeguarding personal health information. These technologies provide the means to conduct meaningful research while upholding the principles of data privacy and security.

In a country like Taiwan, strides in medical data sharing suggest the global shift toward interconnected health systems, highlighting both advancements and ongoing challenges in securing patient data. The implementation of dynamic consent frameworks reflects a growing recognition of the need for more flexible approaches to data privacy, particularly in an era of personalized medicine and digital health records [15]. As the landscape of medical research evolves with these developments, the interplay of data sharing, privacy, and technology continues to reshape the boundaries of what is possible in health care innovation, marking a critical junction in the journey toward more open, collaborative, and ethically responsible research environments.

This review aims to provide a 25-year perspective on the evolution of medical open databases, tracing their impact on biomedical research and health care innovation, and to examine how emerging PETs and data-governance frameworks, including dynamic consent systems, shape the ethical, technical, and collaborative landscape of digital medicine worldwide.

The Rise of Medical Open Database

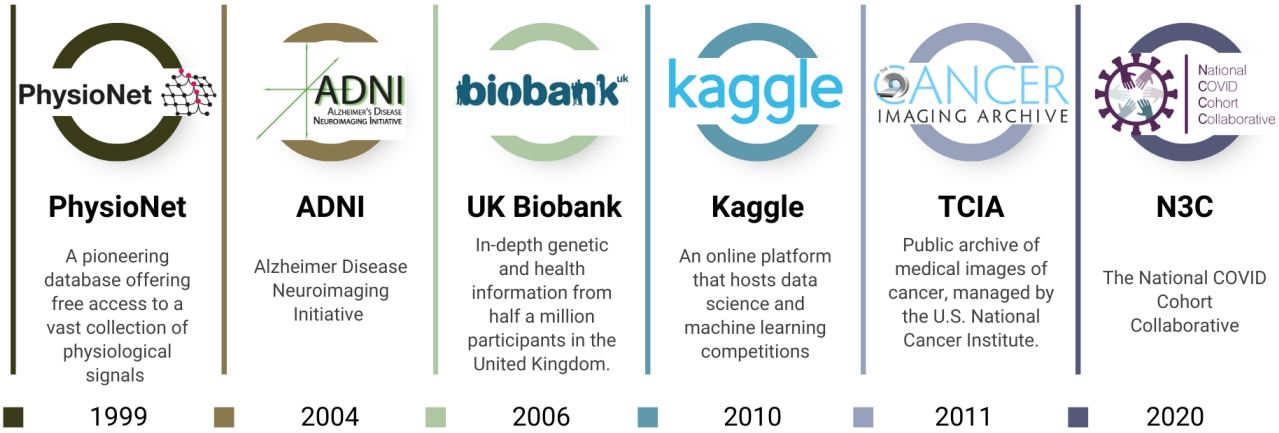
The rise of medical open databases represents a transformative shift in the landscape of biomedical research and health care innovation. Among the pioneers in this movement is PhysioNet. Established in 1999, PhysioNet is a pioneering open database that provides free access to a wide range of physiologic signals and related open-source software for research in medicine, physiology, and biomedical engineering [4,16]. It was initiated by a collaborative project involving researchers from Boston's Beth Israel Deaconess Medical Center/Harvard Medical School, Boston University, McGill University, and Massachusetts Institute of Technology [4,17]. The database contains a diverse collection of physiological datasets, including those related to cardiovascular and other complex biomedical signals [4,18]. PhysioNet has had a significant impact on the development of medical open databases, serving as a model for the establishment of similar resources. It has also played a key role in promoting the dissemination and exchange of medical resources.

A significant contribution of PhysioNet to the scientific community is its annual PhysioNet Challenge, which has markedly influenced the field by promoting innovation and collaboration among researchers and clinicians. These challenges

stimulate the creation of novel algorithms and methods aimed at solving complex biomedical problems, thus expanding the limits of what can be achieved in medical data analysis and application. For instance, the challenges have catalyzed the development of innovative algorithms capable of detecting obstructive sleep apnea from electrocardiograms [19], illustrating the practical impact of these competitions on advancing medical diagnostics and treatment strategies [20].

Since the success of PhysioNet, numerous other medical open databases have emerged globally, fostering a more cooperative and transparent research atmosphere (Figure 1). The impact of these large-scale databases on biomedical discovery is profound. One notable example is the UK Biobank [21], launched in 2006, which provides a vast repository of genetic and health information from half a million UK participants. This database has become an essential tool for unraveling the complex interplay between genetics, lifestyle, and disease, thereby enhancing our understanding of the factors influencing human health [22-25]. By leveraging large neuroimaging cohorts such as Alzheimer Disease Neuroimaging Initiative and the UK Biobank, researchers have developed AI-based models that generate an Alzheimer disease risk score from structural magnetic resonance imaging (MRI), enabling the identification of prediagnostic populations suitable for early intervention and preventive trials [26]. In cardiovascular research, analysis of the UK Biobank's genetic and imaging data has enabled the development of NeuralCVD, a neural network–based risk model that integrates polygenic and clinical predictors to estimate the 10-year risk of major adverse cardiac events, improving risk discrimination and reclassification beyond established clinical scores and Cox models, and highlighting the added predictive value of genetic predisposition in early prevention [27]. Similarly, the Cancer Imaging Archive, inaugurated in 2011 in the United States, offers a dedicated platform for the cancer research community, enabling access to a comprehensive array of imaging datasets [28].

Figure 1. Historical development of major medical open databases and data-sharing platforms over the past 25 years.



Beyond these examples, the ecosystem of medical open databases has diversified into numerous specialized domains. For instance, OpenNeuro provides a vast repository for neuroimaging data, particularly functional magnetic resonance imaging, electroencephalogram, and magnetoencephalography, supporting reproducible brain research [29]. The Neuroimaging Informatics Tools and Resources Clearinghouse offers a rich collection of imaging and data-processing tools [30]. Similarly, the National Database for Autism Research [31] and the Federal Interagency Traumatic Brain Injury Research informatics system [32] provide deeply phenotyped datasets crucial for research in their respective fields. These platforms underscore the field's shift toward creating specialized, high-quality resources to tackle specific biomedical questions. They display how shared resources can drive forward innovation and improve patient care worldwide, illustrating the critical role of collaborative environments in the advancement of health care research and application.

Additionally, Kaggle, an online platform for data science and machine learning (ML) competitions, has emerged as a pivotal player in the field of ML analysis and data sharing [33]. Launched in 2010, Kaggle facilitates collaboration and competition among data scientists and researchers by hosting challenges in various domains, including health care. These competitions often involve complex medical datasets, encouraging participants to develop innovative solutions and algorithms for disease prediction, medical imaging analysis [34], and other health-related issues. Kaggle has not only democratized access to large medical datasets but has also fostered a global community where knowledge and techniques are openly shared. This environment has led to significant breakthroughs and advancements in medical research and analytics, further suggesting the importance of open data and collaborative problem-solving in improving health care outcomes and accelerating medical innovation.

Balancing Privacy and the Need for Medical Open Databases

The success of open medical databases such as PhysioNet poses the challenge of balancing patient confidentiality with research enablement on open platforms [35,36]. Research datasets in health care often contain protected health information (PHI), and the process of removing this information, a process known as deidentification or anonymization, can be challenging and prone to errors [37]. Despite the use of these datasets, the need for deidentification introduces a significant barrier to data sharing due to the effort and cost involved.

The HIPAA, established in the United States in 1996, plays a vital role in safeguarding patients' medical information. In response to the HIPAA mandate, U.S. Department of Health and Human Services published a final regulation in the form of the privacy rule in December 2000, which became effective on April 14, 2001. Central to this rule is the designation of 18 specific categories of PHI that, if disclosed, could be used to identify an individual (Textbox 1). These categories encompass a broad spectrum of personal data, including, but not limited to, names, geographic details smaller than a state, various identifiers like social security numbers, medical record numbers, and contact information, as well as certain biometric and photographic images [38].

Textbox 1. Eighteen categories of protected health information.

- Names
- All geographic subdivisions smaller than a State
- All elements of dates (except year) for dates directly related to an individual
- Telephone numbers
- Fax numbers
- Electronic mail addresses
- Social security numbers
- Medical record numbers
- Health plan beneficiary numbers
- Account numbers
- Certificate/license numbers
- Vehicle identifiers and serial numbers
- Device identifiers and serial numbers
- Web URLs
- IP address numbers
- Biometric identifiers, including finger and voice prints
- Full face photographic images and any comparable images
- Any other unique identifying number, characteristic, or code

Additionally, HIPAA mandates that covered entities must ensure they do not possess knowledge that the remaining information could be used, whether alone or in conjunction with other data, to identify the subject. By strictly adhering to these guidelines, entities can share deidentified health information for broader uses, such as public health and research, without infringing on individual privacy rights, thus striking a balance between privacy protection and the beneficial use of health data [39]. Despite these efforts, the tension between the promise of big data and patient privacy in health care research remains a challenge [40].

PhysioNet is a pioneer in medical public databases, ensuring that the datasets it provides do not compromise individual privacy. This involves ensuring that any data shared does not contain PHI or has been sufficiently anonymized to prevent the identification of individuals. The challenges posed by the HIPAA privacy rule are not insignificant; they include the need for informed consent from data subjects and potential limitations on access to health information that can hinder clinical research [41,42]. Furthermore, the rule's interaction with other regulations, like the common rule, adds complexity to privacy concerns in research, leading to inconsistencies and additional burdens for researchers.

Despite these challenges, the privacy rule does allow for certain disclosures without patient authorization, particularly for public health purposes. This is intended to facilitate the use of medical data in important public health endeavors without undermining individual privacy protections [43]. The balance sought by the HIPAA privacy rule between protecting privacy and facilitating research is a critical aspect of its implementation, particularly in the context of medical open databases. By navigating these regulations successfully, repositories can contribute to the advancement of medical research while ensuring compliance with privacy standards [44].

The emergence of medical databases, such as the PhysioNet, UK Biobank, and the Cancer Imaging Archive, has significantly advanced collaborative research in health care [45,46]. These databases have the potential to transform cancer research and improve patient outcomes [45]. However, the collection, linking, and use of data in biomedical research raise ethical concerns, particularly regarding privacy and security [36,47,48]. Despite these concerns, the benefits of open data in health care, including improved diagnostics and treatment, are substantial [48]. The push for data sharing in cancer trials by pharmaceutical companies further underscores the importance of open medical databases in driving innovation and improving patient care [49].

Privacy Enhancing Technology

Overview

A range of studies have been conducted to explore the increasing frequency and impact of health care data breaches, highlighting the rising number of incidents and their detrimental effects on patient privacy and health care providers [50-53]. These breaches are often caused by a combination of technical, organizational, and human factors [50-52]. Human vulnerabilities, such as lack of awareness and training, play a significant role in these breaches [51]. The use of the Swiss Cheese Model can help assess vulnerabilities and risks [50]. Cloud computing breaches are a particular concern, highlighting the need for digital forensic readiness [54]. Hacking and unauthorized internal disclosures are the most prevalent forms of attack [53]. Further studies may examine specific cases and the implications for digital forensic readiness, emphasizing the importance of adhering to regulations.

Below, we reviewed several PETs and their applications in enhancing data privacy and security in health care settings (Table 1). PETs, such as encryption, anonymization techniques, and secure multiparty computation, offer powerful mechanisms to protect sensitive health data. Implementing these technologies, alongside robust privacy policies and employee training, can significantly reduce the likelihood of data breaches and bolster the trust between patients and health care providers.

Table . Summary of privacy-enhancing technologies.

Technologies	Core principle	Advantages	Challenges and trade-offs
Differential privacy	Adds calibrated statistical noise to query results to make it impossible to determine if an individual's data were included.	Provides strong and mathematically provable privacy guarantees.	Inherent trade-off between privacy and data use; high privacy can reduce analytical accuracy.
Synthetic data	Creates an artificial dataset that mimics the statistical properties of the original data without containing real patient information.	High use for model training; no real patient data are shared, eliminating reidentification risk.	Can be difficult to generate high-fidelity data that captures all complex correlations; potential for model bias.
Homomorphic encryption	Allows computations to be performed directly on encrypted data without decrypting it first.	Offers extremely strong security, as the raw data are never exposed.	High computational overhead; currently too slow for many complex ML[a] tasks.
Secure multiparty computation	Enables multiple parties to jointly compute a function over their inputs while keeping those inputs private.	Allows for collaborative analysis without a central data repository; no single party sees another's data.	High communication overhead between parties; can be complex to set up and scale.
Federated learning	Trains a central AI[b] model across decentralized devices or servers holding local data samples, without exchanging the data itself.	Keeps raw data local, enhancing privacy and data sovereignty.	Vulnerable to model poisoning/inversion attacks; performance can degrade with heterogeneous data.

[a]ML: machine learning.

[b]AI: artificial intelligence.

Differential Privacy

Differential privacy, a method for protecting individual privacy in data analysis, has been increasingly applied in the health care sector. It involves adding noise to the data to prevent reidentification of individuals. This approach has been used in various areas of health research, including genomics, neuroimaging, and health surveillance [55]. However, there are challenges in its practical application, such as the theoretical nature of the privacy parameter epsilon [56]. To address these challenges, researchers have proposed differentially private data release strategies and noise mechanisms, such as the Laplace and exponential mechanisms [57]. However, a key challenge is the inherent trade-off between privacy and data use; increasing the amount of statistical noise to protect privacy can reduce the accuracy of analytical outcomes.

The application of differential privacy in medical questionnaires has also been explored, with the randomized response mechanism showing promise in improving privacy while retaining data use [58]. Furthermore, the use of differential privacy in geospatial analyses of standardized health care data has been demonstrated, with the development of geodatabase functions for privacy-aware analysis [59]. Finally, the combination of differential privacy and decision tree approach has been proposed for data publishing, and the differentially private mini-batch gradient descent algorithm for model publishing of medical data [60].

Synthetic Data

Synthetic data, generated through simulators, is increasingly used in health care to address the challenges of data availability and privacy [61]. PETs, such as differential privacy, are combined with synthetic data generators to create private synthetic data, preserving statistical properties while ensuring privacy [62]. These technologies have been applied in various use cases, including clinical risk prediction [63] and medical research [64]. However, the evaluation of synthetic data's privacy and use metrics remains a challenge, with a lack of consensus on standard approaches [65]. Despite these challenges, the potential of synthetic data in preserving data use

and patient privacy in electronic health care data is being explored [66].

Homomorphic Encryption

Homomorphic encryption, a powerful tool for preserving privacy in medical data, allows for computations to be performed on encrypted data without the need for decryption. It has been successfully applied in various medical data scenarios, including ML models for classification and training, secure genomic algorithms, and predictive analysis tasks [67-69]. For example, it has been used to securely manage personal health metrics data, process medical images [70,71], and enable secure medical computation [72]. The use of homomorphic encryption in these applications ensures that sensitive medical data remains private and secure. Despite its power, the primary limitation of homomorphic encryption is its significant computational overhead, which can make it slow and resource-intensive for complex computations on large datasets.

Secure Multiparty Computation

Secure multiparty computation is a cryptographic technique that enables data analytics without sharing the underlying data, making it a valuable tool for preserving privacy in medical data analysis [73]. It has been applied in various health care scenarios, including collaborative systems [74], statistical analysis of health data [75], and electronic medical record (EMR) data [75]. Secure multiparty computation has also been used in health care internet of things systems to handle privacy issues [76], prevent data disclosure in sensor networks [77], and enable the reuse of distributed electronic health data [75]. Furthermore, it has been applied to enable privacy-preserving query processing on EMRs [78]. Notably, secure multiparty computation has enabled research on highly sensitive data (such as HIV, rare diseases, and population genomics) that would otherwise be inaccessible due to privacy concerns.

Federated Learning

Federated learning (FL), a decentralized ML approach, is increasingly being applied in the medical field due to the sensitive and fragmented nature of health care data [14,79]. It allows for the collaborative development of ML models without sharing raw data, thus preserving privacy [80,81]. This approach has been used in various medical domains, including oncology and radiology, for tasks such as image analysis and disease prediction [81,82]. However, there are challenges to be addressed, such as data homogeneity and transparency [81]. Furthermore, FL can be vulnerable to security risks, such as model inversion attacks that attempt to reconstruct training data from the shared model updates, and require careful design to ensure robustness. Despite these challenges, FL shows promise in improving the efficiency and privacy of medical data processing [83-85].

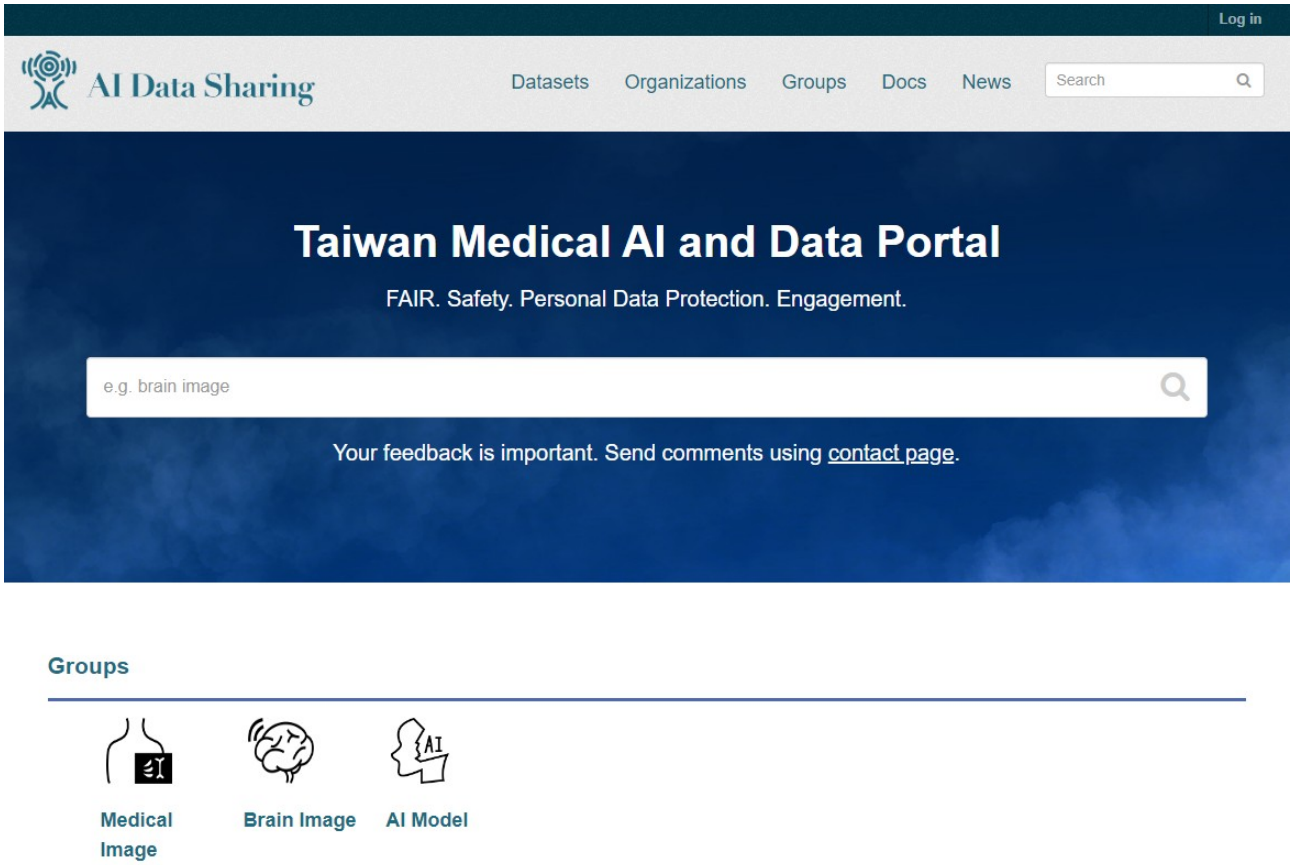
To address the challenge of data heterogeneity in FL, we have proposed the Dynamically Synthetic Images for Federated Learning method, significantly improving the conventional FL framework by integrating local information from local multiple institutions with heterogeneous data types [86]. The core principle of its implementation involves a dynamic process where, at the start of each training round, a client's local data are evaluated by the current global model to identify misclassified images. Using a synthetic minority oversampling technique, the system generates new, synthetic images based on these misclassified cases, which are then added to the local training set to compel the model to focus on features it previously failed to learn. In terms of effectiveness, experimental results demonstrated that Dynamically Synthetic Images for Federated Learning-based models achieve higher accuracy than conventional FL approaches and that their performance can be comparable to that of traditional centralized learning, proving especially beneficial for institutions with smaller or more heterogeneous datasets [86].

Taiwan Medical AI and Data Portal and Dynamic Consents System

Taiwan has made significant strides in medical data sharing, particularly in the areas of privacy protection and electronic health records exchange. The country's comprehensive embedded integrated circuit-based health insurance card system, implemented by the Bureau of National Health Insurance, Taiwan, allows for the secure sharing of health information [87]. The use of blockchain technology has been proposed as a means to further enhance the security and privacy of medical data sharing [88,89]. The Taiwan Electronic Medical Record Template and the National Electronic Medical Record Exchange System have been developed to facilitate the exchange of EMRs [90,91]. However, concerns about unauthorized access and secondary use of EMRs persist, particularly among highly educated individuals [92]. The country has also established guidelines for the security and privacy protection of health information, drawing on international best practices [93].

In the past 4 years, funded by the National Science and Technology Council of Taiwan, we have assembled teams from National Yang Ming Chiao Tung University, Taipei Veterans General Hospital, Academia Sinica, and National Taipei University of Nursing and Health Sciences to form a data repository task force known as the Smart Medical AI and Repository Taskforce Center. We launched a medical AI and data-sharing platform aimed at advancing the field of medical AI research in October 2023 [94]. This platform not only provides the public and researchers with access to a multitude of shared datasets but also ensures a meticulous evaluation process (Figure 2). Researchers can apply for access to the data by providing an abstract of their research proposal. Dataset managers assess applications based on their intended use, specific needs, and detailed research plans.

Figure 2. Taiwan medical artificial intelligence and data portal. AI: artificial intelligence.



Currently, seventeen datasets have been released on the platform, covering neuropsychiatric disorders, brain tumors, ophthalmic diseases, musculoskeletal disorders, and cardiopulmonary diseases. All datasets have undergone deidentification and delinking processes and include annotated information to facilitate AI training and validation. Specifically, our data-sharing platform includes: MRI images of vestibular schwannoma; computed tomography (CT) images of intracerebral hemorrhage; brain Fluorodeoxyglucose-Positron Emission Tomography/Magnetic Resonance Imaging images for dementia diagnosis; primary brain tumor MRI datasets, including meningioma, glioma, and pituitary adenoma; MRI data of brain metastases, which represent the largest collection nationwide; hand and foot X-rays of rheumatoid arthritis; X-rays of compression fractures; spinal X-rays of ankylosing spondylitis; chest CT images and clinical data of atrial fibrillation patients; chest X-rays for lung cancer screening; annotated preoperative liver CT images; neck lymph node CT images with postoperative pathology results; the Taiwan Aging and Mental Illness Cohort brain imaging database; the dementia molecular imaging database; fundus image datasets for glaucoma; and fundus image datasets of polypoidal choroidal vasculopathy.

The data sharing platform is built on a comprehensive architecture designed to support AI research by integrating 3 core systems: a CKAN-based sharing platform for dataset management, a data application system, and a dynamic authorization consent platform for patient privacy. Specific features include a robust user authentication and authorization mechanism, allowing dataset managers to grant access to specific users or collaborators. The platform ensures data integrity and ethical compliance through a multistep deidentification process for all medical images and by linking to the dynamic consent system (for sensitive clinical data), which allows patients to manage their data sharing preferences in real-time. To use the database, researchers first search for datasets on the platform, then apply for access through a formal registration and review process. Once approved and authorized by the dataset manager, users can obtain a login key to programmatically access the data through standardized protocols, such as DICOMweb, ensuring a secure, convenient, and interoperable environment for third-party AI applications.

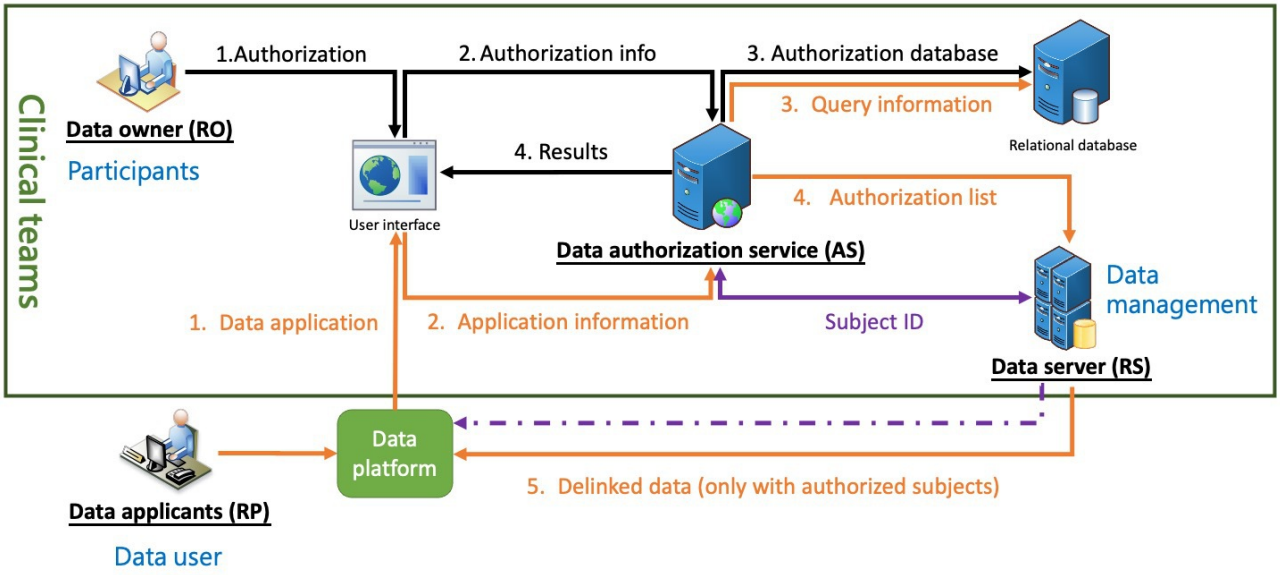
This effort aims to advance research across 7 crucial clinical areas that greatly benefit from AI technology, including heart disease, neurological disorders, mental illness, diabetes, cancer, genetic predispositions to complex diseases, and medical imaging. Moreover, the platform underpins collaboration between distinct teams specializing in AI methodology, science and law, and data governance, jointly fostering a robust data governance framework that emphasizes FL, cloud-based AI solutions, and trusted AI practices. Importantly, the system is designed to streamline the research process while maintaining a focus on ethical standards and participant privacy. In line with this, the platform incorporates a dynamic informed consent mechanism, especially for datasets that are anonymized but cannot be completely separated from their sources. This approach ensures that participants' privacy is safeguarded while also enabling their informed and ongoing consent, reflecting

our commitment to ethical research practices and the dynamic nature of consent in medical studies.

Dynamic informed consent, a concept that has been explored in various contexts, is a personalized, digital communication interface that allows participants to manage their consent preferences [95]. It has been proposed as a solution to improve patient confidence and trust in the use of electronic patient records in medical research [96]. In the context of privacy-aware pervasive health and well-being, dynamic consent enables granular data consent and management [97]. It has also been suggested as a potential solution to challenges in modern biomedical research, including participant recruitment, informed consent, and consent management [98]. The use of blockchain technology has been proposed to enhance the privacy-preserving aspects of dynamic consent in genomic data sharing [99]. The concept of dynamic informed consent has been further explored in the context of personalized medicine, emphasizing the need for a more dynamic and enriched consent model [100].

To enhance the privacy of participants contributing to the data in our platform and increase participants' engagement, we have developed a dynamic informed consent system, named the Health Data Authorization Service Platform (Figure 3). This collaborative effort involves our data governance, humanities, science and law, and clinical teams, aiming to facilitate scalable, dynamic consent operations suitable for complex data environments. The platform supports flexible data governance, allowing data owners to dynamically express their consent preferences, thereby making dynamic consent practical and sustainable.

Figure 3. Health data authorization service platform. This diagram depicts the architecture of a medical data-sharing platform that integrates dynamic consent for secure and transparent data sharing. The system centers on 4 key roles: the resource owner (RO), who owns the data; the resource server (RS), where medical data are stored and managed; the requesting party (RP), typically researchers seeking data access; and the authorization server (AS), the core component facilitating connections among the roles. This framework ensures data access is based on explicit consent from the data owner, allowing real-time adjustments to consent settings for different data types and uses, such as academic research. The platform's primary tasks are to establish individual preferences, maintain consent history, and ensure trust and transparency between data owners and users, thereby advancing responsible data science development.



The platform's architecture encompasses 4 key roles: the resource owner, usually the participants, who owns the data; the resource server, which stores and manages medical data; the requesting party, typically researchers seeking data access; and the authorization server, the backbone of our dynamic consent system, connecting the 3 roles. This system ensures that data are accessed only with the owner's express consent, respecting their preferences and enhancing data use transparency. Resource owners can modify their consent settings at any time, reflecting changes in their willingness to share different data types, like EMRs or medical imaging, for specific purposes such as academic research. This flexibility ensures that data use aligns with the owners' current preferences. The platform seamlessly integrates with our shared data framework, maintaining each citizen's consent history and enabling swift updates to consent forms as needed. By streamlining the consent process and ensuring data are shared according to owner permissions, our platform respects individual preferences while promoting responsible data science development. It exemplifies a forward-thinking approach to data governance, enabling real-time adjustments in consent and fostering a culture of trust and transparency between data owners and users.

These initiatives in Taiwan can be understood within the global context of evolving data privacy regulations. Unlike the "one-time, broad consent" model often used in US-based research under the Common Rule, Taiwan's move toward dynamic consent aligns more closely with the principles of the European Union's General Data Protection Regulation [101]. The General Data Protection Regulation mandates that consent must be specific, informed, and easily revocable. The dynamic consent system builds on this by providing a technological interface for participants to manage their preferences granularly and continuously, representing a best-practice approach to balancing research needs with individual autonomy and privacy rights.

Acceleration of Medical AI Research Through Open Databases

The advent of medical open databases has significantly accelerated the field of medical AI research, fostering an environment of innovation and rapid development [102]. By providing researchers with access to vast amounts of health-related data, these databases have become a cornerstone for advancements in predictive analytics, diagnostic algorithms, and personalized medicine.

One of the most notable contributions of open medical databases to AI research is the democratization of data [103]. Historically, the scarcity and inaccessibility of medical data posed substantial hurdles to AI development. However, platforms like PhysioNet, established in 1999, have bridged this gap by offering a plethora of datasets ranging from physiological signals to clinical outcomes [104]. However, challenges remain, including the need for large datasets and the lack of external validation in perioperative medicine [105]. The use of open science approaches, including data liberation and crowdsourcing, can help address these challenges [106]. The integration of networked medical devices and clinical repositories based on open standards can further enhance AI research in high-acuity medical environments [107]. This enhanced availability allows researchers from diverse backgrounds and institutions to engage in health care innovation, leveling the playing field and stimulating a surge in AI-based solutions.

The availability of open databases has catalyzed the application of diverse AI methodologies to complex medical problems. Deep learning, particularly convolutional neural networks, has achieved state-of-the-art performance by leveraging large-scale imaging datasets; for example, researchers have trained convolutional neural networks on millions of images from The Cancer Imaging Archive to develop algorithms capable of detecting and classifying tumors in radiological scans with accuracy comparable to human experts [108]. For structured data such as the genetic and clinical information in the UK Biobank, traditional ML models like random forests and gradient boosting have been widely used, excelling at identifying complex patterns to predict disease risk, including the calculation of polygenic risk scores for coronary artery disease based on thousands of genetic variants [109]. In addition, natural language processing techniques have been applied to large repositories of unstructured clinical notes, such as those in the Medical Information Mart for Intensive Care version IV (MIMIC-IV) database (part of PhysioNet), to extract critical information on symptoms, treatments, and outcomes, thereby enabling large-scale retrospective studies that were previously infeasible [110].

Open medical databases encompass a wide variety of data types, including EMRs, imaging, genomic sequences, and more. This diversity enables AI researchers to explore multifaceted health care questions, from predicting disease trajectories to optimizing treatment plans. Moreover, the rich, varied datasets facilitate the training of more robust and generalizable AI models, capable of addressing complex medical scenarios across different populations and settings. The shared nature of open databases fosters collaboration across the global research community [111]. Through platforms that offer shared data, researchers can combine their expertise to tackle larger and more complex problems than they could individually. This collaborative approach has led to significant breakthroughs in AI, such as algorithms that can detect diseases from images with accuracy rivaling that of trained professionals [112,113].

Open databases also streamline the validation and implementation phases of AI development [114]. Access to diverse datasets enables researchers to rigorously test their algorithms under various conditions and patient demographics, ensuring their reliability and effectiveness. The expansion of these databases has significantly propelled medical AI research forward, marking a new phase of health care innovation with faster discoveries, collaborative efforts, and a commitment to ethical data use. As the field evolves, the role of open databases in shaping the future of medicine remains pivotal.

Conclusions

In conclusion, the evolution toward medical open databases, exemplified by the inception of platforms like PhysioNet in 1999 and their progression over the past 25 years, alongside the integration of PETs, marks a significant milestone in the domain of biomedical research and health care innovation. This journey not only fosters an unprecedented level of collaboration and accessibility but also emphasizes the crucial need to address privacy concerns and ethical considerations diligently. The ongoing efforts to balance data sharing with individual privacy protection are underscored by the adaptation of legal frameworks and the implementation of cryptographic and data management solutions. The introduction and growth of medical open databases have been pivotal, providing a wealth of data that has propelled research and innovation while highlighting the challenges and responsibilities of managing sensitive information. Specifically, the availability of open medical databases has significantly accelerated AI research, leading to breakthroughs in disease prediction, diagnostics, and personalized medicine. As we continue to explore the vast potential of open science and FL, the landscape of health care research is on the brink of remarkable transformations. These advancements promise enhanced patient outcomes, faster medical discoveries, and a more inclusive global research community, all achieved by adhering to the highest standards of privacy and ethical integrity.

Acknowledgments

The authors thank Dr Watson Lin for supporting the infrastructure of the data-sharing platform and for providing valuable perspectives on the guidelines for medical data sharing. The authors also thank the National Science and Technology Council for offering legal insights on privacy policies related to medical data sharing.

Funding

This work was supported by grants from the National Science and Technology Council, Taiwan (grant number NSCT 114-2634-F-A49-006 and 113-2634-F-A49-003). ACY was also supported by the Mt. Jade Young Scholarship Award from the Ministry of Education, Taiwan, as well as Brain Research Center, National Yang Ming Chiao Tung University, and the Ministry of Education (Aim for the Top University Plan), Taipei, Taiwan.

Abstract

Digital innovations hold immense potential to transform health care delivery, particularly in sub-Saharan Africa, where financial, geographical, and infrastructural constraints continue to hinder progress toward universal health care delivery. Although a growing health tech sector offers creative solutions, few digital health interventions reach scaled implementation. In this paper, we present the digital fit/viability model—an adapted determinant framework to describe facilitators and barriers to moving from digital tools to integrated digital health implementation. We then use this model to describe the specific challenges and recommended solutions when developing digital health tools for health systems in sub-Saharan Africa.

KEYWORDS

digital health; Africa; digital health solutions; digital technologies; health care access; fit/viability model

Introduction

Digital tools can improve health care delivery and enhance health outcomes by addressing long-standing challenges in health care access, quality, and efficiency [1]. This potential is particularly salient in sub-Saharan Africa, where persistent barriers to health care, including inadequate infrastructure, workforce shortages, and resource limitations, could be alleviated or entirely bypassed with digital health interventions [2,3]. There are notable examples of scaled digital health interventions in sub-Saharan Africa. For example, District Health Information Software 2, a digital informatics platform operating in 40 countries, facilitates electronic data entry at health facilities, making information available for surveillance and program monitoring in near real time [4]. Zipline offers a digital platform for immediate order and drone-led distribution of health products in Rwanda [5]. In Kenya, M-TIBA allows users to access their health insurance through a mobile payment technology called m-pesa [6]. However, despite some successes, the digital health field suffers from "pilotitis," where the vast majority of digital interventions do not move beyond the pilot phase [7].

Over the last decade, the World Health Organization (WHO) and the World Bank have issued several policy documents outlining priority areas for digital interventions, as well as identifying systems gaps that need to be addressed for digital health interventions to achieve their full potential [8-11]. However, these documents do not systematically specify the facilitators and barriers that affect the progression of a specific digital health tool from concept to implementation. Drawing from our experience in developing, researching, and implementing digital health interventions in sub-Saharan Africa, we introduce the digital fit/viability model (dFVM) for health. This model adapts the fit/viability model developed by Liang et al [12] for the use of mobile technology in business and is an example of an implementation science determinant framework to describe the facilitators and barriers that influence implementation outcomes. In this paper, we explain how this model can be adapted for digital health interventions and use dFVM to illustrate challenges specific to sub-Saharan Africa as well as the potential solutions.

Positionality Statement

This work is the result of a 2-day convening of a multidisciplinary group of clinicians, researchers, technologists, entrepreneurs, policymakers, and health delivery service providers. The group included individuals with experience in Ghana, Kenya, Nigeria, Rwanda, Tanzania, Uganda, United States, and United Kingdom, and spanned different age groups, ethnicities, genders, and professional experience; all had experience of working within the African digital health ecosystem. The group held the shared perspective that digital tools have the potential to transform health care in sub-Saharan Africa. From this perspective, we discussed challenges to the implementation of digital innovations in these contexts and strategies to develop, evaluate, and scale context-appropriate and sustainable digital health solutions.

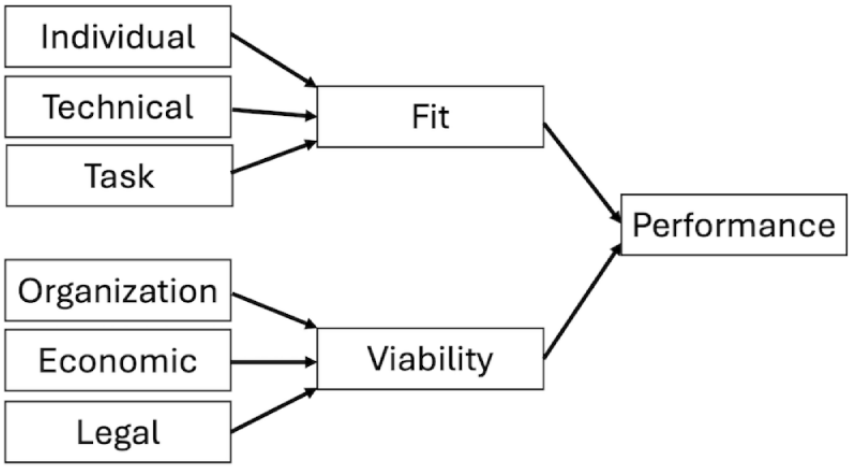
Digital Tools, Interventions, and Implementation

Here, we define digital health tools, interventions, and implementation to clarify the role of dFVM. Digital health tools encompass a variety of technology-enabled products and services developed to improve health care services [13]. Broadly, digital health tools have been categorized into virtual interactions (such as platforms for teleconsultations), paperless data (such as electronic health records), patient self-care (such as mobile apps to support chronic disease management), patient self-service (such as e-booking platforms), decision intelligence systems (such as hospital patient flow management systems), and workflow automation (such as medical equipment tracking systems using radiofrequency identification) [13]. Digital health interventions refer to the services, practices, and strategies that utilize digital health tools. For example, Zipline is an intervention that engages a cluster of digital tools—drones, online ordering systems, etc—to facilitate timely order-to-delivery of health products. Finally, digital health implementation involves integrating a digital health intervention into broader health care delivery. For instance, the successful deployment of Zipline is embedded within the larger health care framework, where the ordered health products are identified as part of patient care and delivered accordingly, outside of the Zipline system itself. Despite a surge in digital health tools over the past decade, few have successfully been integrated into interventions, and even fewer digital health interventions have achieved widespread, sustained implementation into health care systems, particularly in sub-Saharan Africa [1].

The Fit/Viability Model

Liang et al [12] developed the fit/viability model in 2007 to support the adoption of new technology in the business sector [14]. In this original framework, "fit" evaluates how well a technology aligns with its intended environment, while "viability" assesses whether the technology can be feasibly implemented given the organization's constraints. Both fit and viability are essential for a technology to succeed at scale within a business. These overarching "fit" and "viability" questions have been valuable for our team when developing digital health tools as part of complex interventions in sub-Saharan Africa. In the next section, we explain how we adapted Liang et al's [12] framework and incorporated additional subdomains to create dFVM for health (Figure 1; [15]).

Figure 1. The digital fit/viability model (adapted from Liang et al [12], which is published under Creative Commons Attribution 4.0 International License [15]).



dFVM Concept

Defining the "Fit" of Digital Health Tools

Similar to that defined by Liang et al [12], we define "fit" as the appropriateness of a digital health tool in a specific setting as part of a specific intervention. Generally, we are asking questions such as "Who will be using this digital health tool?", "What is this digital health tool designed to do?", and "Does this digital health tool align with the organizations aims?" (Figure 1). These questions are best addressed in the early design and conception stages. Although these fit concepts are important for a digital health tool in any context, the particular challenges in sub-Saharan Africa require deeper exploration of these questions.

Individual Fit

Individual fit, which was not included in the original fit/viability model, assesses whether the digital health tool is appropriate for those who engage with the tool. This category emphasizes that technologies should be designed with end users in mind.

Challenge

In sub-Saharan Africa, one particular challenge for individual fit is the varied levels of digital literacy [16,17] and access to digital platforms [9,18]. For example, a digital intervention that requires a patient to have a smartphone to engage with an app may fail either because the patient does not own a phone and/or because the patient is not comfortable navigating a digital App.

Solution

As a first step, anyone developing a digital tool should conduct end user digital accessibility assessments, including assessing digital literacy, device ownership, and access to other system requirements such as cell networks or electricity. There are numerous tools to assess digital literacy [14], but few are designed specifically for a sub-Saharan African context. One alternative is to outline the gaps in device ownership or digital literacy that must be addressed when deploying the digital health intervention so that anyone adopting a digital health tool understands the pathway to ensure individual fit.

Technical Fit

Technical fit assesses whether the technological infrastructure exists to support the digital health tool. This domain was not included in the original fit/viability model developed by Liang et al [12], which focused on deploying e-commerce tools in high-income country contexts—settings already primed for new technologies. In our iteration, we consider the potential mismatch between the infrastructure in which a tool was designed and the setting in which it will be deployed.

Challenge

In many sub-Saharan African settings, foundational infrastructure such as electricity and internet remains unreliable, and hardware needs such as hardware durability, power consumption, and maintenance are often overlooked. Tools developed for high-income country contexts may rely on stable cloud access, regular software updates, or consumables that are expensive or difficult to source in sub-Saharan Africa. As a result, imported technologies often end up in "equipment graveyards," unused due to incompatibility with local systems, lack of technical support, or excessive training requirements [19-22].

Solution

The first question should often be "Are there nondigital solutions that are equally suited for this task?", ensuring that implementers are not missing more accessible, viable, and equally impactful solutions. When digital health interventions offer clear advantages, developers must assess infrastructure needs early and design for low-resource environments, considering offline functionality, portability, power efficiency, and local repair capacity. Nationally, more advocacy is needed to support initiatives that expand digital infrastructure. Projects like Health Connect Africa [23], a partnership between Centre for Disease Control Africa and Global System for Mobile Communications Association, which aims to connect 10,000 health care facilities to the internet by 2030, and Power Africa [24], which focuses on electrifying health facilities, are examples of essential infrastructure-building efforts that make digital health tools viable at scale.

Task Fit

We expand Liang et al's [12] considerations of task fit to assess whether a digital health tool is able to complete the task for which it is designed. A tool may be well matched to the infrastructure and the user but still fail to achieve the task for which it is intended.

Challenge

In the digital health field, we often start with tools developed for high-resource environments and adapt these tools to accomplish specific tasks in sub-Saharan Africa [25], which can lead to numerous problems. One notable example is for digital tools that engage artificial intelligence. These often do not include data representative of individuals in sub-Saharan Africa and can have high bias and low validity when implemented in those settings [26].

Solution

First, we must center health program implementers and policymakers to identify the priority gaps we are addressing through digital health interventions. Once we have these priority areas, we must move beyond simply adopting tools and instead validate them through dedicated studies, be willing to adapt or retrain them for context, and, when necessary, design tools from scratch. For AI-enabled digital tools, better and more accessible datasets are needed on the African continent. Although funding and data formatting have been obstacles, recent initiatives such as the National Institutes of Health–funded DS-i Africa [27] along with Masakhane [28], the Lacuna Fund, and Zindi [29], are actively creating shared open repositories. These platforms will accelerate health care innovation by providing representative, high-quality data that directly addresses the bias and validity issues of the existing tools.

Defining the "Viability" of Digital Health Tools

Liang et al [12] considered viability as the organization's economic, technical, and social readiness to adopt a digital tool. We have expanded this to also include legal and ethical considerations that present significant challenges when developing digital tools for interventions and implementation in sub-Saharan Africa. The viability domain considers "Can this tool or intervention thrive in the ecosystem into which it is being deployed?", "Does this tool or intervention have the legal and financial backing to be sustainable?", and "Is the technical infrastructure available to support this tool?" Although fit questions should be addressed early, viability questions are addressed as the digital tool is integrated into interventions and implemented on small or broad scales.

Organization Viability

In the original model, organization viability describes factors such as management support, digital literacy of team members, user competence, and experience [12]. We have shifted several of these individual features such as digital literacy and user competence to "fit" since these must be addressed early as the digital tool is being developed. We have expanded the management support to include plausible integration of the tool into program implementation structures. Adopting technologies that are well matched to their organizational environment can promote uptake and sustainability.

Challenge

Organizational viability considers whether health systems and institutions have the leadership, governance, and operational capacity to sustain digital health interventions. In sub-Saharan Africa, frequent staff turnover and fragmented leadership structures often undermine long-term adoption [30]. Ministries of health may have alternative health priorities or lack the resources to integrate new tools across departments and levels of care. These factors mean that even technically sound and contextually appropriate interventions may struggle to move beyond pilot projects if organizational systems are not aligned to support them.

Solution

Early involvement of multidisciplinary teams is key to assessing feasibility and organizational readiness. Usability testing can help establish workflows, training, and tools that support smooth adoption. For developers, designing solutions that integrate easily with existing infrastructure and that can be bundled with current systems promotes interoperability and long-term alignment. Engaging leadership early and ensuring interventions reflect national health priorities helps secure ownership, buy-in, and resource allocation, thereby reducing the risk of tools operating in isolation from the systems they aim to strengthen.

Economic Viability

In the study of Liang et al [12], economic viability encompasses a cost-effectiveness and cost-benefit analysis. We extend this definition to ask whether a digital health intervention can be sustained financially, including through Ministries of Health and Finance, with the support of philanthropy or multilateral organizations or through the private sector.

Challenge

The digital health sector in sub-Saharan Africa is a patchwork of solutions, with many promising digital health interventions failing to achieve scale due to a lack of coordinated national strategies or shared infrastructure [31]. This decentralized approach, often led by individual clinicians, researchers, and small nongovernmental organizations, limits the ability to benefit from economies of scale [32]. This is compounded by persistent infrastructural barriers like high data costs, unreliable electricity, and poor connectivity as well as inconsistent funding avenues [33]. These issues place a disproportionate financial burden on smaller organizations and new companies. The high cost of entry and limited seed funding make it difficult for promising early-stage innovations to gain traction, leading to isolated successes rather than widespread impact.

Solution

To ensure the continued funding of digital health interventions, a combination of coordinated investment and new funding models are needed. Blended financing, which combines public funds, donor contributions, and socially responsible investment, can help bridge the gap and move interventions from pilot to scale [34]. Health systems–level investment into basic

infrastructure and platform will make any single digital health intervention more economical and cost-beneficial [9].

Legal Viability

Legal viability refers to the presence of clear, enforceable policies that govern the implementation of digital health technologies, with a focus on data privacy, security, and system interoperability. Although this was not included in Liang et al's [12] model, in our experience, this has been a major challenge and often missed step for digital health interventions in sub-Saharan Africa.

Challenge

National and regional policies for digital health interventions are nascent in sub-Saharan Africa. Without clear regulations on data privacy, security, and interoperability, implementers face an uncertain and rapidly changing regulatory landscape [35-37]. This lack of maturity in frameworks creates significant uncertainty for both innovators and investors, making it difficult to establish a strong foundation for technological advancement [35].

Solution

Strengthening legal viability requires investing in national and regional regulatory capacity and developing robust data governance systems. This includes improving regulations to ensure trustworthiness while still supporting innovation [38]. Harmonizing standards across borders will facilitate the ability to share and use tools beyond the specific contexts for which they were developed [36].

dFVM Application

Table 1 shows a summary of the application of dFVM to identify the challenges and possible solutions for implementing digital health interventions in sub-Saharan Africa.

Table 1. Applying dFVM[a] to identify the challenges and possible solutions for implementing digital health interventions in sub-Saharan Africa.

Domains, subdomains of dFVM	Challenges and solutions identified when applying dFVM to sub-Saharan Africa	
	Challenges	Solutions
Fit		
Individual	Limited digital literacy and access to digital platforms among potential end users.	Conduct end user digital assessments, including digital literacy and device ownership assessments prior to tool development. Build digital skills and awareness as part of intervention development.
Technical	Unreliable electricity, frequent power outages, poor internet connectivity, high cost of mobile internet data.	Consider nondigital alternatives. Assess infrastructural capacity early and develop tools that comply to that infrastructure. Invest in foundational infrastructure to connect facilities, health workers, and patients.
Task	Imported technologies may not align with the actual tasks or workflows in health systems. Tools often assume task environments similar to high-income countries. Artificial intelligence tools can also perform poorly due to algorithmic bias.	Address priority areas identified by health practitioners and policymakers in the local context. Ensure co-design with frontline health workers to reflect actual care tasks and workflows. Test, validate, and adapt digital health tools as needed. Build Africa-specific data repositories.
Viability		
Organizational	Fragmented leadership, staff turnover, and organizational priorities, which differ from the tools that are developed.	Bundle tools with existing infrastructure, promoting interoperability and integration; engage leadership early; and promote system-level alignment and ownership.
Economic	Insufficient funding and lack of sustainable financing mechanisms leads to premature abandonment of promising initiatives or poor scaling of established interventions.	Invest in national digital health platforms, which will reduce the per-tool costs. Prioritize national funding models, complemented by blended public-private financing.
Legal	Lack of clear policies and regulations regarding data privacy, security, and interoperability.	Develop robust data governance and digital regulations for countries. Seek, where possible, cross-continent regulations to facilitate portability.

[a]dFVM: digital fit/viability model.

Discussion

We developed dFVM to help individuals designing digital health tools and interventions, particularly innovators working in sub-Saharan Africa, think more critically about the development of these tools and interventions with the goal of successful digital health implementation. We have identified 3 other determinant frameworks relevant to digital health interventions, namely, the Train, Restructure, Incentivize, Mandate, Integrate (TRIMI) framework [16]; a modified version of the Consolidated Framework for Implementation Research (mCFIR) for mobile health tools [17]; and a third developed by Olu et al [3]. Each of these frameworks offers a different vantage to consider when developing digital health tools and interventions. For this paper, we adapted the fit/viability model because this most closely mirrored how we approach our digital tool development—asking questions about whether a digital health tool will fit a specific task, for a specific user, in a specific

infrastructure, and whether a digital health tool achieves the organizational integration, financing, and legal compliance needed to be viable.

Although applicable to any digital health tool, we made sure that dFVM addresses the unique obstacles we have encountered in sub-Saharan Africa. Throughout our description of dFVM, we have highlighted these challenges and offered solutions. Broadly, these solutions fall into 2 buckets. First, what is the responsibility of the individuals developing the tools and interventions? These individuals must design for context and, through the deployment of digital health interventions, build institutional capacity for digital health interventions more broadly. Second, in the context of sub-Saharan Africa, governments play a crucial role, particularly in ensuring the viability of digital health interventions. Investing in digital infrastructure provides a foundation for sustaining various tools and reduces per-tool costs. Moreover, establishing robust legal frameworks, including cross-national agreements, ensures compliance and demonstrates government commitment as partners alongside private and public technology providers.

dFVM offers high-level guidance for individuals developing digital health tools and interventions to ensure their fit and viability within health systems. However, we recognize that moving from idea-to-implementation requires more detailed steps and involves multidisciplinary teams capable of navigating these complexities. As a next step, we are expanding dFVM and integrating it with other digital health implementation science frameworks to develop a step-by-step roadmap to guide teams throughout the development process.

Conclusion

We believe that digital health interventions have great potential to transform health care delivery and improve outcomes worldwide. However, successfully implementing these interventions in sub-Saharan Africa requires careful attention to their fit and viability within local contexts. dFVM maps challenges across both digital health design and deployment environments and links these challenges to practical solutions drawn from lived experience. Although digital health tool developers are responsible for addressing these considerations, governments in sub-Saharan Africa play a crucial role in ensuring that the necessary organizational and legal frameworks are established to support the adoption of digital health interventions.

Acknowledgments

We acknowledge the contributions of all authors on this paper and the role of the Harvard Radcliffe Institute in hosting the seminar from which this paper was conceptualized.

Funding

The workshop was hosted by the Harvard Radcliffe Institute. Additional funding was provided by the Harvard Global Health Institute and Harvard’s Motsepe Presidential Research Accelerator Fund for Africa.

Authors' Contributions

BH-G and AAB conceptualized and acquisitioned funding for this work. AJ and AN were writers of the original draft with intensive inputs from NB, PE-N, and TO. All authors participated in the investigation, developing the content through an iterative engagement process, and the writing (reviewing and editing).

Textbox .

Key Takeaways

- The US Food and Drug Administration's warning letter to WHOOP and ensuing battle have highlighted a critical moment in the wearables space as the US regulatory framework has been evolving in real time.
- New lines have been drawn. The 2026 Food and Drug Administration wellness guidance has established new norms around the ability to noninvasively detect and relay information to users.
- Ultimately, however, the wellness exemption remains poorly defined for companies seeking clear guidance on user interfaces and how they can interpret and relay data to users while remaining a wellness device.

Blythe Karow [1] *is a strategic management consultant and fractional executive with a biomedical engineering bachelor's degree from Johns Hopkins University, an MBA from the UVA Darden School of Business, and over twenty years of experience leading, advising, and consulting as a medtech, digital health, wearables, and regulated healthtech expert. She is the founder of The Karow Advisory Group and author of The Device Files* [2]*, a Substack where she shares strategy, insights, and practical tips for getting devices to market. She has covered the evolution of the WHOOP/US Food and Drug Administration (FDA) regulatory conflict since it began and shares her reflections here.*

In July 2025, the fitness wearable company WHOOP received a warning letter from the FDA [3] for their "Blood Pressure Insights" (BPI) feature, noting that it was clearly a medical device requiring proper 510K clearance. For anyone following the wearables space, this wasn't surprising. WHOOP, like many wearables companies, has slowly been evolving from performance optimization and wellness toward monitoring and diagnosing medical conditions [4].

The warning did not just kick off another regulatory spat. It raised important questions and considerations for the future of wearables and other medical devices, spurring debates across the medical device and wearables communities for 6 months, and culminating in the release of new FDA guidance on January 6, 2026 [5]. In this analysis, I review both the FDA's and WHOOP's original arguments around the regulatory status of the BPI feature, looking at the evolution of the conflict up until now.

Where the July 2025 FDA Warning Letter Arguments Fell Short

The "Inherent Association" Doctrine

The FDA's original position hinged on "inherent association"—that blood pressure measurement is "inherently associated with the diagnosis of hypo- and hypertension" regardless of disclaimers or intended use [3].

In my view, this legal theory was always a bit of a stretch. If any biometric that *can* be used for diagnosis automatically *becomes* a medical device, then the wellness device exemption Congress created in the 21st Century Cures Act [6,7]—that software intended for general wellness and not medical diagnosis or treatment is not considered a medical device—becomes meaningless. By this logic, bathroom scales would be medical devices because weight is "inherently associated" with obesity diagnosis, but you can walk into any store and buy a scale without FDA oversight.

In my original analysis, I argued that the real conversation shouldn't be whether all blood pressure measurements are inherently diagnostic, but rather how the FDA's wellness guidelines could and should be revised to allow biomarker collection while providing clear guidance on handling detected extremes.

The Language Trap

The FDA found specific language from WHOOP that crossed into diagnostic territory, such as "higher blood pressure may be an indicator of poor sleep" and materials indicating that the feature was intended to identify "higher blood pressure" [3].

The distinction between "higher" and "high" blood pressure matters here. "Higher" describes a relative change from an

individual's baseline and should be acceptable for wellness devices. However, "high blood pressure" suggests comparison with clinical diagnostic thresholds. While WHOOP appears to have used "higher," the FDA appeared to have interpreted this as "high blood pressure."

The Color-Coding Absurdity

The FDA objected to WHOOP's user insights interface, claiming the color-coded (green/yellow/orange) readings imply medical interpretation, but most fitness wearables use similar color-coding schemes: for example, Garmin shows heart rate zones in green, yellow, and red, and Apple Watch displays activity rings with traffic-light logic.

If color-coding implies medical interpretation, are we going to start requiring submissions from manufacturers of street lights? This may be a tongue-in-cheek comparison, but the question remains: when does color-coding imply diagnostic categorization?

The Misuse Argument

The FDA cited "evidence of individuals using BPI to monitor their hypertension" as a sign that WHOOP had overstepped the line. This original argument concerned me for two reasons.

First, using anecdotal misuse by some users to justify broad regulatory classification, especially when they provided no details about scale, frequency, or how this evidence was collected, would have set a concerning precedent. Second, people use fitness trackers for wellness purposes all the time, and those wellness issues often connect to more serious health conditions. Sleep quality can impact anxiety or cognitive health [8] and getting your 10,000 steps can help with overall cardiovascular wellness [9]. That shouldn't make wellness device manufacturers liable for medical device indications.

While we want to be careful of products purposefully trying to skirt a medical device pathway, some off-label use is probably acceptable when it leads people to healthier lifestyles that could improve more serious conditions. And what's the harm in someone with hypertension wanting to get an idea of their blood pressure, especially when the next step is probably to seek proper medical testing if they see warning signs?

Where WHOOP Might Have Been Wrong

WHOOP might have had legitimate grievances about the FDA's approach to their BPI feature, but they also seemed to escalate the situation by (1) not adjusting their marketing or features claims early on when discussions started in May 2025, (2) continuing to leave up the "offensive" product features while arguing with the FDA, (3) making a buzzworthy end run to RFK Jr instead of working with the agency [10], and (4) having their CEO, Will Ahmed, making public statements arguing their "legal" case.

The Fatal Phrase

Buried in the FDA warning is language that likely sealed WHOOP's fate: their website originally described the blood pressure feature as delivering "medical-grade health & performance insights" [4,11].*

That single term was regulatory poison. In the FDA's world, "medical-grade insights" implies clinical accuracy, validation standards, and regulatory approval, whether intended or not.

My original argument: you can have a wellness device that collects medical-grade *data*—in fact, this is preferred, because algorithms perform best when data are high-quality [12-14]. The problem was that WHOOP had originally used the term in reference to providing medical-grade *insights*, implying diagnostic-level blood pressure measurement.

If WHOOP had proposed changing this language in May, the situation may have been resolved sooner. However, the back-and-forth, while refusing adjustments, seemed to have gotten the FDA's ire up. Additionally, with Aktiia and Apple subsequently receiving clearance for blood pressure and hypertension claims [15,16], it likely became harder for the FDA to give leniency.

The Media Defense

Shortly after the FDA warning letter, WHOOP CEO Will Ahmed posted counterarguments on LinkedIn [17], making good points but ultimately overrelying on disclaimers to protect the company from oversight. In medtech, just telling consumers not to use a device a certain way often isn't enough, especially if it contradicts other marketing claims.

There were also weaknesses in the arguments Ahmed made during his CNBC appearance at the end of August 2025 [18]:

1. He appeared to believe that wellness exemptions override the core intent of the FDA's mission to protect patients and provide medical device oversight, stating that "Intended use is what matters—and the law agrees." But once you make claims that your device does something a medical device does, you can't just say, "Yeah, but we're just here for wellness purposes," because guess what? So are all medical devices!
2. He mentioned that their blood pressure feature requires calibration with a blood pressure cuff (a medical device), as though acknowledging reliance on a medical device made it clearer that WHOOP itself isn't performing a medical function, but if you need a medical device to calibrate your "wellness" feature, that suggests you're doing medical device work.
3. He claimed that WHOOP should set a new precedent because regulations could thwart tech innovation, blind to an entire medical device industry that has been innovating for decades while following the rules.
4. He claimed that WHOOP members "overwhelmingly support us fighting for [BPI]." This attempt to position himself as defending consumer access read as a deflection rather than acknowledging that the company had created a regulatory mess.

The Marketing Smoking Gun

Most damning to me when reviewing this debate is how WHOOP still structures subscription tiers, separating blood pressure insights from general "health monitoring" and bundling it specifically with FDA-cleared medical features in the highest tier [19]. They're explicitly categorizing blood pressure insights

alongside actual medical device features, telling consumers through product positioning that blood pressure monitoring belongs in the medical device category. It feels a bit like a magician's misdirection—it implies medical device credibility to the consumer, while denying the need for medical device status to the FDA.

New Year, New Guidance

Ahmed's claim that the FDA was "on the wrong side of the law" [18] was somewhat remarkable given the FDA's enforcement position. WHOOP appealed the formal warning letter but continued to market much the same way throughout 2025. This could have brought additional serious legal trouble [20]; the FDA had multiple escalation options, including court orders to force WHOOP to disable blood pressure features while pursuing appeals.

I was fairly confident that WHOOP's attempted lobbying to RFK Jr wouldn't be effective in swaying the FDA, given the precedent set by the Aktiia and Apple clearances and additional pressure from public scrutiny. But I was wrong.

In the first week of 2026, the FDA responded with new guidance that very clearly states that they will allow blood pressure measurements via optical sensing to remain in the wellness category as long as companies make no claims to having "medical-grade" data or insights [5]. The new guidance seems an obvious win for WHOOP, and it also seems clear from current FDA Commissioner Dr Marty Makary's comments during his January 6 interview on Fox Business News [21] that the FDA is moving to relax and clarify control and oversight in the wellness space. He stated, "We want to let companies know, with very clear guidance, that if their device or software is simply providing information, they can do that without FDA regulation."

While the new guidance provides clear direction on whether WHOOP can market BPI, there remains a lack of clarity in a few areas. The guidance does not specifically address all of the concerns originally outlined in the warning letter (for example, it does not address whether you can use color coding in a user interface) and WHOOP does not seem to have adjusted their interface or marketing beyond specifically removing claims of "medical" or "clinical grade" in reference to BPI [4,11]. And, although multiple examples are provided on how to describe a product or its features without crossing into medical device territory, there is very little to guide developers on appropriate user interface and alerts, leaving other technologies with a great deal of gray area to navigate in the future.

Ultimately, this case has shone a spotlight on some of the weaker elements of the wellness carve out and will likely continue to play a major role in how the FDA decides to evolve in this new world of wearables, artificial intelligence, and the quantified self. We're watching the real-time evolution of the wellness doctrine; while I expect some continued upheaval, a line appears to be forming around collecting versus interpreting user data as the new distinction between wellness and medical devices. Innovators would do well to keep a close eye on the wellness space as it continues to evolve.

**Note: Following the January 2026 FDA guidance, the WHOOP web pages were revised, and the original marketing language is no longer retrievable in the current versions.*

Textbox .

Key Takeaways

- UnitedXR Europe 2025 highlighted that health care extended reality (XR) is no longer constrained by technical capability but by alignment between industry, academic evidence, and clinical governance.
- Persistent gaps remain between how success, risk, and readiness are defined by developers, researchers, and health care professionals.
- Formats that enable direct cross-stakeholder dialogue may be as critical as technological advances for translating XR potential into routine clinical practice.

Extended reality (XR) is not new to health care, but over the past decade, its use has become more widespread in medical training, rehabilitation, pain management, and mental health care, supported by a growing body of evidence [1-4]. Despite clear gains in technical maturity, the adoption of XR in health care remains uneven. Immersive tools are increasingly capable, yet their integration into routine clinical practice appears to depend less on technical performance than on organizational readiness, governance, and professional acceptance—a pattern well described in implementation research [5,6].

UnitedXR Europe 2025 offered a concentrated view of this tension and an effort to resolve it. The event marked the first joint edition of two historically distinct strands of the European XR ecosystem. Stereopsia—anchored in Brussels since 2009—has long served as a meeting point for immersive research, cultural production, and policy dialogue. In parallel, the Augmented World Expo evolved into a global, industry-led platform focused on enterprise deployment and market scale.

Their integration under UnitedXR Europe has brought these traditions into direct contact, highlighting gaps and areas of convergence, as well as creating a shared space for dialogue between industry, academia, health care, and policy actors.

What the Program Revealed About Health Care XR Readiness

UnitedXR Europe 2025 brought together more than 125 exhibitors across 14 parallel tracks, including a dedicated Healthcare, Pharma, & Wellbeing track. Across the event's agenda, health care XR appeared to be entering an infrastructure phase, positioned not as a peripheral demonstration but as a maturing vertical confronted with questions of scale, integration, and long-term sustainability.

Beyond formal sessions, interaction extended into curated environments, such as the European Market for Immersive Creativity and business-to-business matchmaking between developers, researchers, and institutional actors. Roundtables, workshops, start-up pitch competitions, and the European XR Awards Gala reinforced the event's dual role as a space for exchange and an indicator of technical maturity.

This shift was visible on the expo floor, where novelty gave way to utility. Across the XR ecosystem, major headset vendors relied on real-world implementation partners to demonstrate use cases rather than on product-centric stands, with a dedicated demonstration pavilion hosted by the International Virtual Reality Healthcare Association. Within this context, hands-on demonstrations, such as those by VirtualiSurg [7], illustrated how VR is being embedded into established training pathways, particularly when combined with modular haptic systems, such as those provided by SenseGlove [8].

The scientific program reflected a similar maturation. As noted by Oliver Schreer, PhD, track chair, submissions increased from barely a dozen in previous editions to over 45 this year, accompanied by a clear shift toward more application-oriented research.

Moving between tracks revealed a persistent asymmetry. Enterprise discussions were supported by a settled language of scaling, procurement, and return on investment. Health care discussions, by contrast, were anchored in regulation, safety, and professional accountability. Side by side, these perspectives exposed a central tension: while the XR industry largely seems prepared to scale, health care systems are still negotiating why, and under what conditions, that scale should occur.

XR as a Coordination Challenge

What emerged from these observations was a coordination problem. The remaining barriers to health care XR adoption lie less in hardware or software performance than in the absence of shared decision-making structures.

This gap surfaced repeatedly in discussions about adoption criteria. In one interactive panel within the health care track,

participants were asked to rank factors that guided XR implementation. Priorities clearly diverged, with safety treated as a nonnegotiable baseline by some and as one consideration among many by others. The exchange was brief but revealing, with high audience participation.

Figure WL1. Audience engagement during an interactive panel session. Faces have been blurred to protect participant privacy. Photograph credit: Sonya Seddarasan, track chair for Healthcare, Pharma, & Wellbeing at UnitedXR Europe 2025.

What this exchange made visible was that XR initiatives often stall not because immersive systems fail to perform but because organizations lack an agreed framework for guiding early-stage decisions about readiness for clinical use. A recurring takeaway from the session was the growing consensus that health care XR must move beyond repeated proofs of concept. Without a shared way to assess safety, credibility, and contextual fit before implementation begins, pilots tend to accumulate without a clear pathway toward sustained, real-world integration.

Format Matters for Cross-Stakeholder Dialogue

Points of agreement and divergence became most visible during interactive panel sessions. For example, open discussion forced participants to make their criteria explicit and revealed how differently evidence, risk, and readiness were understood across institutional and professional contexts.

The organizers appeared attentive to this dynamic. Sonya Haskins—Augmented World Expo's head of programming—noted that future editions may place greater emphasis on roundtable formats intended to support cross-disciplinary negotiation. Alexandra Gérard—codirector of UnitedXR Europe—similarly pointed out the need to broaden participation within the health care track, including participation by patients and frontline practitioners with direct insight into care delivery.

For health care XR, where adoption depends on trust and legitimacy as much as it does on performance metrics, creating conditions for this kind of dialogue may be as consequential as any technical advance.

Immersion as a Clinical Responsibility

Health care discussions at UnitedXR Europe reflected a growing recognition that immersive technologies carry a different kind of responsibility than that of most digital health tools. XR was framed not merely as a delivery medium but as a technology that directly shapes perception, attention, and embodied experience—a distinction that is well established in prior experimental and neuroscientific work [3,9,10].

This concern surfaced most clearly in informal exchanges. Sonya Haskins described XR creation as "hacking the brain," using the phrase as a metaphor to underscore why immersive systems

cannot be treated as neutral software development. When technologies act directly on perception and experience, questions of intent, safety, and oversight move rapidly to the foreground.

Policy frameworks are beginning to respond, albeit unevenly. The event coincided with the launch of the European Partnership for Virtual Worlds, which explicitly identifies health care as a strategic domain [11]. This marks progress when compared with earlier global digital health strategies, including those of the World Health Organization, where immersive technologies remain largely unnamed despite their growing use in practice [12,13].

Terminology remains a point of friction. As several clinicians noted, framing clinical XR under the umbrella of "virtual worlds" sits uneasily with health care practice. Recent European policy work differentiates professional and health care uses of immersive technologies from consumer-oriented virtual worlds, emphasizing that clinical applications are bounded; task specific; and subject to heightened safety, ethical, and governance requirements [4]. In this sense, UnitedXR functioned as a translation layer, highlighting where policy language must be refined to align with the risk-aware logic of patient care.

Implications

UnitedXR Europe 2025 made clear that health care XR has moved beyond the phase of technical proof. What remains unresolved is not what the technology can do but how it is integrated into the social, ethical, and organizational fabric of health care. From my perspective as a clinician-researcher involved in real-world XR deployment, these tensions are familiar from practice and, importantly, addressable.

The challenge ahead is one of alignment; synchronizing industrial velocity with clinical deliberation; and narrowing the vocabulary gap between policymakers, developers, and practitioners.

As this event demonstrated, that work rarely happens through polished presentations alone. It happens in shared spaces where assumptions are tested, priorities collide, and the real conditions for responsible adoption begin to take shape.

When Lived Experience Designs the Intervention

Trevor van Mierlo

(J Med Internet Res 2026;28:e91371) doi:10.2196/91371

KEYWORDS

mental health; telemedicine; health services accessibility; cultural competency; patient participation; patient-centered care; co-design; lived experience

Textbox .

Key Takeaways

- Co-developing a digital mental health intervention with contributors who have lived experience of displacement revealed how language, meaning, engagement, and design choices can carry unanticipated cultural and emotional risks.
- To ensure safety, trust, and effectiveness on a global scale, interventions must move beyond adaptation to lived experience co-design.

Digital mental health interventions are increasingly deployed across borders, reaching people whose lives and circumstances may differ dramatically from the teams who build them. As these tools proliferate, traditional approaches to cultural adaptation—often focused on translation—have become insufficient.

Translation conveys language; it doesn't always convey *meaning*. And meaning is culturally constructed and emotionally rooted in ways that can be impossible to anticipate from the outside. I recently learned this lesson through co-developing a mental health resilience course with a team of Ukrainian software developers—many of whom were displaced by war, and some who were actively participating in it.

This experience illuminated a frequent blind spot in global digital mental health design: without lived experience embedded in creation—not merely consulted afterward—we risk building tools that are well-intentioned and evidence-based but potentially unsafe.

Digital Mental Health at Scale and Cultural Distance

Scalable, low-cost interventions promise to reach global populations that traditional services cannot, particularly during humanitarian crises, displacement, and conflict. Yet most digital mental health tools are conceived, designed, and tested in relatively stable Western contexts before being deployed elsewhere [1-3].

This development pattern introduces cultural distance at precisely the point where sensitivity matters most. Evidence of clinical efficacy does not ensure cultural legitimacy, trust, or safety [4]. When interventions cross geopolitical and cultural boundaries, they enter environments shaped by historical trauma, media narratives, power asymmetries, and collective memory. These contextual forces rarely appear in design specifications, yet they profoundly shape how digital tools are perceived and used.

The challenge, then, is achieving scale without reproducing blind spots that undermine efficacy.

From Adaptation to Co-Development

Most cross-cultural digital health efforts rely on cultural adaptation frameworks [5]. These typically involve translating content, substituting examples, and adjusting tone to fit a new population. While necessary, these steps assume that meaning is largely transferable and remains intact once linguistic barriers are removed.

Our experience suggests otherwise. When conducted without lived experience embedded in the design process, cultural adaptation risks addressing surface differences while missing deeper layers of meaning.

In contrast, lived-experience co-development treats those with direct experience not as informants, but as co-designers. This approach requires cultural and epistemic humility [6]: acknowledgment that certain insights cannot be inferred, researched, or validated externally. They must be shared by those who live within the context the intervention seeks to address.

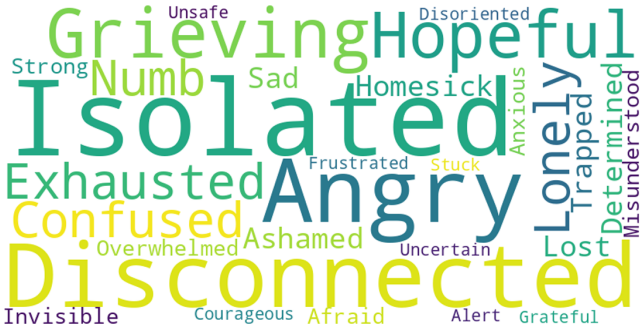
Collaboration With Lived-Experience Designers

The collaboration at the center of this article emerged when the Ukrainian team—displaced by war, living in Ukraine, or actively deployed—approached our group at Evolution Health to help build a digital mental health resource for Ukrainians living in displacement and uncertainty.

These developers were active contributors throughout development, shaping decisions about language, tone, pacing, and presentation. Their technical expertise allowed them to participate fully in design discussions, while their lived experience grounded those discussions in their reality. Decisions were no longer guided solely by evidence hierarchies or best practices, but by continuous dialog about how content would

be interpreted emotionally, culturally, and symbolically by people living with war-related disruption.

Figure WL1. Left: original English draft. Right: adapted Ukrainian version.



The divergences were striking. Even when words appeared similar, their emotional weight and associations differed substantially. Terms that Western designers associated with isolation, anger, exhaustion, disconnectedness, or optimism carried layered meanings for the Ukrainian team. Some evoked loss. Others echoed bureaucratic language encountered during displacement. Still others were associated with political messaging or wartime media narratives.

Two examples help illustrate the limitations of conventional adaptation and the benefits of co-design.

The first involved a simple vocabulary exercise. The North American team generated a word cloud, and the Ukrainian team was asked to identify words that felt emotionally relevant, neutral, or problematic within the context of displacement and war and to add or remove words accordingly.

The second example involved an introductory video developed using an artificial intelligence (AI)–generated Ukrainian-language voice-over. From a Western perspective, the voice sounded professional, neutral, and supportive—a practical solution that aligned with common digital production practices.

The video was swapped, however, when the Ukrainian team explained that it was likely to evoke distrust. Synthetic Ukrainian voices had become widely associated with Russian disinformation campaigns, where AI-generated Ukrainian speech was routinely used to deliver propaganda.

This risk was invisible to the non-Ukrainian team. Traditional usability testing might have detected disengagement, but only after trust had already been compromised. The issue was not usability, but cultural safety.

These examples underscore two central lessons: that language is not merely semantic, and that trust is built on signals of authenticity, safety, and legitimacy that are culturally situated. Without lived experience in design, even carefully translated content and well-intentioned choices can misfire and risk harm.

What Lived Experience Changed in Practice

Co-development reshaped the intervention in several ways.

Language as Lived Experience

First, meaning consistently took precedence over literal accuracy. Language that was technically correct but emotionally misaligned was revised or discarded. The goal shifted from fidelity to original phrasing toward fidelity to lived interpretation.

Second, engagement strategies were reconsidered. Structures intended to support participation occasionally felt directive or intrusive within a displacement context [7]. Lived experience helped distinguish between supportive guidance and unwanted pressure, particularly for individuals navigating chronic uncertainty and loss of agency.

Finally, harm prevention became an explicit design outcome. Lived-experience contributors identified risks that would not have appeared in formal risk assessments—symbolic associations, emotional triggers, and trust signals embedded in design choices. These insights allowed potential harms to be addressed before deployment, rather than retroactively.

Ethical Responsibilities

There are ethical responsibilities inherent in working with individuals who are actively living through the experiences an intervention seeks to address. Co-development can be experienced as empowering and meaningful, but it also raises questions about psychological safety that appear insufficiently explored in the digital mental health literature [7].

Even when voluntary, participation can involve exposure to emotionally charged language and experiences, increasing the potential for distress. At present, there is limited empirical guidance on how to assess, monitor, or mitigate potential psychological risks for lived-experience contributors in digital intervention development [8].

Designing With, Not For

This collaboration revealed limits in what even experienced digital mental health designers can know from the outside. Lived experience did not simply improve the intervention; it fundamentally reshaped it. It prevented harm, deepened resonance, and challenged assumptions embedded in the original, North American content.

As digital mental health tools continue to scale, lived-experience co-development should be treated as a methodological and

ethical necessity rather than an optional enhancement [9]. Even technically sound, evidence-based design alone cannot prevent contextual misalignment and ensure cultural legitimacy, trust, or safety.

Researchers and designers must consider how lived experience is integrated, compensated, sustained, and supported throughout development. Funders and policymakers should evaluate interventions not only on efficacy, but on how they address cultural meaning and safety.

Ultimately, if digital mental health interventions are to be trusted, culturally legitimate, and safe at global scale, the field must move beyond designing *for* others toward designing *with* them.

Conflicts of Interest

The author is the founder and a strategic advisor of the Evolution Health platform and acts as a consultant for academic and commercial digital mental health initiatives. The views expressed in this article are those of the author.

A Frontline Worker's Take on Hybrid Care Implementation in the Hospital Setting

Jenna Congdon

(J Med Internet Res 2026;28:e90879) doi:10.2196/90879

KEYWORDS

telemedicine; delivery of health care, integrated; digital health; hospital medicine - organization & administration; health personnel attitudes; hybrid care implementation

Textbox .

Key Takeaways

- Hybrid care can enhance patient outcomes and workflow efficiency, but only when thoughtfully implemented with frontline staff input.
- Variability in hospital resources, patient populations, and infrastructure leads to inconsistent adoption and effectiveness of hybrid care models.
- Without adequate support, training, and realistic workflow planning, hybrid technologies risk adding burden to bedside staff and generating ineffective spending rather than improving care.

Hybrid care in the hospital setting—combining in-person care with telehealth services—has increased dramatically since 2020 [1,2]. During the COVID-19 pandemic, frontline workers relied on remote access to care for patients from afar. In the succeeding years, hybrid care use has remained much higher than prepandemic levels [1]. At different points in my own practice as an intensive care nurse, depending on its implementation, hybrid care technology has been a distracting hindrance to patient care or has greatly supported my ability to treat patients in critical condition.

For other staff working at the bedside, reactions are similarly mixed: while some report safer patient care and more efficient workflows, others feel that hospitals now push telehealth technology as an ineffectual fix for staffing shortages and organizational issues.

Hybrid Care on the Ground

The day-to-day realities of in-hospital hybrid care use are varied. Location, patient demographics, and facility-to-facility differences in budgets and priorities play a part in determining the specific implementation, delivery models, and rate of adoption by both patients and staff for these modes of care [3].

Examples include using video calls to patch in specialty providers for emergencies and consultations, providing remote physician rounding for rural or underserved communities, and leveraging digital apps for patient communication and video visits.

Additional uses include monitoring confused or unstable patients via video; supporting nursing workflows with remote nurse assistance; facilitating admissions, discharges, and patient education; and offering a way for families to connect virtually with loved ones if they are unable to visit in person [1].

These tools represent a unique opportunity to augment patient care and improve safety measures. However, without collaborative implementation and ongoing support services, some frontline staff express concern that more technology simply adds to their already burdensome workload [4-6].

When Hybrid Care Saves the Day

At its best, hybrid care technology can save lives and ease stress for bedside staff, patients, and their loved ones.

Gwen*, a nurse in a postanesthesia care unit in Portland, Oregon, recalls a time when her patient experienced a stroke soon after surgery: "In that situation, we were able to use the telehealth neurologist during a code stroke. It worked really smoothly, and the other staff and I felt more confident in that emergency. That patient absolutely received better care because we were able to talk to a neurologist immediately." Gwen's experience demonstrates how faster access to specialty care via a remote provider can dramatically improve patient outcomes.

Avah*, a nurse who works in the postpartum unit of a hospital in Madison, Wisconsin, reported: "Our NICU [neonatal intensive care unit] has cameras that let parents see their baby from home." She cites this use of telehealth technology as an important bonding tool for new parents of hospitalized infants.

Other benefits to hybrid care include fewer admissions and readmissions, reduced length of hospital stay, improved chronic disease management, enhanced patient safety, reduced health system costs, better integration of care services, better adherence to recommended best practices, and increased efficiency in provider workflows [4,5].

When Hybrid Care Gets in the Way

Nurses frequently become the point person for new in-hospital technology, including hybrid care tools. When patients struggle to log in to a phone app for a video appointment or the camera used for physician consults needs to be set up, it often falls to

the nurse to first troubleshoot and then call for assistance if needed. They become the liaison for patient concerns and digital snafus, taking time away from patient care activities and adding to an already hectic workload.

Other concerns relayed by frontline health care workers regarding newly integrated hybrid care models include technical issues such as unstable Wi-Fi or poor equipment maintenance, patient and staff competency in adopting new technologies, and lack of ongoing support as uses for hybrid care modalities evolve [4,5]. Additional technology may also create interruptions in the workflow and degrade the quality of patient-nurse interactions [6].

Rhonda*, an intensive care unit charge nurse at a large Midwestern hospital, explains that her unit recently installed electronic intensive care unit (eICU) cameras in each patient room. These devices are meant to bring in ICU-trained registered nurses (RNs) via video to provide nursing support. “We rarely use them, and we never asked for this kind of device. Instead of being a help, they are a hindrance. The eICU staff call us to ask questions that are irrelevant to patient care. It wastes time. I’m sure [the cameras] were expensive, and they don’t help patient care in any way.”

She worries that this follows a recent trend at her facility of cutting staff and attempting to replace in-person RNs with nurses who can only watch from the other side of a screen.

These challenges and concerns suggest that additional technology is not a replacement for proper staffing or efficient organizational workflows.

Making the Most of Hybrid Care Tools

If in-hospital hybrid care models are to be effective, nurses and other frontline staff must be involved in the entire decision-making process, not brought in after adoption [5,6]. The choice of hybrid care technologies needs to be decided based on real-life clinical needs and centered around realistic patient behaviors. If patients struggle to use an app or cannot understand a provider on the other end of a video call, the technology becomes useless, burdensome to staff, or worse, an active impediment to the quality of patient care.

Designing for flexibility is crucial as technology develops, patient needs shift, and health care continues to see rapid change [7]. Ongoing and easily accessible tech support for both patients and staff should be included to increase use and reduce errors, work-arounds, and frustrating workflow disruptions [6]. While staff are often receptive to new technologies becoming part of their daily workflow, needs and perceptions vary by facility and department, highlighting the need for a tailored approach that includes bedside staff’s voices [8].

In-Hospital Hybrid Care Succeeds When Frontline Staff Are Involved

While hybrid care can be a powerful tool, everyday complications show gaps that hospital leadership and policymakers sometimes overlook. Without the involvement of these frontline workers, hospitals risk spending budget dollars on technology that simply does not serve its full purpose.

By continually seeking out and incorporating the input of frontline staff, health systems and hospital administrators can make realistic, informed, and effective decisions about which tools will increase safety, efficiency, staff retention, and patient experience in their facilities. Administrators should survey frontline staff about their daily challenges and perspectives on which models of hybrid care would best address staff and patient needs before purchasing, policy change, or implementation begins. Additionally, nursing focus groups may provide an opportunity for unit-specific representation so that hybrid care execution can be tailored to departmental needs.

Hybrid care tools cannot replace the human touch in health care, but they certainly have the power to create better outcomes for patients and lighten staff workloads. Hospital systems should invest in thorough research and open conversation with staff to generate flexible and human-centered hybrid care models that best serve the people under their care.

What Health Care Organizations Have Learned From Telecommunication Outages

Catharine Solomon

(J Med Internet Res 2026;28:e91456) doi:10.2196/91456

KEYWORDS

telecommunications; telecommunications standards; health services administration; health care quality; access; evaluation; infrastructure; risk management; emergency preparedness; health care resiliency

Textbox .

Key Takeaways

- Health care facilities' ability to provide patient care can be threatened by large-scale telecommunication outages, requiring providers to build additional redundancy into their own infrastructure.
- While steps have been taken to formalize accountability for some telecommunication providers (such as, in Canada, via the Memorandum of Understanding on Telecommunications Reliability), gaps remain.

Telecommunication (telecom) breakdowns at massive scales are fresh in recent memory; in Canada, the Rogers Communications outage of July 2022 cut off over 12 million users' wireless and wire-line services for over 24 hours [1], and in 2024, a single faulty update to CrowdStrike's cybersecurity software caused an estimated 8.5 million Microsoft systems worldwide to crash [2]. In the past several months alone, widespread outages from internet infrastructure providers, like Cloudflare and Amazon Web Services (AWS), have alerted users to the fragility of an internet that relies on a handful of companies to function [3].

Health care facilities, which use telecom for everything from faxing prescriptions, to accessing electronic health records (EHRs), to virtual care, have to navigate these breakdowns under an additional unique pressure: their patients' well-being on the line. In the months and years following major outages, health care institutions have taken steps to mitigate the threat of service disruption to patient care.

The Rogers Outage

On the morning of July 8, 2022, Canadians woke up to a phone and internet outage hitting nearly every sector. While upgrading their IP core network, Rogers staff had removed a policy filter, which allowed IP routing data to flood and then crash the core routers, leaving user traffic unable to reach their destinations and over 12 million Rogers users without service [1].

Many of these users were health care providers and organizations, as well as patients trying to access health care. Family medicine clinics found themselves suddenly unable to carry out basic functions, like faxing prescriptions, scheduling appointments, and attending virtual care appointments [4]. The outage disproportionately affected health care services in remote locations, which often rely on network access to consult with specialists; this was compounded by the loss of connectivity across other health system partners [4]. In Toronto, immunization clinics lost access to the provincial COVID-19 vaccination management system, long-term care facilities lost access to their residents' EHRs [5], and hospitals had to scramble to mitigate the outage's effects on patient care.

According to Michael Garron Hospital's (MGH's) Chief Information Officer Amelia Hoyt, the brunt of the outage at MGH fell on corporate staff, who use Rogers cellular services for their work phones. This loss of corporate cellular mobility threatened patient care only indirectly, but physicians who relied on Rogers for their own mobile phones also couldn't be reached. MGH leadership gathered an emergency command center to develop a plan for how to navigate the outage.

"We did need to come together to figure out how to make sure that we didn't have delayed communications that inadvertently would affect patient care," says Hoyt. The solution in the moment was to identify affected staff and, by using a fan-out list, set alternate communication routes.

The outage allowed Hoyt and her team to identify a gap in their IT strategy and then fix it. "We had no other redundancy for if cell services are down." Redundancy—the strategy of duplicating system components or functions—works by keeping fail-safes and backup components at the ready.

"What we decided to do was invest in eSIMs from a different cellular provider for corporate mobile devices," she explains, "loaded onto select individuals' phones....If Rogers went down again, we would be able to activate this alternate provider's eSIM, and that would allow for continuity."

The CrowdStrike Outage

On July 19, 2024, University Health Network (UHN) staff trying to connect with clinical systems were met instead with blue error screens. A defective content configuration update released by the cybersecurity company CrowdStrike had caused millions of Windows hosts worldwide to crash, resulting in disruption

of services across multiple industries and organizations, including government agencies, airlines, health care facilities, and even 911 connectivity in some areas [6,7]. In the health care sector, the outage disrupted everything from EHR access, to telemonitoring, to operational management, to research [8].

According to Carl Virtanen—chief technology officer for UHN Digital (UHN's IT department)—the UHN's downtime procedures for switching to manual documentation helped mitigate disruptions to patient care, though several nonurgent appointments had to be rescheduled.

"UHN was able to prevent more significant technological disruption by pausing software updates and limiting the number of devices affected by the CrowdStrike outage," Virtanen says, noting that UHN Digital's protocols, which include prioritizing critical areas (such as emergency departments, intensive care units, and operating rooms) when responding to technological problems, have not been updated since. "All critical clinical systems were back up and running normally by the end of the day the outage began."

Importance of Redundancy

The telecom ecosystem is deeply interconnected. For complex critical systems, like health care, that rely on telecoms [9], interconnectivity facilitates seamless and efficient data sharing across a network of health system partners. But these interconnected systems can be disrupted on a large scale by a single point of failure in the infrastructure upon which they depend. So, how can disruptions be avoided?

Virtanen says that the best strategy for avoiding downtime is already, ideally, in use: "It is critical to have redundancy layers built into technical infrastructure to maintain operational efficacy in the event of service disruptions, such as the CrowdStrike outage."

On the most basic level—the physical infrastructure underpinning telecom services—a lack of redundancy can result in, for example, a beaver taking out nearly half of a town's internet connection by chewing through the network's single fiber-optic cable [10]. The 2022 Rogers outage itself exemplified the peril of putting all of one's technological eggs in one basket; since the Rogers management network relied on the very IP core network that had crashed, staff struggled to communicate with one another and remotely investigate the issue, delaying repairs for hours [1].

Health care facilities' preparations for outages, such as MGH's eSIM investment and UHN's downtime protocol of switching to paper records, act as another redundancy layer. In a perfect world with an unlimited budget, Hoyt says that her team would invest in additional redundancy for all IT services at MGH; at one point, they had even toyed with the idea of low-tech backups, like walkie-talkies. The solution is practical but not without its drawbacks; maintaining redundant systems can be cost-intensive, particularly for health care facilities with fewer resources [4].

Who's Accountable?

The fallout and appropriate redress of telecom outages have often been framed in terms of monetary loss, which can be reimbursed through vendor refunds and credits [5]. But when essential services, like health care, rely on network access to function efficiently and effectively, a framework that accounts only for economic impact falls short.

"Telecommunication is really foundational," says Hoyt. "I liken it to 911 service—there are some standards that are expected, that you should be able to require some of these telecom companies to follow."

Steps have been taken to hold Canadian telecom companies accountable for the essential services they provide; in September 2022, thirteen major telecom companies signed the Memorandum of Understanding (MOU) on Telecommunications Reliability [11]. The signatories of this MOU agreed to provide one another with emergency roaming and assistance in the event of a major outage, building ready-to-go redundancy into Canadian telecom services.

The MOU is "a positive step," according to Hoyt. "What will be interesting to see is how this agreement is put into practice if and when the next unplanned outage occurs."

What about the rest of the telecom ecosystem? Health care organizations' ability to access and relay information is only as stable as the infrastructure they use to communicate, and unlike health care providers who can be held liable for medical malpractice or medical devices that are held to rigorous standards of reliability and accuracy, many telecom services—particularly newer cloud-based models, like software as a service, that boast cost-effective scalability for clients—have frequent downtimes without consequence.

For health care organizations, using third-party services carries an inherent risk: tech disruptions that can't be addressed in-house. "When the infrastructure is under local IT's control, like my department, it's something my team would have more direct accountability for," says Hoyt. "If AWS is out, then you're kind of stuck between a rock and a hard place. There's nothing really a local IT team can do about that because we actually don't have any control over it."

Health care organizations must weigh this risk in choosing whether and when to rely on such services. Unless these services are reliable enough to meet health care standards, the scalability boost may not be worth it.

As more and more of our essential systems rely upon telecom infrastructure, redundancy and resiliency strategies are key to avoiding more outages that, at best, create delays and administrative burden in health care and, at worst, can lead to real patient harm. In an interconnected telecom ecosystem, all providers, companies, and organizations have the opportunity and the responsibility to do their part in keeping critical services running smoothly.
